PREFACE

TO THE THIRTY-SEVENTH EDITION

Human Anatomy is a part, not merely of medical science, but also, beyond that, of biological knowledge, and beyond that also a part of the totality of mankind's understanding of his universe. But it has been customarily isolated, and usually still is in many schools and texts. Yet it is impossible to pursue anatomy intelligently in intellectual isolation. Even in our two previous editions we did not merely press for the amalgamation of structure with function; we also recognized that mature structures must be viewed in the light of their development, evolution and kinetics, *and* at all levels down to cytological, even molecular, detail, if one is to *understand* them. In this, our third joint edition, this outlook has further expanded, partly to emphasize, wherever possible, the intimate physico-chemical processes which collectively constitute an individual life—the arena of much current research. We have in particular essayed to review—in the full sense of the word—much that is and goes on in the human frame as a *living* complex.

It has never been the aim of scientific thought to explain the 'Whys' of existence, though many philosophers and divines over the ages have attempted to do so. But even if we confine our thinking to the 'Hows' of existence, it is stultifying to confine enquiry or description to the artificially bounded 'subjects' of 'education'. Anatomy has been a particular sufferer in this compartmentalization; the structure of things, including the human body, must include physics, chemistry, biochemistry, kinetics, mathematics and much more. There are, in fact, no real boundaries between 'anatomy' and *all* other fields of human enquiry, including not only the supposedly separate Sciences but also, to some extent, the Arts; the human individual has not only applied himself to the creation of innumerable skills and crafts for mere survival, but has, in the unceasing development of mind, evolved the arts—painting, literature, poetry, music, sculpture and drama —to enrich our culture. Even this is not the end of the expansion of a structured being into its environment, because the human being has never been content to exploit its ever-burgeoning talents in accomplishment.

Human beings are social animals—like their forebears—and mere aesthetics were not long sufficient; individuals are parts of communities, themselves parts of races, continents, a world, an earthly biological system, beyond which extend planets, stars and nebulae. For the sake of order in a community, morals, ethics and religions inevitably evolved, side by side with attempted explanations of the Universe, the totality of what *is*. All these developments stimulate a duality of impulse: to seek the factual truth, i.e. scientific research, and to look for explanation, i.e. philosophy, a term of special significance to us. Philosophy—the love of knowledge—has engaged many of the best human minds over millenia of time. It has one peculiarity, which takes it a little beyond what we commonly regard as Science: it is not content with the accumulation of provable observations alone, though this approach has led to greatest change, applied or theoretical, in the human situation. But philosophy, even more than science, which at times uses the same mental gymnastics, is dependent upon ideas and ideals. In fact, in both fields of endeavour, it is human imagination —the refusal blindly to accept traditional knowledge—which has been the most fruitful attitude to *expansion* of knowledge.

So much of our knowledge, our 'science', is open to further investigative expansion, given the ability to form new ideas and tests for them—to blend even the best established knowledge with scepticism—a freedom to think again. This is the philosophy of our third joint edition.

London, 1989 PLW, RW, MD and LHB

ACKNOWLEDGEMENTS

During the preparation of this edition, we have had the great advantage of the meticulous professional assistance of:

DOUGLAS LUKE BSc BDS PhD FDSRCS—*Dental Anatomy*
ANDREW G S LUMSDEN MA PhD—*Dental Anatomy*

GRAY'S ANATOMY

HENRY GRAY

FRS FRCS

Since readers of *Gray's Anatomy* will be interested to learn something of the original author, Henry Gray, the following information as to his career has been extracted from an article which appeared in the *St George's Hospital Gazette* of 21 May 1908.

Gray, whose father was private messenger to George IV, and also to William IV, was born in 1827, but of his childhood and early education nothing is known.

On 6 May 1845, he entered as a perpetual student at St George's Hospital, London, and he is described by those who who knew him as 'a most painstaking and methodical worker, and one who learnt his anatomy by the slow but invaluable method of making dissections for himself'.

While still a student he secured, in 1848, the triennial prize of the Royal College of Surgeons for an essay entitled 'The origin, connexions and distribution of the nerves to the human eye and its appendages, illustrated by comparative dissections of the eye in other vertebrate animals'.

At the early age of twenty-five he was, in 1852, elected a Fellow of the Royal Society, and in the following year he obtained the Astley Cooper prize of three hundred guineas for a dissertation 'On the structure and use of the spleen'.

He held successively the posts of demonstrator of anatomy, curator of the museum, and Lecturer on anatomy at St George's Hospital, and was in 1861 a candidate for the post of assistant surgeon. Unfortunately he was struck down by an attack of confluent smallpox, which he contracted while looking after a nephew who was suffering from that disease, and died at the early age of thirty-four. A career of great promise was thus untimely cut short. Writing on 15 June 1861, Sir Benjamin Brodie said, 'His death, just as he was on the point of obtaining the reward of his labours ... is a great loss to the Hospital and School'.

In 1858 Gray published the first edition of his *Anatomy*, which covered 750 pages and contained 363 figures. He had the good fortune to secure the help of his friend, Dr H Vandyke Carter, a skilled draughtsman and formerly a demonstrator of anatomy at St George's Hospital. Carter made the drawings from which the engravings were executed, and the success of the book was, in the first instance, undoubtedly due in no small measure to the excellence of its illustrations. This edition was dedicated to Sir Benjamin Collins Brodie, Bart, FRS, DCL. A second edition was prepared by Gray and published in 1860.

The portrait of Gray published in the present section is a reproduction of one which appeared in the *St George's Hospital Gazette* of 21 May 1908, where the original is described as being 'a very faded photograph taken by Mr. Henry Pollock, second son of the late Lord Chief Baron Sir Frederick Pollock, and one of the earliest members of the photographic society of London'.

GRAY'S ANATOMY

INTRODUCTION

1

AN ANALYSIS OF HUMAN ANATOMY

ANATOMY: ITS STATUS AS A DISCIPLINE

As the terminal decade of the 20th century approaches, the revision, sculpture and modulation of the 37th British Edition of *Gray's Anatomy* (published *in continuo* since 1858) has proceeded apace. Limited and leisurely in earlier editions, such activities perceptibly increased in tempo and included occasional bibliographic footnotes over the intermediate years; overall objectives were, however, largely unchanged. Close scrutiny led the present editors to attempt a complete reappraisal of content, approach and format; their views, initiated and advanced in the 35th and subsequent editions, involved a great broadening of scope to reflect the richness of modern anatomy in its various aspects. The origin and current suitability of the name *Anatomy* merits consideration; as we shall appreciate, a commonly held view is that its content is 'axiomatic', 'self-evident' and 'complete and wholly understood for centuries': all false propositions. Similarly, disciplined caution should obtain when contemplating the use of many terms, e.g. 'form', 'structure', 'morphology', 'permanence', 'change', 'dynamism', 'function', 'mechanism', 'vitalism', 'evolution'. Attempts at *definition* of any terms should be made, together with a clear statement of any known, but ever present, constraints on that definition.

Over the millenia there occurred an exponential arborescent growth of recorded observation, contemplation, dialogue, action, prediction and experimentation. The total record, however imperfect and incomplete,—human *Philosophy*—constitutes the broadest encompassing study constructed by mankind. The trunk, main branches, small growing terminal twigs etc. are analogous to the principal and lesser (although sometimes extensive) partial divisions and subdivisions. After the initial dichotomy into natural philosophy and moral philosophy, the next order includes, amongst others, ethics, metaphysics, mathematics, science, philosophies of religion, logic and the contemporary schools of philosophy. The divisions between these segments, zones (or 'whirlpools') of human thought constructs are incomplete in that they are artificially imposed on a continuum; each overlaps, interlaces with but most prominently *interacts with* its neighbours. Attempts to study a discipline in isolation contribute little; greater significance accrues when the state of advancement of its surrounding interacting disciplines is included.

On this basis, recent decades have seen Human Anatomy firmly placed as an essential facet of the core of the *Philosophy of Natural Science*; within *Biology*, the study of the biosphere, it is that area of Zoology directed towards the phylum *Chordata*, and, within the eutherian mammals, the *Primates*. Human anatomy is, therefore, a crucial feature of mankind's unending study of man, which embraces the arts, sciences, mathematics, politics, religions, ergonomics and environmental manipulation—all percepts of human cerebration. Assessing the structure (form or morphology) of the parts, or whole, of the human body is the province of anatomy. However, since all material systems known to man show dynamic changes, some apparently random, others cyclical or directional (ontogeny, learning, evolution), the structural elements selected for comparison should be assessed (in theory) simultaneously. Thus, pedantically, the *structure* of a system is 'the array of parametric variables measured at one instant in time'. Anatomy is no longer merely descriptive and anecdotal, but a central *science* that is numerate (involving measurement, data storage, statistical analysis, mathematical modelling) and, whenever possible, *experimental*. Rote repetition of 'acceptable' answers to specific questions, although engrained in many vocational examinations, is an actual impediment to progress. Uncertainty, in the face of insufficient soundly based data, should be stated and will only lessen as these accumulate.

THE DEVELOPMENT OF GRAY'S ANATOMY

Since its publication in 1858 Gray's Anatomy has evolved, under successive editors, reflecting to varying degrees many recorded facets of international anatomy available to them at any period. Thus, the following pages initially give a concise historical survey of this evolving volume. This is necessarily viewed against the principal landmarks of anatomy as a whole and those of neighbouring and interacting philosophical disciplines.

Henry Gray's *Anatomy—Descriptive and Surgical* was published in the same year, 1858, as Virchow's *Cellular Pathologie*. Microscopes were improving and Schwann (1839) and Schleiden (1838) had established a cell theory. Broca, Bell, Magendie and others were founding neurology. In 1858, 'The Year' as we might say, Darwin and Russell Wallace presented papers at the same meeting of the Linnean Society, though Wallace was still in the Malay Archipelago, having left his partner, the collector of fossils par excellence Henry Bates, on the Amazon for another ten years.

Gray's book was indeed sandwiched among great events, between Karl Marx' *Communist Manifesto* (1857) and Charles Darwin's *Origin of Species* in 1859, a year which also saw Florence Nightingale's epochal *Management of Hospitals*. The Crimean War and Indian Mutiny were just over and Britain had become 'the Workshop of the World'. The Railway Age was still in full swing; the Liverpool/Manchester link was made in 1850. Victoria Regina was near to becoming Imperatrix and about a third through her reign. Prince Albert, aided by Paxton and Brunel, had promoted the 'Great Exhibition' in Hyde Park in 1851 and Brunel's *Great Eastern* was launched in the same year as Gray's *Anatomy*.

The Industrial Revolution, arising in Britain, was reaching a peak (but could not reach countries such as Japan for half a century). All the Western World, led and supplied technologically by British factories, was in a state of increasing dynamism. The loss of American colonies by European powers was turning Britain, at least, to a second, larger, empire in all other continents and many islands elsewhere. The Napoleonic wars and Trafalgar were memories; Wordsworth, Shelley, Byron and Keats were becoming part of the literary heritage.

Into this stirring era Henry Gray was born (1827). Matriculating at 18, he entered St George's Hospital (1845), qualified and became a demonstrator in the Hospital's department of anatomy (1850). But in his third student year he had already taken the Royal College of Surgeons' triennial prize for his work on the development of the optic and auditory nerves; when still only 25 he was elected to the Royal Society, probably due to his study of the developing endocrine glands. In the next year (1853) he won Guy's Hospital's Astley Cooper Prize with his dissertation *On the Structure and Uses of the Spleen*.

If this were all, Henry Gray had already accomplished far more than most professional men at 27 years but, four years later, as a result of his careful dissections and a clear appreciation of the needs of students and surgeons, came his greatest triumph, the book which became an instant success, despite bad reviews in the *Lancet* and *British Medical Journal*, a book which was to carry his name throughout the international medical world and beyond.

His publisher was John Parker, who also undertook a second edition (1860); but Gray, while still a mere candidate for an assistant surgeonship at St George's, succumbed to smallpox in 1861, while nursing a nephew with the same infection.

Gray had procured the help of a talented fellow demonstrator, Dr H Vandyke Carter, as his illustrator; his work, a pleasing compromise between diagram and reality, was a large contribution to the book's success.

Longmans bought out Parker's business in 1862 and the 3rd edition came out under their imprint; the copyright has remained in their hands. Like their earlier successes, Macaulay's *History of England* and Roget's *Thesaurus*, Gray's *Anatomy* has become a major factor in Longman's empire, although Gray's Centenary volume (1958) was scarcely mentioned in Longman's 250th anniversary volume in 1974. Gray's book, even more significantly, has become globally perhaps the best known textbook in the world of medicine, not only in its original British version but also in an American format since 1859 and in many translations, e.g.

Chinese, Portuguese, Italian, Spanish, and most recently Japanese.

It is worthy of note that Henry Gray was writing about three centuries after the *De Fabrica Humani* of Vesalius had established a tradition of accurate *description*, with little or no reference to function—a tradition still with us, though in Gray's time and even more so today the advent of microscopy and other techniques had added vastly to descriptive detail. It is curious that although much of Gray's research, especially the 'uses' of the spleen, recorded much more than structure, this side of his mind did not enter his book.

Subsequent editors were at first largely surgeons. The 3rd to 9th editions (1863–1880) and the 10th to 14th (1883–1897) were prepared respectively by Timothy Holmes and T Pickering Pick, both surgeons of St Georges. But in the 15th and 16th editions (1901–1905) Pick was assisted by a professional anatomist, R Howden of the University of Durham, who carried on as sole editor of the 17th to 23rd editions (1909–1926). The book was then about halfway through its 128 years of continuous publication. T B Johnston (Guy's Hospital Medical School) was responsible for the 24th to 27th editions (1930–1938) and was assisted in the 28th to 31st (1942–1954) by his colleague James Whillis. In 1954 Peter L Williams began his close association with Gray's Anatomy, initially as Indexer and, since 1968, as joint editor with Roger Warwick. In the 32nd Centenary edition (1958), Johnston was joined by D V Davies (St Thomas' Medical School) and F Davies (University of Sheffield), the latter two preparing the 33rd edition. D V Davies revised the 34th edition (1967). The current editors (P L Williams and R Warwick) have produced the 35th (1973) and 36th (1980) editions.

Editing by professional anatomists has certainly changed Gray's text, but initially at a very slow pace, the main burden of change being accumulations of more and more structural detail, especially at the histological and cytological levels. There has also been an increase in quotation of the actual origins of new descriptions, especially under D V Davies' editorship. The book's subtitle in more recent editions, 'Descriptive and Applied', still approximated its content and priority. But in the 35th edition the present editors deliberately expunged this subtitle, since they regard human anatomy, as do some others, not as a mere structural commentary but as a science in its own right, worthy of independent pursuit but at all times inseparable from other studies, particularly physiology, embryology, biochemistry, and so forth. The Vesalian tradition has served its turn; in fact its protraction has led to the division, amongst other ill effects, of function and structure. Physiologists are more fortunate; all functions occur in structures and the basic medical discipline, anatomy, necessarily provides a basis for all functional studies. But the anatomist may, and often does, stop the machine, describing it, even ad nauseum, without appeal to its function. This policy, though fortunately not often nowadays pursued to the ultimate, deprives the subject of its content of rationality. It is difficult to imagine investigation of structure without a concomitant desire to elucidate function, development or any other aspects of structure. Long ago Descartes described Man as a complex of machinery —biochemical, micro- and macro-anatomical—and machines work; all *living* structures are constantly changing at one level or another.

Of course, detached anatomical detail may often, but not always, serve the needs of surgeons and other clinical workers; and this may lead to such spurious concepts as 'surgical anatomy', 'radiological anatomy', and the like. But this obscures the fact that anatomy is concerned with a continuum of knowledge. Moreover the entire subject is merely a subdivision of the larger continuum of science, embracing much knowledge. This is our conviction and hence our policy.

Thus, as intimated (p. 2), human anatomy is approached, in this volume, as a numerate, reference-based, where possible experimental, natural science, notionally directed at structural parameters (previously defined). Structural correlations with many other disciplines may prove of theoretical or practical help; however, the *structure/function* relationship is *indivisible* and central to our thesis. The term function, although commonplace, is infrequently defined, other than 'actions proper to a part'; lexicographers are unhelpful, prominent sources avoid the semantics. For our present purposes, and including our structural definition, *function* may be considered as 'the sequential changes in the array of parametric variables with the passage of time'. This formalized definition offers few constraints; spatial coordinates may span vast distances across the universe, or the minute interparticles, clefts of subatomic units; temporal coordinates extend from the inception of the universe to the time of observation, and range from thousands of millions of years to microseconds. Diverse phenomena, all with their distinctive evolutionary histories, are relevant to our present theme. Some major ones are outlined briefly in the following pages and include: theories of the origin of the universe, stars, star clusters, galaxies, supernovae and planetary systems; the changing nature of matter with the emergence of wide varieties of atomic and molecular species and chemical compounds; alternative (perhaps dualistic and parallel) views of the origin of terrestrial life, its diversification, increasing complexity, dispersion; organic evolution and sexual reproduction; a survey of the animal kingdom with particular reference to the primates and man's place within them; and evidence concerning man's origins. These opening subsections are intended to provide a foundation, before a more detailed specific study of mankind's fabric—cells, intercellular material, tissues—and *functional topography* is undertaken.

ORIGIN OF LIFE ON EARTH

Our knowledge of human origins remains largely conjectural. It relies on fragmentary evidence from many different disciplines and is liable to major reassessment as new clues arrive, which they will no doubt continue to do and with increasing frequency. Relevant data arise from two major sources: the study of the fossilised remains of extinct forms, and comparative investigations of the anatomy, biochemistry and genetics of living species.

Of these, the first is the only reasonably direct means of establishing human ancestry; but because the fossil record is incomplete and it is difficult to interpret skeletal remains in their widely varying states of preservation, this approach has limitations. The more indirect comparative methods have also provided many useful clues about man's relationships, and the younger disciplines of molecular biology, particularly those dealing with molecular genetics, hold out great promise of unravelling the mechanisms by which the form and function of the human body are and were shaped. Of course the processes which gave rise to mankind have operated over immense periods of time, with widely varying influences of environment, both geological and biological. To understand the significance of these events we must also think of the physical forces which created the possibility of human emergence, of the preceding aeons and cosmic background from which life arose at first. Although these considerations may seem out of place in a textbook of anatomy, they are very relevant to our appreciation of the living substrate of the body, of its principles of construction and operation at all of its levels of organization including the cellular, tissue, developmental, systemic and integrated whole body grades, which are the themes of this book.

Present astronomical evidence points to emergence of the material universe from a single event 10–20 thousand million years ago, when the components of matter and perhaps with them the dimensions of space and time first appeared (1.1). In mathematical models of this event, it is envisaged that it occurred with unimaginable explosive force, generating temperatures of many millions of degrees and at first permitting the free existence of the fundamental, subatomic particles of matter. Within microseconds, as they began to cool, these assembled themselves into larger aggregates and finally atoms and then molecules of hydrogen. This matter expanded rapidly outwards and continues to do so even at the present time. From this singularity, the 'big bang', hydrogen molecules were first scattered fairly evenly in space but with some locational variations in density. Then under gravitational influences, they drifted together in denser clusters which eventually became massive and compact enough to convert the gravitational energy into temperatures sufficiently high to start thermonuclear fusion reactions and mass-energy conversion, so creating stars. (Currently, some theoreticians are even

exchanging views of innovative, but speculative, mathematical models which may assist the approach to the problems of the prevailing conditions preceding, and at the inception of, the 'big bang'.)

Clusters of stars were drawn together into galaxies, and as they aged they sequentially, but asynchronously, passed through various changes in physical state, depending on their original dispersion and mass. At the enormous temperatures they generated, hydrogen atoms fused into progressively heavier atoms, forming the varieties of elements we know today. Some particularly massive stars became unstable and eventually exploded as supernovae, strewing the products of their fusion reactions into interstellar space where they cooled enough to form complex chemical compounds. It may have been that such material was captured by the gravitational fields of other stars, coalescing into larger masses which circled around them as planetary systems. Our earth appears to have been formed in the solar system at about five thousand million years ago as a hot mass of rocks rich in elements such as carbon, silicon, oxygen, sulphur and phosphorus as well as many metals, e.g. sodium, calcium, potassium and iron. This world appears to have been at first highly volcanic but, as it began to cool, water vapour could condense, forming the early seas, rivers and lakes, and generating the processes of erosion and sedimentary deposition which dominate the geology of our planet today. This early period was now cool enough to allow hitherto impossible chemical reactions in aqueous solution and the early water masses may have teemed with a wide variety of molecules in a dilute solution of inorganic ions. In particular, many carbon-based compounds were stable at these temperatures, yet could react with each other rapidly enough to create a rich carbon chemistry. It is likely that life arose in such an environment.

All matter, living or non-living, consists of the same basic subatomic units, and, varying quantitatively, many common atomic species. The most obvious distinction between the living and non-living is the dynamic level of molecular organization of this matter, that exhibited by the living being greater. Furthermore, development, growth and maintenance of living organisms involves a temporary increase in order, the ability to effect this increasing with the organism's level of complexity. Living organisms are usually ascribed a common series of attributes, e.g. the ability to sense and respond to environmental changes, to move, to grow and to reproduce. These vital attributes are considered further on p. 6. To describe is not to define, however, and what distinguishes the living from the non-living eludes precise definition.

How living matter originated is still speculative. It is generally assumed, but rarely challenged among scientists, that life evolved exclusively *on Earth* from non-living matter. The commonest hypothesis is that when our planet had cooled sufficiently for the water vapour in its atmosphere to condense and begin to erode its rocks, the elements which dissolved in it combined to form simple inorganic molecules which, in response to solar energy, reacted chemically to produce the amino acid units of the enzymes essential to the life process. These interacted further, some evolving into 'living' self-replicating units, resembling viruses, in which the information necessary to ensure the accurate duplication of enzymes and other proteins was encoded in nucleic acids. Enclosure of some such units within proteolipid membranes might have produced the first unicellular organisms, perhaps like bacteria, each able to exert a measure of control over its internal environment, leading to increases in local order, longevity and reproductive capacity.

The results of experiments by Miller & Urey in 1953 suggested that amino acids could have been formed in the terrestrial atmosphere presumed to have existed some 4500 million years ago; this strengthens the hypothesis that life could have originated from non-living systems on earth, but the next and literally vital evolutionary step, the chance interaction of these amino acids to form the proteinaceous enzymes necessary for self replication, has not been demonstrated. Lack of such a demonstration does not, of course, invalidate the hypothesis but equally the demonstration that amino acids could have formed in the then prevalent conditions does not prove that they actually did.

During the last two decades a novel, and controversial, alternative to the traditional hypothesis that life arose on Earth from non-living matter has emerged. According to Crick & Orgel (1973), Hoyle & Wickramasinghe (1981) and others, the concept of the Earth as the biological centre of the Universe is as erroneous as the pre-Copernican notion that it was its physical, geometrical centre, and the possibility of an extraterrestrial origin of living matter has been raised. This proposal is claimed to be supported by the identification in meteorites of what is presumed to be once-living matter preserved as microfossils possibly resembling viruses and bacteria. A modern bacterium, *Pedomicrobium*, has features suggesting what such organisms may have been like. This species obtains energy by oxygen transfer from salts to either ferrous iron or manganese, a process which could explain how deposits of ferric iron came to be laid down in rock formations as long ago as 3800 million years, well before sufficient free oxygen had been produced by photosynthesis for atmospheric oxidation to have given rise to them. If organisms resembling *Pedomicrobium* were responsible for such processes, would there have been sufficient time, and were conditions suitable, for such organisms to have evolved de novo on Earth? Until 1979 the earliest geological evidence for microbial, prokaryotic life was dated at about 3200 million years ago; since this predated the earliest eukaryotic fossils, it accorded with the theory that eukaryotes had evolved from prokaryotes. However, in 1979 Pflug et al found what they interpreted to be yeast-like and therefore eukaryotic fossils in rock deposited about 3800 million years ago, throwing some doubt on both the theory of their evolution and on the possibility that such complexity could have been reached by chance in the time available. An alternative explanation (Hoyle 1983, and others) is that both prokaryotes and primitive eukaryotes could have had an extraterrestrial origin, existing as components of the interstellar dust and arriving on Earth and on other planets in an already living, though dormant, form after being carried in, and protected by, the frozen water which forms the bulk of comets. According to Bruch (1967) the hazards to the survival of dormant microbial spores under such conditions have been exaggerated, for they could be shielded from the chief dangers, solar ultraviolet irradiation and the solar proton wind, by a thin layer of overlying material, and could also have survived descent through the Earth's atmosphere. If this hypothesis of an extraterrestrial origin of life and its mode of transport to Earth is correct, then the continual bombardment of the Earth with such material may have influenced, and still be affecting, the progress of evolution. The fundamental, fascinating problem of how life, whether originally terrestrial, extraterrestrial *or both*, began remains unresolved. Clearly the temporospatial coordinates of these events also await resolution.

It may also be noted that the idea of an extraterrestrial origin does not solve many of the central problems of life's origins but displaces it to some other cosmic site. However, the theory is notable for its stimulating, controversial nature rather than, as yet, the strength of evidence in its support.

EVOLUTION OF LIFE ON EARTH

However life arose, many remain persuaded that it appears to have done so only once, since the highly complex macromolecules of different living organisms and their metabolic interactions share too many common features to have arisen independently. (More strictly, whatever view of life's origin is envisaged, the 'only once' of the preceding paragraph should, perhaps, imply *one common mechanism*, whatever its possible multiplicity of sites and times.) The simplest living cells are the bacteria, blue-green algae and similar forms (collectively termed Prokaryotes), which have most of the essentials of other cells, except that they do not carry their genetic material in a nuclear compartment and, apart from the outer cell membrane, they lack membranous organelles. More complex cells (Eukaryotes) are likely to have arisen from these (however, vide supra) but differ from them in having nuclei

1.1 The origins of biological organization as envisaged from present cosmological, biochemical and palaeontological data.

containing larger quantities of genetic material in multiple chromosomes sequestered away from metabolic damage. Such cells needed a special (mitotic) apparatus to handle their more elaborate chromosomes at cell division and also perfected ways of exchanging genes in meiosis which increased their variability and therefore the potential to exploit a variable environment. These cells also had complex membranous organelles within their cytoplasm so that different areas of the cell could be allocated to specialized functions. These developments appear to have been crucial because they allowed the formation of progressively more elaborate genetic material, structure and metabolism and consequently more complex form and function. It is likely that there were many different types of cell during this early experimental period, only some of them ancestral to the forms of life we know today, e.g. protozoa, unicellular algae, fungi, multicellular plants and animals (1.1,2) (see Vidal 1984). Some of these may have arisen as combinations of cells giving greater metabolic potential; thus both mitochondria and the chloroplasts of green plants have their own genetic apparatus distinct from the rest of the cell and may have arisen as independent organisms (see Margulis 1981). It is also likely that many of the earliest eukaryotes were able to use sunlight for their energy needs and had photosynthetic pigments. Certainly once the early nutrients in the environment had been depleted this would have been the only source of energy for the biological world, herbivorous and carnivorous animals depending for their supply of chemical energy on green plants. From this point onwards there must have been a great proliferation of different forms and the development of multicellular organisms in which different cells could carry out specialist tasks (see Romer 1968, Attenborough 1979).

THE ANIMAL KINGDOM: SELECTED PHYLA

The fossil record of these events begins with any clarity only when many of the major groups of invertebrates had already appeared, by about 500 million years ago, and the line of descent (1.2) can only be surmised. It is thought that the first truly multicellular animals (*Metazoa*) possessed two layers of cells (i.e. they were diploblastic), but that later a third layer was added giving an outer, ectodermal layer, a middle mesoderm and an inner endodermal lining to the gut (enteron). The outer layer provided an interface with the environment, the inner was concerned mainly with nutrition while the middle layer provided mechanical support, muscular systems and a route for nervous and circulatory systems. In the simplest *triploblasts*, such as flatworms (Platyhelminths), the mesoderm is usually a solid mass but in more complex forms it splits into an outer (somatic) and an inner (splanchnic or visceral) layer, the latter surrounding the gut which is now free to move within the cavity (coelom) so formed within the mesoderm. In these animals (coelomates), an efficient vascular system is essential to convey nutrients absorbed in the gut across the coelom to the outer parts of the body and we find that they all possess propulsile heart-like structures as well as branching vascular channels. The freeing of the outer mesoderm from the gut also made further locomotor advances possible and many such animals are organized on a segmental pattern of repeated muscle blocks and attendant nerves and blood vessels which facilitated many different types of movement and specialized local body functions. This segmental pattern is fundamental to many groups of animals including ourselves and it is significant that at least some of the genetic mechanisms for generating segmentation and local specialization of segments (homiotic genes) appear to be much the same in both insects (e.g. *Drosophila*) and mammals.

From these segmented coelomates, which include annelid worms, arthropods, molluscs and echinoderms (i.e. starfish and their allies), are thought to have arisen the *chordate phylum*, possibly from an echinoderm-like stock. The simplest chordate-like animals we know today are aquatic filter-feeders such as seasquirts (Urochordates) and the fish-like Cephalochordates (the lancelets *Branchiostoma* or *Amphioxus*). These filter their food from water through a series of slits flanked by supporting bars in their pharyngeal walls, which appear to be the forerunners of the embryonic pharyngeal clefts and arches of all vertebrates. Many of these primitive creatures also have hollow dorsal central nervous systems, derived perhaps by the invagination of superficial nerve nets such as those we see in starfish. They have bilateral symmetry and, at some stage in their lives, segmental muscle blocks grouped around a longitudinal stiff but flexible rod (notochord) permitting sinusoidal swimming movements. At least some of them also develop an additional embryonic group of cells, the neural crest (see p. 132), which is of great significance in the development of many typical chordate features.

The origin of the true vertebrates from such groups appears to have been relatively late, the first well preserved fossil forms, armour-plated fishes called Ostracoderms, occurring in Silurian rocks about 410 million years old, although fragments of fish-like scales also occur in much older strata. Ostracoderms lacked a true jaw mechanism (the agnathan condition) and were apparently rather poor swimmers, judging from the rudimentary state of their fins and the presence of only two semicircular canals in their inner ears. However, they had all of the typical vertebrate features including a brain and surrounding skull, a ventral heart and effective high pressure blood system. Their pharyngeal arches supported gills and the clefts between them allowed the flow of water in a respiratory current. The heart pumped blood through a series of vessels lying in the pharyngeal arches, the basic number being six pairs. Although these were used for perfusion of the gills in respiratory gas exchange, they created a pattern which persists even in human embryonic development, where it is modified to form the great vessels leaving the heart (see p. 213). The modern cyclostomes (e.g. lampreys) are the descendants of these fishes.

The next advance was the modification of the most anterior pharyngeal arch to support the mouth, its ventral part becoming the mandibular arch (see p. 165); this allowed the development of more efficient and varied feeding (the gnathostome grade of organization) and teeth could be anchored to the jaw to increase its effectiveness. (For the upper jaw and teeth see p. 167 et seq., and p. 1299.) Often the next (hyoidean) arch was used to support the first, as well as to contribute to the tongue apparatus. At the same time, swimming ability improved greatly with the formation of complex fins, a third semicircular canal and no doubt advances in brain organization to control movement more efficiently. These steps proved very successful and most later vertebrates arose from this stock (1.2). These early fishes included many different types, most of which became extinct although some, like the cartilaginous sharks and rays (Chondrichthyes), persisted and thrived. Another group of fishes with bony skeletons (Osteichthyes) divided into a line leading to the majority of modern rayfinned fish and another, the Sarcopterygians, in which the fins were highly muscular and had an axial skeleton, a situation we see in modern lungfish and the Coelacanth *Latimeria*, anticipating the limbs of early terrestrial vertebrates. Some of these fishes may have been able to breathe air as well as to use their gills for respiration. Their upper jaws (p. 340) were fused with their brain case (neurocranium) to increase the skull's mechanical stability and various plate-like bones derived from scales in the dermis reinforced the neurocranium, the skeleton of the jaws and other pharyngeal arches. These 'scale bones' correspond to the membrane bones of the human skull, while the more primitive neurocranial and viscerocranial elements are represented by its endochondral bones (see p. 304).

From such fishes emerged the earliest land-living vertebrates, during the Upper Devonian era about 270 million years ago. These were amphibians with many fish-like features but instead of pectoral and pelvic fins they had muscular limbs, each with five digits and a characteristic pattern of axial bones (the pentadactyl limb) as in all terrestrial vertebrates, or tetrapods. They were therefore able to move around on the swampy ground of the coal forests, where their remains became fossilized. Lacking gills except during larval life, they respired through diverticula of the oesophagus, i.e. simple lungs, a common method of accessory breathing even in fishes which live in tropical anoxic waters. Judging from the condition of modern amphibians such as salamanders, frogs and toads, these animals had hearts with partially divided ventricles, allowing them partial separation of blood for systemic and pulmonary circulations and therefore a more efficient respiratory transport permitting increased active movement. With the loss of gills, the arterial arcades of the pharyngeal

1.2 The relationships and different levels of organization of the major groups of animals leading to the mammalian class, based on currently available evidence.

arches were reduced in complexity and number and now were simple, but large, arteries leading to the head, body and lungs. Amphibians were, however, still dependent on an aqueous environment since they laid their eggs in water and probably dehydrated easily through a relatively permeable skin.

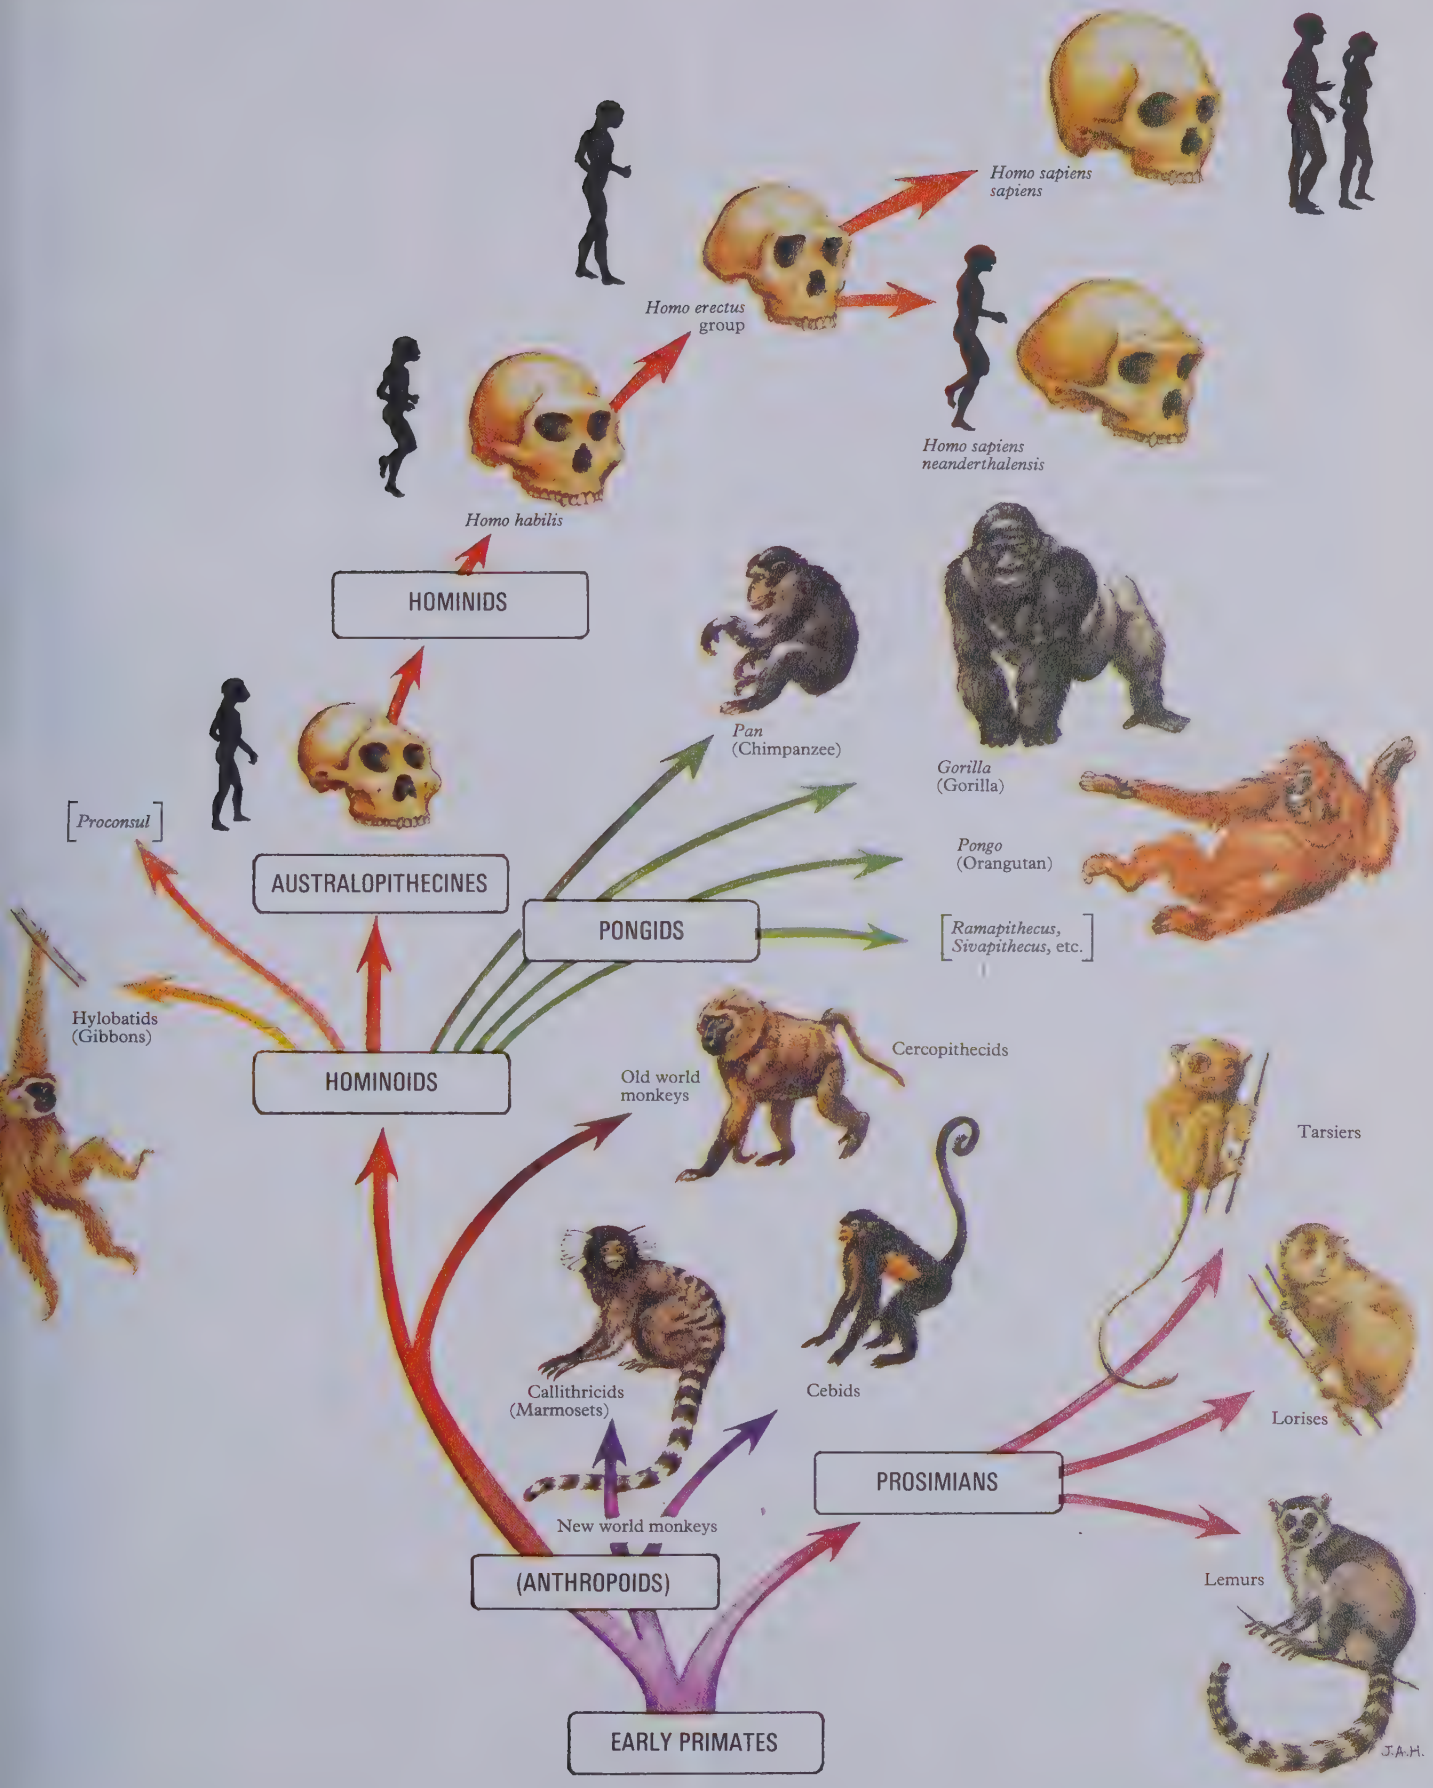
Early reptiles probably emerged soon after the amphibia. Two major advances freed the new group from slavish dependence on water: the skin became keratinized and water resistant; reproduction could take place entirely on land as the young developed in an egg enclosed in a shell which prevented water loss but allowed gaseous exchange. Within the shell the embryo floated in a fluid-filled space; the amniotic cavity and the membranes immediately surrounding it (amnion and chorion) acted as a gill. Except for the egg-shell, these modifications were retained in all descendants of the reptiles including mammals.

Reptiles were now free to exploit the dry places of the earth as well as the humid ones and they became the dominant vertebrate group for many millions of years. Various internal changes took place including: complete separation of systemic and pulmonary circulations; the formation of a vena cava making the return of blood more efficient; development of a high pressure kidney with more effective filtration; various modifications of the brain which increased its ability to analyse sensory data, organize motor activity and to establish more complex behaviour patterns in general.

Although many of the most successful reptilian groups such as the dinosaurs eventually became extinct, some persisted as the turtles, lizards, snakes and crocodiles of the present or became highly modified for flight, the birds. Another group of great significance comprised relatively unspecialized animals emerging quite early in reptilian history. These had a unique skull construction with a fossa in the middle of its lateral surface allowing the expansion of masticatory muscles, the Synapsid condition. Along this fossil line, several remarkable changes occur. These include the expansion of the brain and its braincase, an alteration in the jaw mechanism so that several of the bones which hitherto had formed part of its articular mechanism became reduced in size, adapted for picking up auditory signals and progressively incorporated into the middle ear. Complex teeth of different types and with more than one cusp were also inserted into the jaws, a sign of more effective mastication, and a new, more robust joint formed between the mandibular condyle and the temporal bone. Locomotion was also modified by a rotation of the limbs bringing their intermediate and distal joints *under* the trunk, thus introducing an ability to lift the body off the ground, a change suggesting a cursorial habit commensurate with a high metabolic rate and therefore warm-bloodedness. (The manner of limb rotation and attendant modifications contrasts sharply in the fore- i.e. upper, and hind- i.e. lower limbs: see pp. 174, 399.) Hair probably covered their bodies in an insulating layer.

Such creatures co-existed with the ruling reptiles from the Permian era from about 200 million years ago and, when the latter became extinct, they replaced them as the dominant land vertebrates. By this time the full mammalian condition had been achieved, with a greatly expanded brain, fully functional temporo-mandibular joint, teeth specialized for different functions (incisors, molars, etc.) and showing the primitive pattern of mammalian cusps (see p. 1299). To judge from the nearest descendants of some of these early mammals, the *Prototheria* (Monotremes) of Australasia such as the Platypus, *Ornithorhynchus*, these creatures were certainly homeothermic, covered in hair, suckled their young, although they still laid eggs, and had many other non-reptilian features such as a division of the trunk into a thorax and an abdomen, with a diaphragm allowing thoracic breathing. Their pharyngeal arterial arches were more streamlined, the third being developed only on the left to form the aorta. Such animals were obviously well equipped to deal with the wide variety of climatic conditions and of food sources available in a drastically changing environment. Their more advanced brains could no doubt enable them to exploit their environment more fully and better maternal care, including suckling, favoured the survival of offspring and permitted prolonged development after birth. Many different groups of such animals rapidly spread over the land masses; one of them, which dispensed with laying eggs by retaining the fetus in utero for the early part of its development, became dominant. These were the *Metatheria* (Marsupials), including the pouched forms such as the kangaroos and non-pouched species like the opossums. They had relatively larger and less 'reptilian' brains and a more effective feeding apparatus including highly specialized teeth. Again, from the many different types of marsupials a third mammalian group the *Eutheria* (Placentals) arose and, in turn, supplanted them. In these new mammals, the developing young were retained for much longer inside their mothers, attached, as were marsupial embryos, by a placenta which provided nutrition, respiratory exchange, removal of excretions and other metabolic needs. The placenta of the Eutherians was much more elaborate and effective than that of the marsupials, allowing birth at a very advanced stage of development and in particular permitting the brain to achieve considerable complexity before its use for survival in the outside world. These mammals rapidly replaced most of the other groups. This basic eutherian design which first emerged during the Cretaceous period about 120 million years ago, or possibly earlier, was extremely successful at adapting itself to many different evolutionary niches, radiating into the various mammalian forms we know today.

The closest living relatives of these early *Eutheria* are Insectivores such as the Shrews, small highly active animals with primitive tooth patterns and relatively unspecialized body form. It is thought that from species similar to these arose a group of animals which were ancestral to the Primates.



EVOLUTION OF PRIMATES

From this relatively unspecialized mammalian line arose a group of animals with enlarged brains, well-developed vision progressing to a binocular, stereoscopic condition, strongly developed hearing but reduced olfactory sense and an unusual facility in grasping with their fore- and hind-feet (i.e. manus and pes). We see these features, developed and improved upon to varying degrees, in a range of living and fossil species which constitute the *Primate Order* (1.3).

PROSIMIAN PRIMATES

The earliest true primates are thought to have emerged during the Palaeocene era as long ago as 60 million years, or even earlier. Since recognizable fossils of these animals have not yet been found, ideas of what they were like rely heavily on the most primitive living primates, classified as the Suborder Prosimii. To judge from these, the first primates had a cranium expanded to carry a brain with particularly well-developed cerebral and cerebellar cortices. Their eyes were large and a protective bar of bone separated the orbit from the temporal fossa, while the nasal cavity was reduced. Their limbs had very mobile joints and their first digits (pollex and hallux) were somewhat rotated and separate from the others and could be opposed to them for grasping. In the more advanced species the claws were flattened into spatulate nails which assisted manipulation. Dentition was of a primitive mammalian type with unspecialized tooth-cusps, allowing their possessors to eat a wide range of food.

The earliest of these species were probably arboreal, as are the most primitive living primates, the Lemurs, long-tailed tree-dwellers of Madagascan forests, with large brains, highly mobile limbs and well-developed prehensile hands and feet. In their close relatives, the Lorises, which include the bush-baby (*Galago*), the large eyes are turned forward, giving good stereoscopic, binocular vision allowing precise judgement of distance; the brain case is high and the snout much reduced in length, like the more advanced apes. These different groups, collectively known as the Lemuroid primates, and their more specialized relatives the Tarsiers, agile creatures with huge, forward-looking eyes, are all adapted to a nocturnal, arboreal life-style and a varied diet such as fruit, nuts, leafy shoots and insects which they can hold with their grasping digits to bite and chew with their relatively unspecialized teeth; this type of condition may have been typical of all early primate species. Like all primates, they show a high level of parental care, the offspring being few and suckled by means of two thoracically-sited mammary glands.

1.3 A scheme outlining possible evolutionary relationships between *Homo sapiens* and other living and fossil primates. For simplicity and because of present uncertainties about classification, details of species of fossil primates have not been included (see text).

The considerable variety of remaining primates (previously grouped as the *Suborder Anthropoidea*) appeared and approached the human pattern more closely. Their brains are larger relative to body size and their vision fully binocular, with forward-facing eyes and appropriate orbital geometry permitting conjunct eye movements; instead of a thin bar of bone between the eye and the temporal fossa, there is a solid post-orbital plate which forms a protective posterior part of the orbit. Olfaction is further reduced, the snout being even shorter and the face dominated by the brain case. All such species can sit upright, so that the hand is free for more complex manipulative tasks, and there is a correspondingly more precise neuromuscular control of the fore-limb. With this change of body posture goes a change to a less obtuse angle between the axis of the cranial base and that of the vertebral column so that the foramen magnum is now near the base of the skull rather than at its rear and faces downwards (with the trunk erect). Behaviourally, extant forms are highly explorative, active creatures, usually living in groups and possessing a varied repertoire of communication skills, amongst which are vocalization and a corresponding auditory analysis in the brain. They also use various muscles of the face (those supplied by the facial nerve) to convey mood and, having highly developed colour vision (unlike most other mammals), they often employ brightly coloured areas of skin to signal social and sexual status. These primates include two distinct modern groups (Ceboidea and Higher Primates) with their many subgroups.

THE CEBOIDEA

The *New World Monkeys* (*Platyrrhini* or *Ceboidea*) of South America are a prosimian offshoot which probably separated quite late from the main stock (1.3) and is not considered further here.

THE HIGHER PRIMATES

The *Higher Primates* (*Catarrhini*), originally of Africa and Asia, differ from the prosimians in having fewer teeth (a total of 32 rather than the primitive 36), reducing the number of premolars to two in each quadrant and developing an unusual pattern of four blunt cusps on their molars; their nostrils are also close together and face downwards. The functional significance of these changes is not clear but they point to a common origin of this group of animals.

The higher primates are further divisible into two subgroups: first, the *Old World Monkeys* or *Cercopithecoidea* (e.g. macaques, baboons, mandrills and langurs); and second, the *Hominoidea* which include the great apes (gibbons, orang-utans, gorillas, chimpanzees) and humans. Of these different species, the great apes and related fossil forms are on many counts our closest relatives and are clearly of great importance in our search for human ancestry. Like Man, they differ in several respects from the other anthropoids, their brains being larger, their skulls more dome-like and provided with frontal sinuses and their body size generally greater. All have long arms, powerfully mobile shoulder girdles braced by strong clavicles and long fingers which enable the more arboreal types such as gibbons to swing with great ease and speed through treetops; legs tend to be short, pelvic girdles reduced, with ilia flattened in the coronal plane, and tails absent, thus minimizing the weight of the body which in the more arboreal species is transmitted mainly to the shoulder girdle and arms through a rather straight vertebral column. It is likely that all apes emerged from such tree-dwelling, brachiating forms, although it is improbable that they were as well-adapted to this mode of life as are the modern gibbons.

Structurally, the orang-utans, gorillas and chimpanzees, grouped as the family *Pongidae*, are much more similar than the gibbons (the *Hylobatidae*) are to Man. The orang-utans appear to have remained arboreal, while the line leading to gorillas, chimpanzees and humans became adapted to moving on the ground and the pelvic girdle and legs became more robust as the weight was now carried increasingly on the hind limbs. In the gorillas and chimpanzees walking is mainly quadripedal, the long fore-limbs carrying the anterior body weight on the knuckles; but the hands are also used effectively for manipulation and, in the case of chimpanzees, even to employ sticks as simple tools.

Various types of evidence from comparative anatomy, biochemistry (including comparisons of DNA sequences) and immunology suggest that the line leading to the gibbons was the first to diverge, followed by the orang-utans then the gorillas and finally the chimpanzees, which are generally regarded as closest to Man among living creatures. It is interesting that the gorilla's and chimpanzee's chromosomal patterns and the base sequences in their nucleic acids are almost identical to those of humans, although the great apes have 48 chromosomes rather than the human number, 46, probably because of chromosomal fusion in the human karyotype. However, these relationships are still under review, and some authorities place the orang-utan closer to the human line than the chimpanzee.

The fossil evidence of the emergence and separation of these different anthropoid lines is scant; best known are the skull of *Parapithecus*, a monkey-like fossil with some ape-like features, from Egyptian Oligocene deposits about 30 million years old and, from the same deposits, the more characteristically anthropoid jaw of *Propliopithecus*, which may be regarded as the earliest true ape yet found.

FINAL STEPS TO MODERN MAN

Between the Pongidae and modern humans are important differences in structure. A gradual progression from apes to Man is also fragmentarily detectable in the few fossil forms which span the period between about 20 million to 35 000 years ago, during which the human form probably evolved from apes. During this period, the essential hominid features emerged, the most important being a remarkable increase in brain size (the largest brain in the apes is that of the gorilla at 650 ml, whereas the human cranial capacity has a mean of about 1300 ml) and in the folding of the cerebral cortex, the development of bipedal walking and use of the hands for complex manipulation, especially the making of tools (see Pilbeam 1984).

With these major developments came a variety of anatomical alterations. Bipedal walking was made possible by changes in the shape, strength and orientation of the pelvic girdle, hip joint, femur and lower limb skeleton which allowed the placing of one foot in front of the other during striding locomotion. With upright posture, the vertebral column became strengthened against compressive forces and secondarily curved to absorb the mechanical shock of walking, while in the skull the foramen magnum came to lie almost centrally beneath the cranium as the angle between the base of the skull and the cervical vertebrae approached 90°. The occipital ridges, which in the apes are massive, providing reinforced attachments for the large cervical muscles holding up the head, became small as the skull now balanced on an upright vertebral column. The foot changed from a prehensile structure with an opposable first toe into a coherent though flexible plate with parallel digits and a highly arched general structure suited to prolonged standing, walking and running, sometimes on uneven surfaces.

With this bipedal habit, the upper limb was now completely freed for manipulative tasks; changes in articular angle and lengthening of the thumb made it fully opposable to the other digits; subtle alterations in the length and planes of movements of the other fingers and their muscles resulted in a complex, multipurpose hand capable of delicate tasks such as those involved in tool-making while preserving the powerful grasping action of the apes.

There were also transformations in teeth and jaws, and simplification of the nasal region continued as the olfactory sense further lessened in importance. The maxillae and mandible as a whole protruded less and the tooth rows they bore changed from a rectangular to a more rounded arcade; the canines decreased in size, becoming more spatulate, and the mandibular rami became taller and thinner. However, externally the chin increased in prominence, while on its internal face a ridge for the attachment of muscles, the simian shelf in apes, was reduced to four small genial tubercles (mental spines).

The increase in cerebral size gave the forehead a more domed

appearance and fetal cranial enlargement was reflected in a widening of the female pelvic girdle to allow the passage of the larger head of the young at birth.

Although skeletal remains of possible transitionary species are tantalisingly few, painstaking excavations during the last 50 years, particularly in the East African Rift Valley where the strata are exposed in an orderly sequence of dateable volcanic deposits, have provided increasing numbers of specimens, some of them excellently preserved. Inevitably, much controversy has surrounded the interpretation of these bones but there is general agreement over the major trends, which point to the origin of a distinctively human form by about 100 000 years ago.

Amongst the earliest skulls in this progression is that of a small ape, *Proconsul*, dating from about 14 million years ago in the Miocene of Kenya. Its features suggest that it was already some way along a divergent line leading to the gorilla and chimpanzee rather then a direct human antecendent. Another fossil group, found in deposits 10 to 20 million years old in sites widely scattered in Asia, Africa and Asia Minor, includes three rather similar genera, *Dryopithecus*, *Ramapithecus* and *Sivapithecus*, known mainly from fragments of tooth rows and jaw bones. At first they were considered good candidates for a central role in human evolution but the recent find of larger parts of a *Sivapithecus* skull suggests that this group may be more closely related to orang utans.

THE HOMINIDS

The first undoubtedly bipedal fossil anthropoids yet discovered are the *Australopithecines*, a group of ape-like animals found in the rocks of Eastern and South Africa, dating from 1–3.6 million years ago. They are a heterogeneous collection of different species, some, termed robust Australopithecines, having quite massive skulls, and others with more delicate bones (gracile types). However, some of these variations may reflect differences in gender or maturity. The Australopithecines have many features in common with the great apes, e.g. a relatively small braincase and a large dental arcade, but there are also some human affinities; e.g. an upright, bipedal gait is indicated by the shape of the pelvis and femur and by the form of fossil footprints preserved in volcanic mud at Laetoli in Tanzania, dated to 3.6 million years ago and attributed to *Australopithecus afarensis*.

The number of species within the Australopithecines and their relationships to each other and to mankind are still uncertain but it is very likely that some at least of these forms were close to the ancestral human lineage.

Next came the *Habilines*, found in East African deposits dating from 1.35–1.9 million years ago. This group also contains various forms, some with larger brains but ape-like jaws, others with more humanoid teeth but small brains. Their maximum cranial capacity is estimated at 680 ml, which has been considered sufficient to place them with Man in the genus *Homo*. Stone tools have also appeared in the same strata as their fossils and the hand is sufficiently human to suggest that these creatures were their creators, hence the specific name *Homo habilis* ('Handy Man'). However, the Australopithecines are also suspected of making simple stone tools and the distinction between these and the Habilines has not been made without controversy.

Another more modern series of fossils with many undoubtedly human features is grouped under the name *Homo erectus* (Upright Man). This category includes quite a wide range of skeletal forms of various ages between 500 000 and 1.5 million years, differing widely in geographical location, including Indonesia, China, Africa and Europe. However, they all have large crania, with capacities from 850 ml in Java Man to 1225 ml in Peking Man; there is also evidence of advanced behaviour, e.g. the use of fire at camp sites and the making of advanced stone tools (of the Chellean culture). They also had various non-human skeletal specializations such as massive bones and skulls with immense brow ridges and a sagittal crest, suggesting that at least the most typical of them were not ancestral to mankind but some off-shoot from the main humanoid stock.

Neanderthal Man, found in much more recent cave deposits in several parts of Europe dating from about 100 000–35 000 years ago, shows many features closely resembling those of modern humans, including large cranial capacities, equal to or even exceeding ours. They showed complex social behaviour, including, it appears, ceremonial burial of their dead and the making of quite advanced stone tools. But there were differences; like *Homo erectus*, their brow ridges were large and their skeletons comparatively robust. For these reasons they are accorded the sub-specific status of *Homo sapiens neanderthalensis*.

Remains of modern man *Homo sapiens sapiens* (often termed Cro-Magnon Man after the French location where some of the earliest bones were originally found) have been discovered in strata dating from as early as 35 000 years ago in eastern Europe. This date strongly suggests that the Neanderthals co-existed for some time with modern humans, although there is no evidence of interbreeding. These latest fossils are indistinguishable from modern skeletons, hence the human body which is the subject of this book must have at least this degree of antiquity.

The precise relationships between modern humans and the fossil forms briefly described in this account are far from settled; there is no general agreement on the line which human evolution has followed during most of the last four million years. But it appears likely that the human stock arose in Africa from a Habiline-like group of Australopithecines, although the gap between these and ourselves is so large and devoid of relevant fossils that, until further evidence is at hand, we can only speculate as to our lineage during this period.

The human races living today vary in skeletal, muscular and other details but the relationships between the different ethnic groups and their special physical characteristics are beyond the scope of this account. It is noteworthy, though, that anthropological and biochemical studies point to the emergence of all present-day humans from a small group of individuals, perhaps somewhere in the Middle East. Their descendants soon migrated into all habitable continents and adapted to their differing environments and climatic conditions. However, these developments were relatively recent and, in spite of minor differences, e.g. proportions of blood groups in different human populations, the genetic 'distances' between the races are in general insignificant compared with the genetic variation within them.

Analysis of mitochondrial DNA variation (which is transmitted only through the female line) in different races indicates that modern people descended from a female who lived perhaps 200 000 years ago in Africa, and that several waves of emigration from Africa subsequently colonized other land masses (Cann et al 1986).

The inheritance of form and function from the different stages of evolution, culminating in the supreme development of mental self-awareness and abstract thought, is one of the greatest stories that science has to tell, although understood in only the barest outline. Here we study the functional anatomy of *Homo sapiens*, a form which is not only superbly adapted to a multitude of present activities, but also bears within it a memory of its past; an awareness of this helps us to understand many of the otherwise inexplicable patterns expressed in the human frame, and perhaps to appreciate both its frailty and the most wonderfully effective complexity which it has attained.

Anatomical Nomenclature

A subject such as anatomy, with its accent on description, necessarily requires a very large number of names for structure and processes. For effective communication such words should be as simple as possible and used with unfailing precision. Unfortunately both these aims have only been partially accomplished.

In the first place, as in other sciences, common words do not exist in any language for thousands of structures which require to be named, and the need for new names never ceases. For this reason the manufacture of new names has been based, like the Linnean classification, upon stems of Latin and Greek words. When Latin and often also Greek were a usual part of general education, the actual meanings of these stems were familiar. Even in these days, when classical education is the privilege of only a small minority, many of the words used are familiar because they have to some extent crept into ordinary language, sometimes with

a little distortion: musculus, tendo, arteria, vena, cranium, etc. are so like their vernacular equivalents that use of the Latin form is easy.

Words derived from Latin and Greek have also the advantage of being suitable for international usage and, to ensure uniform usage, efforts have been made since 1895, when the Basle Nomina Anatomica was introduced. In 1950 at the Oxford (5th) International Congress of Anatomists, a new body was instituted, the International Anatomical Nomenclature Committee, whose first Honorary Secretary was T B Johnston (one of our editorial predecessors), the current Secretary being R Warwick.

It must be said at once that the officially and internationally agreed terms (see Nomina Anatomica, Nomina Histologica, Nomina Embryologica, 5th Edn 1983) are not always adhered to in textbooks or atlases. They are, of course, subject to revision at each quinquennial World Congress of Anatomists and doubtless many are still inept and many are far too complex. Who will stringently adhere to 'aponeurosis musculi bicipitis brachii' for what we in English call the 'bicipital aponeurosis'? Of course, each national language is permitted, and even encouraged, to vernacularize Latin terms, as long as the relation to the official Latin remains clear. No one expects a sudden reference to 'biceps femoris' when dealing with the arm, and hence 'biceps' for 'musculus biceps brachii' is safe to use, as long as no misunderstanding occurs.

This is the policy which we have adopted, not, unfortunately, with complete uniformity. We recognize the difficulty of pure Latinity for a large number of our readers and we prefer to anglicize Latin terms but to give the official form, at least once, in parentheses.

Coming also under the topic of nomenclature are the names of lines, planes and directions, used in describing structures. Conventionally the body is regarded as being in the so-called 'anatomical position' (1.4) whenever such descriptions are applied. This position might be called one of supplication—the body upright, facing forwards (anteriorly), with the palms also anterior. There may appear only two real objections to this. In the natural standing position with pendant arms, the forearms are usually well pronated. It is hence sometimes more apposite to speak of radial and ulnar aspects of the forearm, rather than medial and lateral. (However, some Anatomists regret the rigid adherence to the full anatomical position both morphologically and, from some aspects, functionally. Close inspection reveals it as an energy consuming position, seldom actively adopted and involving some scapular rotation and adduction, full lateral rotation of the humerus, direct mediolateral disposition of the elbow joint's axis, full supination of forearm and hand and with the pollex laterally placed! From this stem the somewhat unexpected courses of the radial and ulnar nerves and the disposition of the carpal and digital flexors and extensors. It proves most instructive to compare these and other features with their arrangement in natural standing or in many habitual postures or complex 'precision' activities. Prominent exceptions are placing objects in the mouth or, for examination, before the eyes.) Secondly, due to rotation of the leg at the hip in all but very primitive quadripeds, the originally dorsal extensor aspect has become anterior or ventral with respect to the knee and ankle joints. Furthermore the extensor and flexor aspects of the hip joint are the converse of those at the knee joint.

However, once a little comprehension of the broader facts of mammalian and hence human morphology is established, these difficulties are easily overcome. We have freely used the synonyms: anterior, ventral, flexor, palmar; also posterior, dorsal, extensor are apposite for the trunk and upper limb but they are not always satisfactory synonyms, e.g. the extensor aspect of the leg is *anterior* with respect to the knee and ankle joints and *superior* in the foot and digits; the plantar (flexor) aspect of the foot is, of course, *inferior*, and so on. (Further details and discussion of these problems may be found at appropriate locations throughout Arthrology and Myology.)

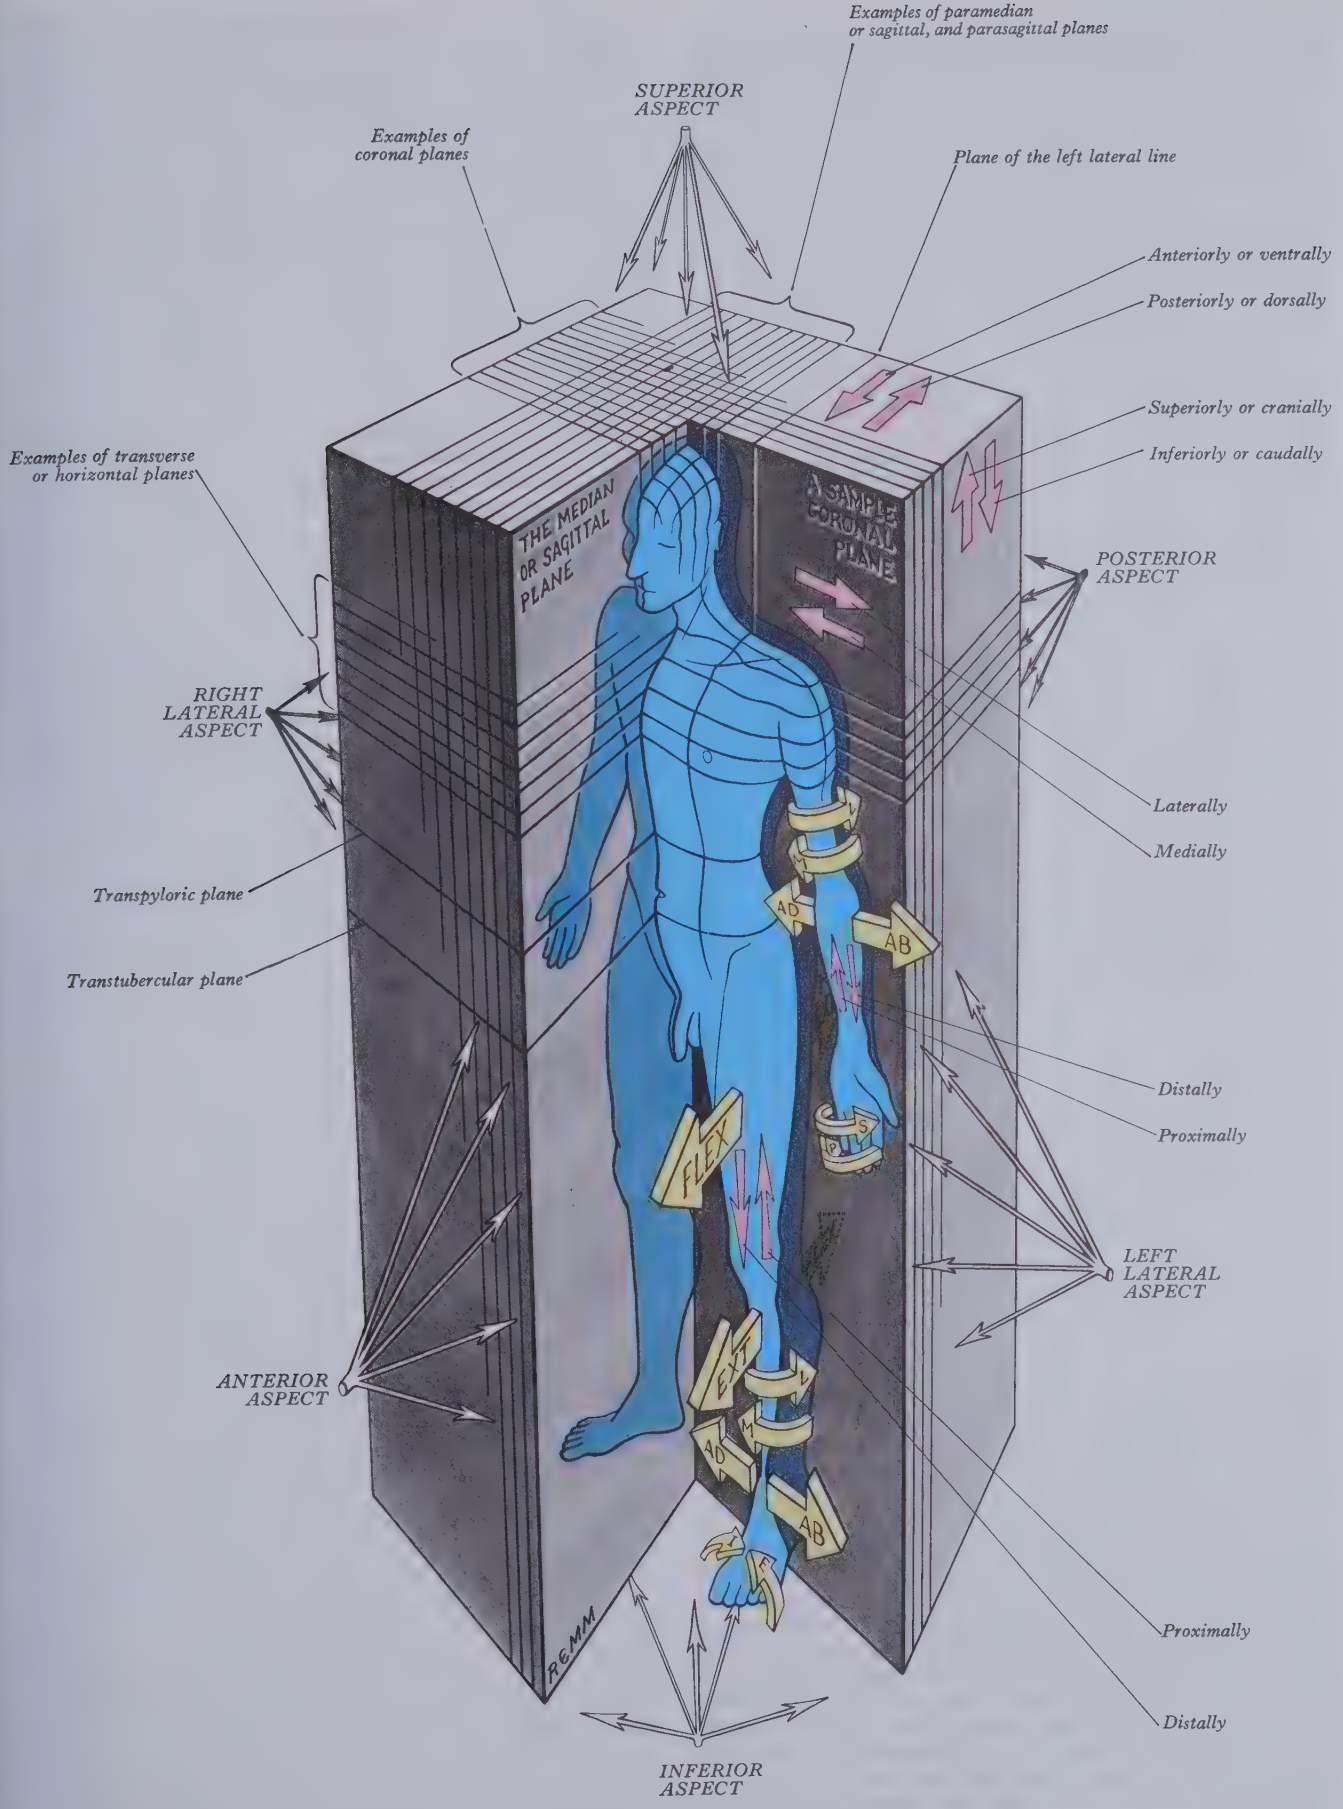
There is also a group of terms defining positions and directions along the axis of the body which is, of course, upright in humans. Structures which are nearer the head end, i.e. *cranial*, are officially *superior* and those nearer the tail end, i.e. *caudal*, are *inferior*. *Medial* and *lateral*, meaning nearer or further from the body's midline axis, are complemented by *median*, meaning in the vertical, anteroposterior (sagittal) midline plane. Other recognized planes are transverse (at right angles to the median axis, or the putative axes of limbs) and vertical (coronal), orthogonal to the sagittal plane.

The whole system can be equated with a cubical reference grid, anterior, posterior, superior, inferior, right and left aspects corresponding to the six faces of the cube, whose orthogonal sections are transverse, coronal and sagittal (1.4). Various degrees of obliquity must, of course, add slight complications, compound terms e.g. posterolateral, being employed; but it is a well tried system and most useful, as long as the somewhat artificial 'anatomical position' is kept clearly in mind.

A variety of other positional terms exist and are used occasionally in this text, e.g. *distal* and *proximal* are useful in describing some structures in limbs, the datum point being the limb's attachment to the trunk. They are also sometimes used in connection with nerves, arteries, veins, lymphatics, bronchi and other branching structures. Other terms are often found appropriate e.g. superficial, deep, radial and tangential.

We recognize that our readers may at first find some of these conventions unfamiliar and even irritating but familiarity with this positional system and reasonable adherence to it and its terms are as essential to clear, unambiguous communication (in clinical, academic and *all* such circumstances) as is the use of internationally recognized unequivocal terms for structures and processes.

The Study of Cells and Tissues



HISTORICAL BACKGROUND

As already stated, it is the aim of Anatomy as a scientific discipline not only to describe the form of the body but to gain a profound understanding of the biological principles and processes which underlie that form. The body is essentially a cellular structure: it begins its existence as a single cell, the fertilized ovum, it develops by multiplication and differentiation of cells, it matures as the cells and the substances they generate achieve their mature state; senescence is the decay and death the final cessation of cellular activities. It is therefore highly appropriate to consider the body's general construction in the context of its microscopic cellular anatomy.

The study of cells—cytology—and of their aggegations to form tissues and organs—histology—embraces many complimentary approaches, including the study of cell and tissue structure, physiology, biochemistry, biophysics and biometrics, all of which disciplines have greatly contributed to and continue to enrich our comprehension of cellular life.

Our present view of the body's cellular organization has a history spanning at least three centuries (for accounts of this period see the works by Singer 1931, Singer & Underwood 1962, Taton 1966) and, like most scientific advances, it has closely followed developments in technology, in this case, chiefly the design and construction of optical equipment. Simple systems of multiple lenses were first made in the Netherlands during the early seventeenth century and these primitive microscopes gave access to a hitherto totally unknown world of minute objects. There followed the early period of graphic description of the microscopic features of many animals and plants, begun by the members of the Accademia dei Lincei (1609–1630) in Italy, whose number included, amongst others, Galileo, Cesi, Stelluti and Faber of Bambourg (the inventor of the term 'microscope').

During the second half of the seventeenth century, a number of scientists in different countries (the 'Classical Microscopists') carried out more comprehensive investigations of the world of microscopic biology, which were published as a series of beautifully illustrated monographs. In Bologna, Marcello Malpighi investigated a great range of microscopic objects and was the first to examine the microstructure of the skin, kidney and spleen and to establish that capillary networks intervened between arteries and veins. He also laid the earliest foundations of microscopic embryology. In London, Robert Hooke in his great treatise

1.4 The terminology widely used in descriptive anatomy The abbreviations on the solid arrows: AD—adduction. AB—abduction, FLEX—flexion (of the thigh at the hip joint), EXT—extension (of the leg at the knee joint), M and L—medial and lateral rotation. P and S—pronation and supination. I and E—inversion and eversion.

Micrographia (1665) delineated with meticulous care a great richness of microscopic life and first used the term 'cells', although these were actually the network of dead cell walls in cork wood. Anton van Leeuwenhoek in Delft, Nehemia Grew in London and Jan Swammerdam in the Netherlands and France also made great contributions to animal and plant microscopy during this period.

Thereafter, except for embryologists such as de Graaf, Stensen and Wolff, there were few major advances in microscopic investigation until the nineteenth century, when better microscopes began to be made, achromatic lenses appearing in about 1830 and, somewhat later, immersion objectives. At this time there was a great increase in scientific activity in many disciplines and from this period come the first of the modern histologists such as Henle, Schwann, Deiters and Purkinje and later Remak, Ranvier, Leydig, Virchow, Metchinikov, Golgi and Hertwig, among many others. The work of Kölliker in Würzburg, in particular, was a major contribution to histology and this subject as a separate discipline dates from his publication of the first histology textbook in 1852.

However, these developments depended on new insights into the nature of biological organization. A major conceptual advance was the formulation of the cell theory, independently, by the botanist Schleiden in 1838 and the zoologist Schwann in 1839; by this time it was realized that the whole body is composed of aggregations of microscopic living units, cells, each with a nucleus and possessing a measure of independence as well as being subservient to the body as a whole. The physiology, mechanics and pathological reactions of the body reflect the properties and activities of the cells of which it is composed.

Some years before, the French anatomist Bichat (1771–1802) had coined the term 'tissues' (fabrics) to categorize the textures of the different parts of the body, distinguishing 21 different classes. Schwann reduced these to five (in modern times we have four; see however p. 15). In 1844, Owen used the term 'histology' for their study (from the Greek: *histos* = something woven). Different methods of preparation were now being used to demonstrate the microscopic structure of tissues; separation of tissues and cells by maceration and microdissection were largely supplanted by the more refined methods of wax sectioning and staining with dyes appropriated from the burgeoning dye-stuffs industry.

Developments in the theory and technology of lenses culminated in the design of a high resolution compound microscope by Abbe and its construction by Messrs. Zeiss at Jena in the 1870s, setting the field for a rapid expansion of cytology and histology as serious disciplines. Histology was now established as a major branch of Anatomy and, during the following few decades, most of what we know today as classic light microscope histology was established, including the elucidation of chromosome behaviour in mitosis, meiosis and fertilization and the exploration of the cellular structure of the nervous system. The first successes in the culture of cells in artificial media were also achieved during this period, initially in 1907 by Harrison in Baltimore and subsequently developed by Carrel in New York. In a later period, from about 1930–1950, other optical refinements were introduced to allow viewing of living cells, including dark field, phase, interference contrast and ultraviolet microscopy. However, by this time, histology had lost some of its initial impetus and had long since reached its theoretical limit of point-to-point resolution, i.e. twice the wavelength of visible light (about 0.2μm), limiting effective magnification to about a thousand times.

The renaissance of cell biology was heralded by the development in the 1950s of effective electron microscopy, increasing resolution a thousandfold and permitting useful magnifications of up to a million to be reached. An era of great activity followed, in which appropriate methods of tissue preparation were explored and applied to a wide variety of cells, tissues and organs. The result was the discovery of a great richness of structural detail which has revolutionized our understanding of cells and their functional roles. At the same time, cell fractionation methods for studying the biochemistry of organelles were being developed and used in combination with electron microscopy. The powerful techniques of X-ray diffraction were solving many problems of macromolecular structure, the most celebrated success being the double helical organization of deoxyriboncleic acid (DNA) demonstrated by Crick, Watson, Wilkins and Franklin in 1952, leading to the unravelling of the genetic code and its role in protein synthesis.

Various other methods have also proved of great value: e.g. autoradiographic analysis, in which the positions of isotopically-labelled molecules assimilated and transported by cells can be detected in sectioned material by their effects on photographic emulsion; various immunological methods for detecting different types of complex molecules by means of specific antibody binding, greatly assisted by the production of monoclonal antibodies (see p. 675); other major contributions with special structural methods including scanning electron microscopy to study the surfaces of cells, freeze-fracture or freeze-etching methods to expose the interiors of their membranes and related structures, microanalysis of the elemental composition of tissues and cells, computer-dependent analysis of light microscope images to visualize organelle behaviour in living cells, quantitative (stereological) analysis of cellular components and many other applications. Most recently, the growth of recombinant DNA technology to detect and determine the precise composition of particular genes and to follow their expression in the cell (see p. 39) has provided a particularly powerful set of tools not only for the analysis of cell function but also to synthesize cellular products for clinical and commercial use.

Inevitably, during the early decades of electron microscopy, a strong emphasis was placed on the description of microscopic structure, so that by the mid-1970s the forms and intracellular contents of most of the major cell types, tissues and organs of the body had been systematically investigated at the ultrastructural level. Since that time, a more experimental approach has prevailed and we are steadily gaining fresh insights into the principles governing the dynamic organization of cellular systems and their interactions. Many major problems remain to be solved and, judging from past experience, more have yet to be recognized. But at least many of the fundamental questions of biological existence are being addressed seriously and we can begin to expect a rich return from the investment of so much intellectual labour over the past century.

THE GENERAL ORGANIZATION OF CELLS

Before proceeding to describe detailed cellular structure, it is desirable to make a brief review of their general composition. The living matter of which cells are made, protoplasm, is composed mainly of water (70% or more by volume), with dissolved inorganic cations (ions of hydrogen, potassium, sodium, calcium, magnesium, iron, etc.) and anions (chloride, bicarbonate, hydroxyl, phosphate, sulphate, etc.), but is also permeated with assemblies of large organic molecules which compose the cellular structure and the system of enzymes and energy carriers providing the basis of living processes within cells. Of the large molecules, the most abundant are those of lipids, carbohydrates, proteins and nucleic acids. The first three of these provide structural materials and enzymes; nucleic acids are important in directing the activities of the cell and in passing on this ability to new cells and to subsequent generations. Numerous smaller organic molecules also abound in the protoplasm, engaged in the teeming biochemical traffic which comprises cell function.

The cell interior is relatively unstable in composition, and must be held ionically, osmotically and electrically within a narrow range of parameters for it to function effectively. However, each cell is also in a constant dynamic interchange with its external environment, including other cells, and continuous expenditure of energy is needed to maintain a steady internal state. It this is lost, the cell undergoes degeneration and eventually dies.

In the living state, most individual cells are greyish in appearance in transmitted light and each is bounded by a deformable, selectively permeable membrane which separates it from the environment, and confers on cells many properties essential to the maintenance of life. Within, the physical properties of the cytoplasm vary from those of a stiff gel to a highly fluid state, depending on the presence of complex filamentous macromolecules and their interactive states. However, individual cells are composed of many distinctive assemblies of macromolecules

which form centres of functional cooperation; these *organelles* will be described in some detail in this section, as an appreciation of their roles in cell activities is fundamental to an understanding of the organization of cells and their aggregates.

Cell size

Most mammalian cells lie within the size range 5–50 μm in diameter; e.g. resting lymphocytes are amongst the smallest, at about 6 μm across, red blood cells are about 7.5 μm and columnar epithelial cells about 20 μm tall and 10 μm wide. Some cells are much larger than this: mature ova may be 80 μm across and megakaryocytes of the bone marrow over 200 μm in diameter. Large neurons and striated muscle cells have relatively enormous volumes because of their highly attenuated forms—some may be over a metre in length. Generally speaking, limitations of cell size are determined by problems with rates of diffusion, either of substances into and out of cells or within them. The major advantage of cellularity is that diffusion of materials over short distances of up to 50 μm is relatively rapid so that metabolic needs of active cells can be sustained easily and cellular aggregates react rapidly to the control systems of the body. As a cell increases in size, its mass increase outstrips its surface area unless its shape changes, since the mass varies by the cube of the diameter, whereas the area only increases by the square (see the discussion of this problem by D'Arcy Thompson 1942). Processes depending on the surface area (e.g. diffusion of gases, transport of nutrients, etc.) therefore become increasingly hard to maintain at adequate levels. The distance of the cell periphery from the nucleus also becomes greater, so that exertion of nuclear control on the cytoplasm becomes more difficult. In large cells these problems are to some extent overcome by increasing the relative surface area, either by folding or flattening, and nuclear control can be facilitated by creating more nuclei in each cell either by fusion of mononuclear cells (a *syncytium*), as in skeletal muscle, or more rarely by the multiplication of nuclei without corresponding cytoplasmic division (a *plasmodium*, in the human an unusual and irregular finding in some epithelial cells, e.g. hepatocytes, p. 1391). Intracellular diffusion can also be much accelerated by processes of active transport across membranes and motile mechanisms within the fluid regions of the cell.

Motility is a characteristic of most cells, taking the form of movements of cytoplasm or specific organelles from one part of the cell to another (e.g. cytoplasmic streaming). They also include the extension of parts of cells such as pseudopodia, ruffled borders and microvilli from the surface, locomotion of whole cells by complex streaming interactions with their environment (amoeboid locomotion, etc.) or the beating of flagella (p. 32), cell division, muscle contraction and ciliary beating which moves fluid over internal body surfaces. Cell movements are also involved in the uptake of materials from their environment (endocytosis, phagocytosis) and the reciprocal passage of large molecular complexes out of cells (exocytosis, secretion).

Cell and tissues

Cells rarely operate independently of each other and tend to form aggregates by reciprocal adhesion, often assisted by the formation of special structural attachments. They may also communicate with each other either by releasing and detecting chemical messages diffusing through intercellular spaces or more rapidly by membrane contact, in many cases involving small, temporary transmembrane channels (p. 24). Cohesive or spatially aggregated groups of cells constitute tissues and more complex assemblies of tissues form functional systems such as the visceral organs, whose development and maintenance depend on as yet poorly understood cellular interactions.

In the following section we will first consider the general structure of cells, describing briefly our present understanding of the form and functions of their component organelles, their reproductive activities and motility. Then we will consider two types of cellular aggregations: epithelia and general connective tissue, both of which are distributed widely in many parts of the body. Following this, the structure of the skin (a combination of epithelium and connective tissue) will be described. Other tissues, and microscopic aspects of organs and major systems of the body are described where appropriate in later sections: reproductive tissues in Embryology; skeletal tissues (cartilage and bone) in Osteology; muscle tissue in Myology; blood, lymphoid and vascular tissue in Angiology; nervous tissue in Neurology; and various histological aspects of the viscera and endocrine systems in Splanchnology.

CELL STRUCTURE

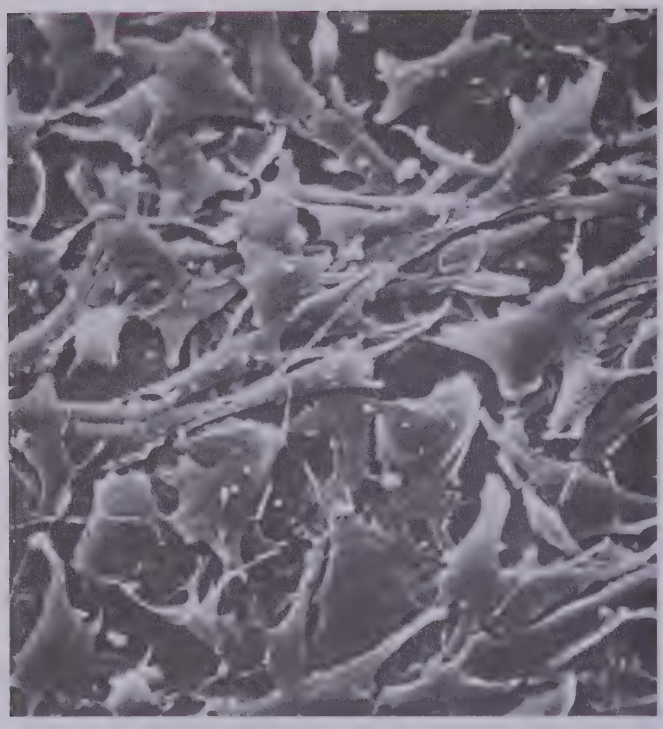
Although great modifications of form and activities may take place in different cells during their development and maturation, a common pattern of organization can be seen in their structure and functions. In describing this pattern, as seen with the methods of electron microscopy coupled with many other techniques, we will consider first the outer parts of the cell, the *cytoplasm*, and then the central *nucleus*. Within the cytoplasm are present several distinct systems of organelles (1.5,8,9). These include a series of membrane-bound structures which form separate compartments within the cytoplasm, such as the endoplasmic reticula, Golgi complexes, lysosomes, peroxisomes, mitochondria and transport, secretory and storage vesicles. They also comprise various structures lying outside these membranous organelles in the portion of the cytoplasm known as the *cytosol*, including ribosomes, several types of filamentous protein assemblies (collectively, the *cytoskeleton*), some assisting to determine general cell shape or supporting special extensions of the cell surface (microvilli, cilia, flagella); others are involved in the assembly of new filamentous organelles (e.g. centrioles) or internal movements of the cytoplasm. Also in the cytosol lie many soluble proteins and metabolites of various kinds. The whole cell is bounded externally by a specialized membrane, the plasma membrane. Within the cytoplasm is the nucleus, a special membrane-lined compartment containing the genetic instructions of the cell, the chromosomes; other nuclear organelles, lying in the nuclear sap, e.g. the nucleolus, are involved in their expression. These different structures and an outline of their known activities will now be briefly described. For further details the reader is referred to other lengthier texts, such as those by Kristić (1979), Fawcett (1981), Alberts et al (1983), P Weiss (1983), Brachet (1985) and Junqueira et al (1986).

Cytoplasm

THE MEMBRANE SYSTEMS OF THE CELL

With the advent of electron microscopy, it was confirmed that cells are bounded by a distinct membrane and internally are permeated by membrane-lined vacuoles and channels. Both external and internal membranes (*cytomembranes*) have many common features. All are composed of phospholipids and proteins, usually in an approximately 3:2 ratio, with a small amount of carbohydrate. The amount of lipid in an external membrane permits a layer two molecules thick to cover the cell surface. As long ago as 1925 Gorter & Grendel proposed that all cell membranes are bilayers of lipid, with the hydrophobic ends of each lipid molecule pointing towards the interior of the membrane and the hydrophilic ends pointing outwards. Later, Danielli & Davson (1935) suggested that the protein might line both sides of the lipid to form a protein/lipid sandwich but more recently the *fluid mosaic* model has been proposed (and widely confirmed) in which the proteins are envisaged as embedded or floating in the lipid bilayer (Singer & Nicolson 1972, see also Bretscher 1985). Some proteins, because of the extensive hydrophobic portions of their polypeptide chains, span the entire width of the membrane

1.5 A three-dimensional reconstruction of some of the principal architectural features of an absorptive cell lying in the simple columnar epithelium of the small intestine. Part of the cell is cut away to expose the nuclear envelope (green); nuclear contents are the nucleolus (red) and chromosomes (black). Outside in the cytoplasm lie the endoplasmic reticulum (yellow) with ribosomes (red) in clusters; the Golgi apparatus (pink) is shown in a supranuclear position, various cytoplasmic vesicles including lysosomes (purple), microtubules (blue), microfilaments, and a centriole pair (grey) are also shown. The apical surface of the cell is covered with microvilli supported by microfilaments which are inserted into a filamentous terminal web. Junctional complexes are seen at the lateral borders of cells apically. A lamina basalis (purple) forms the boundary of the epithelium basally, and lies in close relation to the underlying reticulum and collagen.



1.6 A high-power micrograph of living cells (fibroblasts in tissue culture), viewed by Normarski interference microscopy. Provided by the Paediatric Research Unit, Guy's Hospital Medical School, London. Magnification × 2000.

(*transmembrane proteins*) whilst others are only superficially embedded (1.10). Carbohydrates in the form of oligosaccharides and polysaccharides are attached either to proteins (glycoproteins) or to lipids (glycolipids), projecting outwards from the surface of the membrane (Nicolson & Poste 1976).

These features, deduced partly from biochemical and biophysical data, can be correlated with electron microscopic appearances. Membranes, suitably fixed and stained by heavy metals, show in section two densely stained layers separated by an electron-translucent zone (1.11), the total thickness being about 7.5 nm (the classic '*unit membrane*' of Robertson 1959), probably reflecting binding of stain by the 'heads' of the phospholipid molecules (see also Robertson 1981). Freeze-fractured and/or etched specimens (Branton 1971, Stolinski & Breathnach 1975), in which the deeply frozen sample is cleaved to expose membrane interiors and of which a metal-shadowed carbon replica is then made and viewed by electron microscopy (1.10,12,A,B), have also demonstrated a bilaminar structure in membranes. Cleavage planes usually pass along the midline of each membrane where the hydrophobic 'tails' of phospholipids meet. This method has also demonstrated 'particles' embedded in the lipid layers; these particles are in the 5–15 nm range and in most cases represent large transmembrane protein molecules or assemblies of such molecules. Particles are distributed asymmetrically between the two half-membranes, usually adhering more to one face than the other. In plasma membranes (which form the cell surface), the *inner* or protoplasmic half-membrane carries most particles, exposed at its externally-facing surface (the P face). The corresponding inwardly-directed (E) surface of the *external* half-membrane usually shows pits into which the particles fit (1.10,12,14). Not all the proteins of membranes are *visible* as particles, however; some are either too small or not compact enough to appear in this form and have, as yet, only been demonstrated biochemically. Where they have been identified, particles represent channels for the transmembrane passage of ions or molecules.

Biophysical measurements show the phospholipid bilayer to be highly fluid, allowing diffusion *along the plane* of the membrane at rates as high as 2 μm/sec (Bretscher 1975). Thus proteins are able to move freely along such planes unless anchored from within the cell. Some internal membranes possess much more protein than the external cell membrane, e.g. the inner mitochondrial membrane which is rich in enzyme activity; the fluidity of such membranes is correspondingly much reduced.

The functions of cell membranes are many: they form boundaries selectively limiting diffusion and forming physiologically distinct compartments inside the cell, dividing those regions within the channel system (*vacuoplasm*) from those outside it (*cytosol* or *hyaloplasm*). Membranes actively control the passage of electrolytes and small organic molecules, generate bioelectric potentials and provide surfaces for the attachment of enzymes often associated with the movement of reaction products across membranes (*vectorial metabolism*). Membranes also serve as sites for the reception of external stimuli, including hormones and other chemical agents, and for the recognition and attachment of other cells. Conversely, they may alter the activities of other cells by transmitting to them chemical or physical messages of various kinds. Lastly, they can act as points of attachment of intracellular

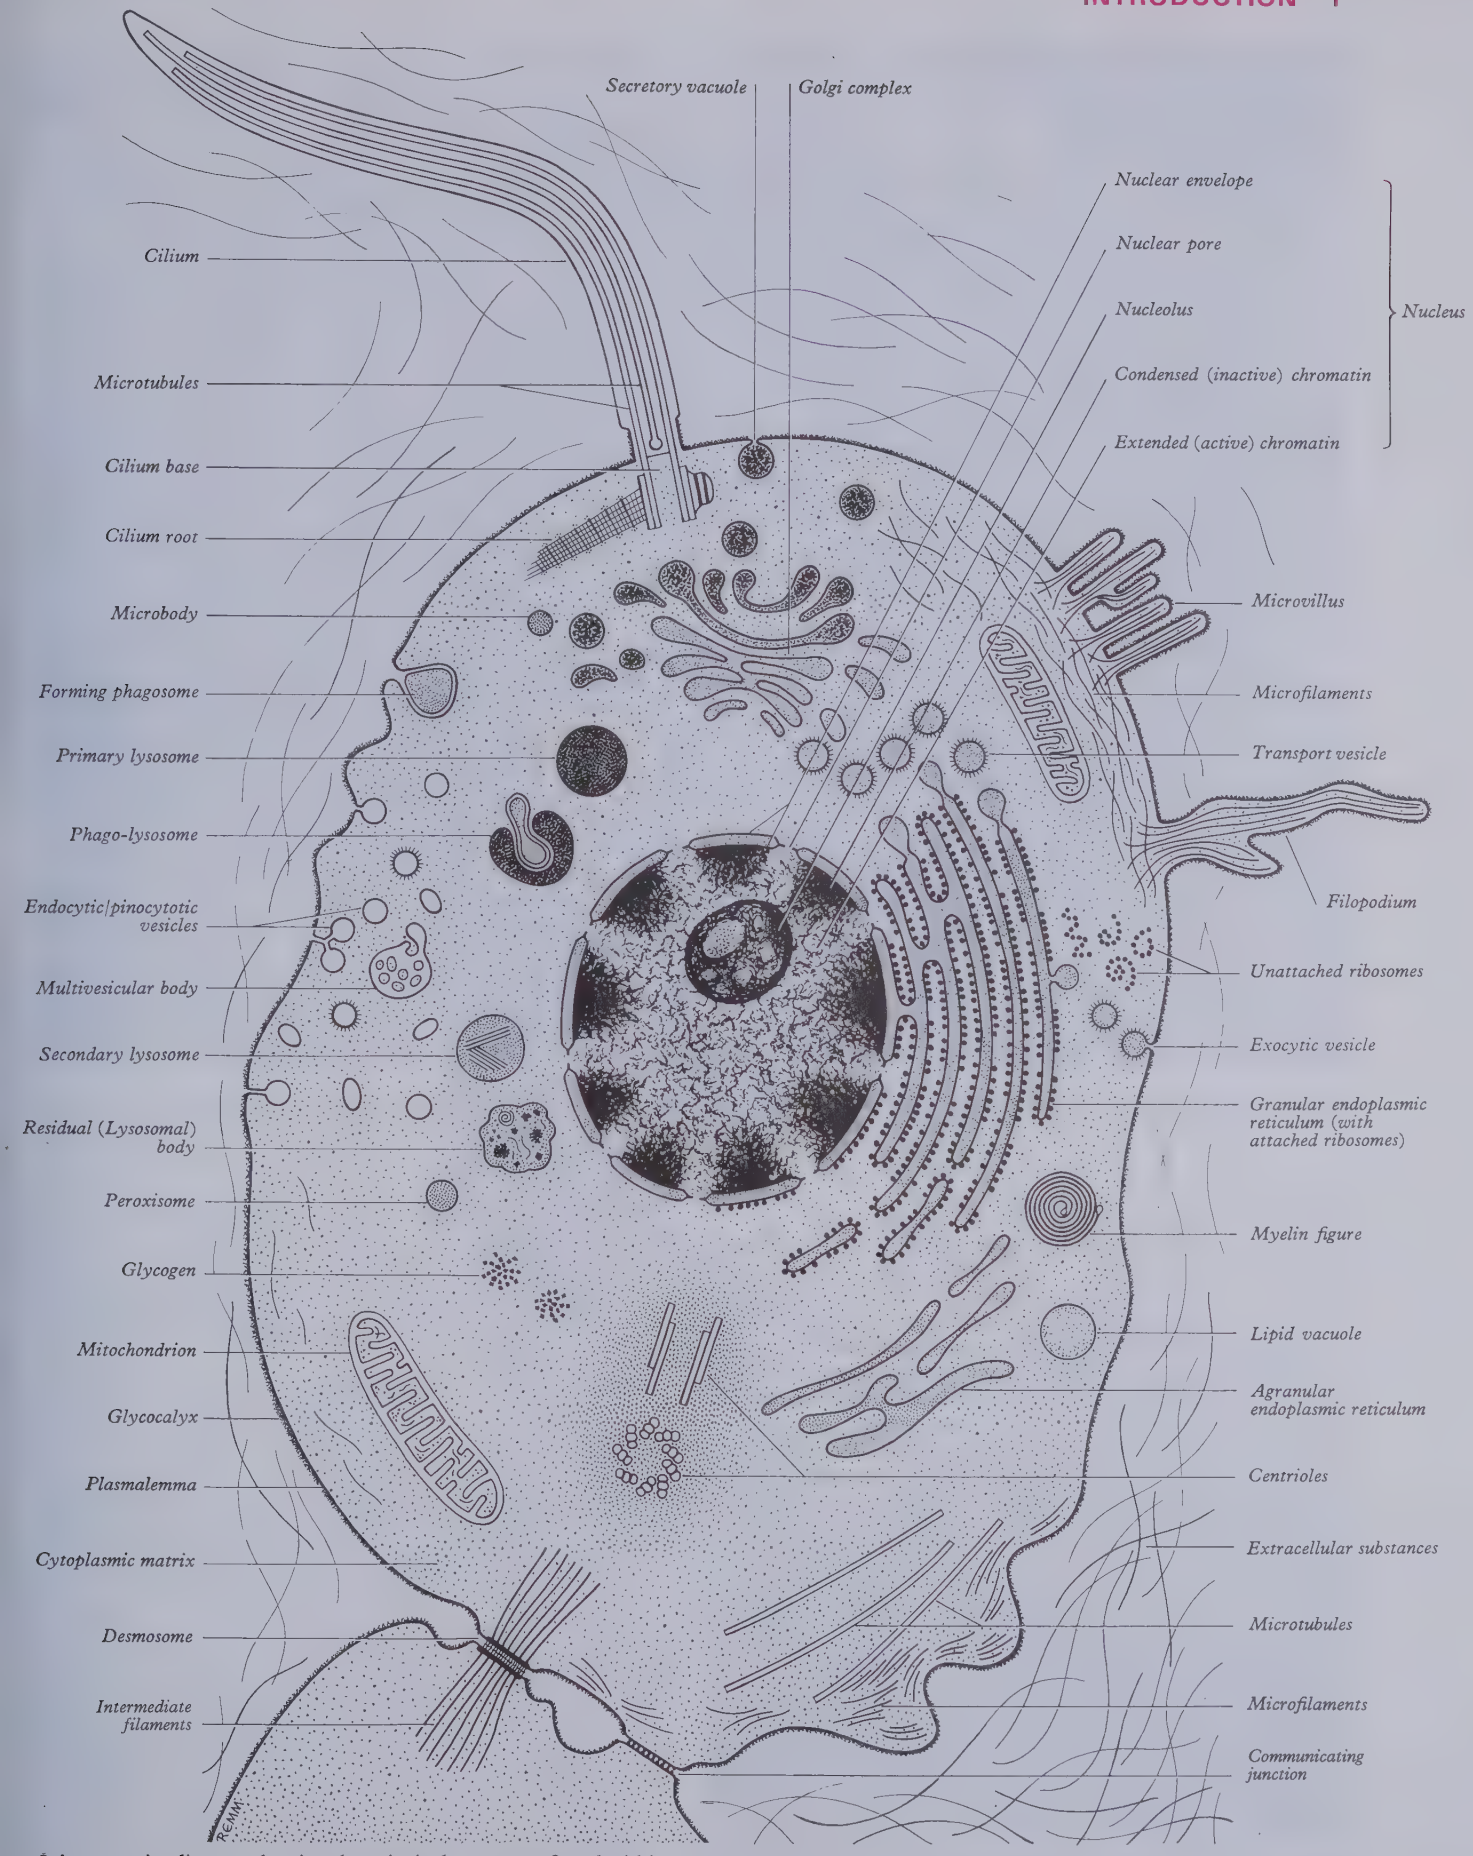
1.7 Flattened fibroblasts growing in tissue culture viewed with the scanning electron microscope. Material provided by L Mallucci. Magnification × 500.

structures—the basis for locomotor activity and for cytoskeletal stability.

Membranes within cells can, on occasion, fuse with each other and so form a potentially continuous system. However, there are barriers to the indiscriminate mixing of membrane components so that each maintains its unique chemical and functional features. So, although the membrane systems of a cell can be viewed as a single entity, they are highly distinctive and localized in their activities.

Cell membranes are synthesized by the granular endoplasmic reticulum (p. 25), usually in collaboration with the Golgi apparatus (Poste & Nicolson 1977).

PLASMA MEMBRANE (PLASMALEMMA OR CELL MEMBRANE)



This differs from other membranes in that it forms the external boundary of the cell and, as such, possesses many distinctive structural features, e.g. it bears a diffuse carbohydrate-rich coat, the *cell coat* or *glycocalyx*, externally. In certain sites it also forms *intercellular junctions* of various types with other cells or *adhesive plaques* with extracellular structures (see p. 24). Within the cell, filaments of the cell skeleton (p. 30) are also anchored to the plasma membrane proteins, immobilizing them or transmitting motile forces from within the cell to the cell surface and thus causing changes of cell shape or locomotion. The plasma membrane is *selectively permeable*, allowing the free passage of some gases and water but restricting the movements of larger ions such as those of sodium, potassium, calcium, chloride and bicarbonate to special proteinaceous channels, which can be opened or closed by the cell to regulate transmembrane traffic. The passage of many other substances such as glucose, amino acids and nucleic acid precursors is also limited to such routes. In all cases, each channel will only admit one species of ion or molecule; substances either move passively through these apertures along diffusion gradients, or by energy-consuming active transport. Movements of such materials into and out of the cell vary greatly, depending on their local concentrations, cell requirements, the availability of chemical energy, action of external hormones and neurotransmitters and many other factors. However, lipid-soluble substances may be able to pass through the lipidic portion of membranes directly so that, e.g. steroid hormones can enter the cytoplasm without passing through protein channels. The uptake of larger molecules involves the invagination and rounding up of the plasma membrane to form small vacuoles termed *endocytic vesicles* (1.8), which are transported to other regions within the cell. The reverse process—extrusion of organic molecules—is achieved by *exocytic vesicles* which fuse with the plasma membrane and release their contents to the exterior.

The plasma membrane, like other cytomembranes, is in constant flux (see Pearse & Bretscher 1981), the whole surface being regularly changed by subtraction through endocytosis or the loss of components externally and by addition of new membrane from exocytic vesicles. Endocytosed membrane may either be degraded in the lysosomal system of the cell or components of it re-cycled back to the cell surface in vesicular form; there is thus a continual traffic between the cell interior and surface, allowing the cell to modify the properties of its plasma membrane in response to metabolic needs or to external stimuli, add new membrane during growth, repair surface damage, take in large molecular complexes from outside and engage in many other interactions with the cell environment.

The plasma membrane also has special roles in co-ordinating many cellular activities by signalling changes in the cell's environment to the cell interior and in maintaining the cell's shape and coherence. It therefore acts as a sensory surface, with a wide variety of special receptor molecules, some responding only to a narrow range of stimuli (e.g. the receptors for insulin, acetyl choline and low density lipoprotein), others being activated by more general factors such as the contact with other cells or inorganic surfaces. Stimulation of the cell surface may result in changes in the bioelectric transmembrane potential causing fluxes of inorganic ions; this is most striking in the *excitable* plasma membranes of nerve and muscle cells in which the 'resting' voltage can change transiently from as much as 100 mV (negative inside) to 50 mV (positive inside) when suitably stimulated, a result of the opening and subsequent closure of channels selectively permeable to sodium and potassium (see p. 878).

Stimulation of surface receptors also often activates a 'second messenger' which may profoundly change the metabolism or motility of the whole cell. Adenylate cyclase, an enzyme associated with the plasma membrane of probably all nucleated cells, is prominent in this process; its activation results in changes in concentrations of cyclic AMP (cyclic adenosine monophosphate) within the cell, leading to alterations in DNA synthesis, gene expression, protein synthesis, actin and myosin interactions and many other intracellular events. Cyclic GMP (cyclic guanidine monophosphate) is controlled by similar enzyme systems and may have effects antagonistic to those of cyclic AMP. Some hormones and neurotransmitters act in this manner and it is probable that many types of intercellular communication use this or similar systems (p. 886). Another mechanism of much current interest involves the phospholipid phosphoinositol and its derivatives in calcium-regulating processes within the cell, which lead to the activation of phosphokinases and phosphorylation of various cellular components, a step with far-reaching metabolic and structural consequences (see Berridge 1985).

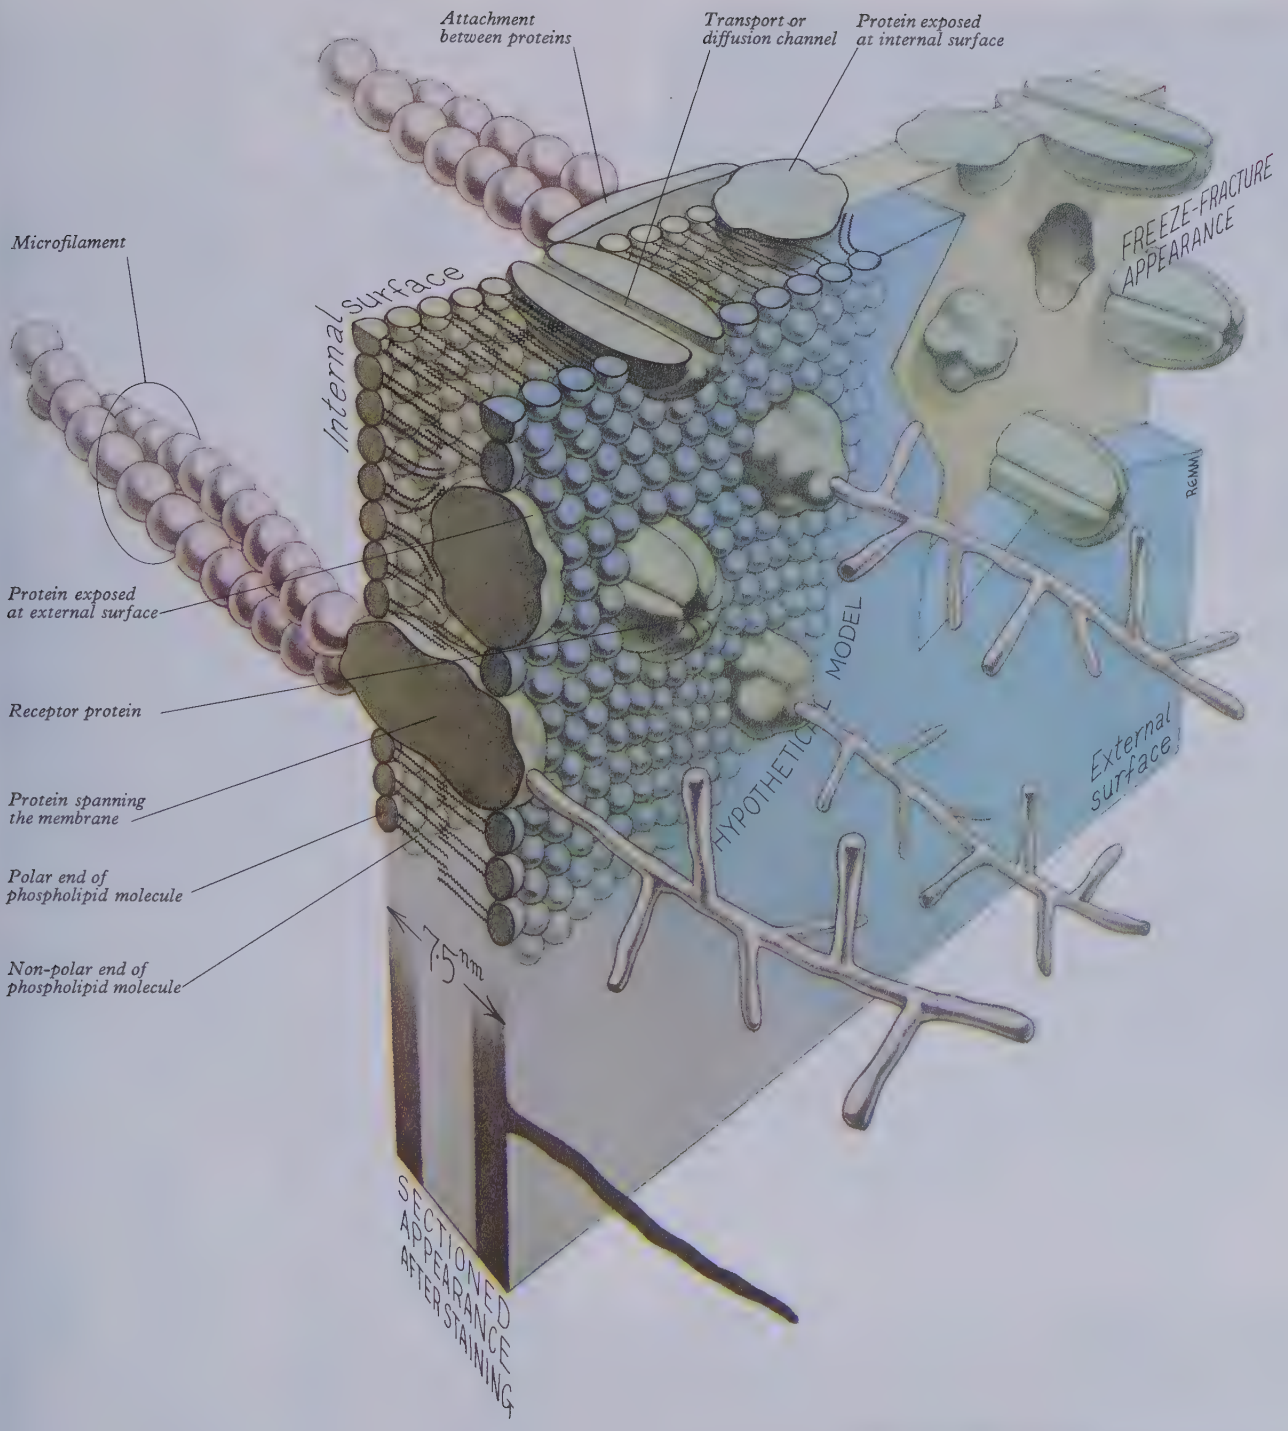
Although these considerations apply to the plasma membranes of all cells, those of specialized cells are often highly developed in some particular respect. Thus, sensory membranes derived from the plasma membrane, e.g. in retinal photoreceptors, have numerous photoreceptive proteins embedded in their surfaces; the acetylcholine-receptive sole-plate membranes of skeletal myocytes likewise are studded with protein particles able to bind the transmitter. Other specialized cell membranes, such as that of erythrocytes, have shape-determining components. Research in this field is indeed of great potential since it may reveal much about cellular functions in general and also give a deeper understanding of the actions of drugs on cells; the cell membrane is undoubtedly the primary target of a wide variety of chemotherapeutic agents, anaesthetics and other substances of medical importance.

1.8 A composite diagram showing the principal structures found within tissue cells. Only a proportion of the features illustrated will be present in any specific cell type.

1.9 An electron micrograph of a protein-synthesizing cell (plasmacyte: mature B lymphocyte) in section showing abundant rough endoplasmic reticulum, Golgi apparatus, mitochondria, lysosomes and a cell membrane with surface protrusions (filopodia). Magnification × 12 000.

The Cell Coat (glycocalyx)

As mentioned above, this forms an integral part of the plasma membrane, projecting as a diffuse filamentous layer 2–20 nm or more from the lipoprotein surface. It is composed of the carbohydrate portions of glycoproteins and glycolipids embedded in the plasma membrane (1.10,11), consisting of much branched oligosaccharides and polysaccharides, the terminal residues of which are usually negatively charged sialic acids, such as n-acetyl neuraminic acid, but are also often rich in galactose residues. These and other carbohydrates can be readily demonstrated by electron microscopy, using dyes such as ruthenium red, or more specifically with plant-derived chemical probes termed *lectins* (e.g. concanavalin A, wheat germ agglutinin, phytohaemagglutinin) which bind to particular carbohydrate groups. By conjugating lectins with fluorescent molecules, or with an electron microscopic tracer such as ferritin, horseradish peroxidase or colloidal gold, the surface carbohydrates can readily be visualized and even quantitated (Nicolson 1974, 1976).

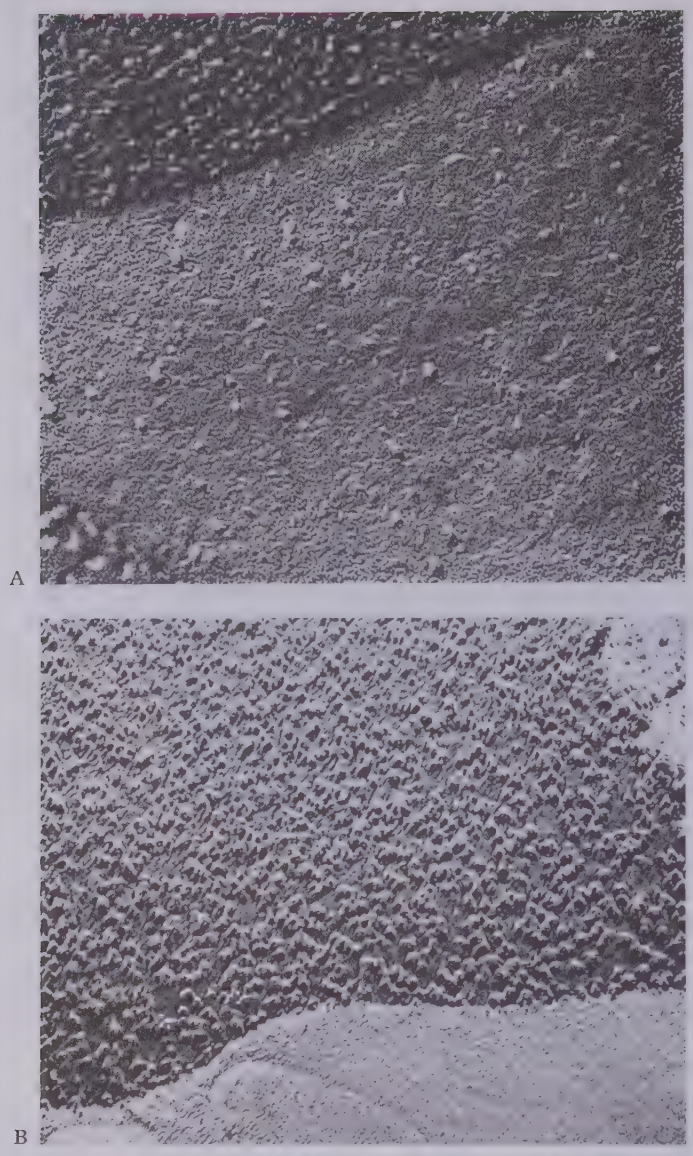


Its precise composition varies with cell type; many tissue antigens are located in the coat, including the major histocompatibility antigen (MHC) systems and, in the case of erythrocytes, blood group antigens (p. 681). Special adhesive molecules enabling cells to adhere selectively to other cells or extracellular material are also present and are of utmost importance in maintaining the integrity of cellular assemblies of all kinds. They are also vital to a wide range of developmental movements and interactions between cells, e.g. the formation of intercommunicating neural networks in the nervous system (see p. 865).

Because of the predominance of negatively-charged carbohydrates at cell surfaces, cells tend to repel each other if they approach too closely. Thus, except at special junctions, there is a distance of at least 20 nm between the plasma membranes of adjacent cells. But some positively-charged molecules also exist at cell surfaces and can form intercellular links with negative charges across the intercellular gap.

Since the glycoproteins and glycolipids are usually free to move in the plane of the membrane, addition of lectins can cause the aggregation of these carbohydrate-rich molecules which become cross-linked to form raft-like groups or 'patches'. If these are further aggregated by motile activities of the cell (an energy-dependent process), they merge to form a 'cap' at one pole of the cell. In other cells (e.g. erythrocytes) the carbohydrate-rich molecules are prevented from wandering or forming patches by internal anchoring proteins.

INTERCELLULAR CONTACTS



The plasma membrane is, of course, the surface which establishes contact with other cells and promotes various kinds of cellular interaction. Structurally there are two main classes of contact: (1) those without obvious cytological specializations in the areas of contact, and (2) those with relatively long-lasting junctional features which establish and maintain intercellular contacts. In the first category (Moores & Partridge 1974), by far the most common, cells adhere to one another at any part of their surfaces, enabling them to form loose aggregations whilst permitting some

1.10 The various 'appearances' of the plasma membrane as studied with different electron microscope techniques, including sectioning and freeze-fracturing together with current interpretations of the results of these and other biophysical methods. In this diagram, membrane proteins (green) are either confined to a single leaflet of the lipid bilayer, or they span both layers. Branched carbohydrate chains (grey) are shown attached to some transmembrane proteins on the external surface of the membrane, and a double helical actin filament (pink) is attached to the inside (left). The hydrophobic tails of the lipid molecules are shown as thin black lines and their hydrophilic heads as spheres: blue for the outer surface of the membrane and yellow for the inner surface. These various shapes are, of course, only schematic, as the various protein, lipid and carbohydrate molecules of which cell membranes are constituted have differing detailed shapes.

1.12 Electron micrographs of the plasma membrane of an erythrocyte prepared by freeze-fracturing. A shows the external (*E*) fracture face, bearing few particles and some pit-like depressions; in B the internal (*P*) fracture face is visible, showing numerous particles. Magnification × 80 000.

relative movement. Membrane surfaces are separated by a gap of about 20 nm, a distance probably determined by the interplay of *electrostatic repulsion* and *adhesive forces* and perhaps by the thickness of cell coats on the adjacent membrane surfaces. It has been suggested that attraction between oppositely polarized surface groups may be important in adhesion, that divalent cations (e.g. Ca^{2+}) may form bridges between adjacent surfaces or that other *non-specific attractive forces* may operate (Curtis & Pitts 1980). There is increasing evidence that in many cases more *specific interactions* may occur between cell surfaces, with complex sites for mutual recognition and adhesion. Such specific adhesion is shown by cells from the same tissues or embryonic germ layers reaggregating after they have been experimentally separated and in migration of cells and growth of cell extensions (e.g. in the developing nervous system) to contact specific types of 'target' cell (see e.g. Edelman & Rutishauser 1981). But the degree of adhesion varies considerably in different cell varieties; epithelial cells normally adhere to one another strongly, but macrophages —often very motile—may move freely over other cells. Reduction of the normal adhesive properties of cells in malignant neoplasms favour their rapid local spread and their formation of secondary colonies (metastases) elsewhere.

Specialized junctional structures are regions of reciprocally adherent cells where distinctive structures are visible by electron microscopy (1.13–15). A number of different types have been demonstrated (Staehelin & Hull 1978), including those at which the cell membranes are separated by a 20 nm gap or more and those where membranes approach closely or are actually in contact. The former include the *macula adherens* and *zonula*

1.13 A high-power electron micrograph of a junctional complex between two epithelial cells showing a zonula occludens (tight junction) (*zo*), a zonula adherens (*za*), a macula adherens (desmosome) (*ma*), and a normal intercellular gap (*g*). Magnification × 130 000.

1.14 Schemata of various junctions commonly occurring between cells, showing current interpretations of the electron microscopic appearances seen after sectioning and with freeze-fracturing techniques. For clarity, the freeze-fracturing data are presented as though it were possible to separate and fold back the two leaflets of the plasma membrane to expose the intramembranous protein particles inserted on their two faces. The *A* face = the *P* fracture face and the *B* = the *E* fracture face in current terminology.

adherens, the latter the *zonula occludens* and the 'communicating junction' or *junctio communicans*, also called the '*gap junction*'.

The *macula adherens (desmosome)* is a plaque-like structure (1.13,14) sited anywhere on the cell surface, where the plasma membrane is coated internally with a layer of dense protein into which intracytoplasmic tonofilaments are inserted. The intercellular gap, a region rich in a glycoprotein, *desmoglea* (Gorbsky & Steinberg 1981), is bridged by thin interlocked filaments, traversed by densely staining bands. This structure forms anchorage points between cells, particularly where strong cohesion is needed, as in the stratum spinosum of the epidermis; here they are responsible for the post-fixation prickly appearances of the cells. Single-sided or *hemi-desmosomes* are also found between epidermal (and other) cells and their underlying basal laminae.

The *zonula adherens* (1.13,14) is a continuous belt formed around the apices of epithelial cells, or between non-striated myocytes, and as a 'single-sided' junction between muscle cells and their collagenous sheaths. Filaments (usually microfilaments) are often inserted into a dense coat on the cytoplasmic side of the membrane. Unlike the macula adherens, no filaments span the gap between the cell surfaces but an adhesive, non-stainable material may intervene at this point. They probably serve to anchor cells to adjacent structures. Extensive areas of similar structure also occur between the myocytes of cardiac muscle, at intercalated discs (p. 557), where they are termed *fasciae adherentes*.

The *zonula occludens* (tight or occluding junction) is a continuous zone (1.13,14) present around the apices of epithelial cells, between endothelial cells and at other sites where there is a barrier to diffusion through the intercellular space (Pinto da Silva & Kachar 1982). Colloidal tracers such as ferritin and horseradish peroxidase fail to move from the lumen of the intestine into the spaces between the epithelial cells or deeper into the mucosa. At a zonula occludens the membranes of the adjacent cells come into contact, obliterating the gap between them. Freeze-etching shows that contacts between the membranes lie along branching and anastomosing ridges formed by the incorporation of chains of particles within the membranes (1.14,15A), distorting and stiffening them at points of contact. Occluding junctions prevent the leakage of toxic substances from the lumina of viscera into the surrounding tissues, retain colloids within the bloodstream and form important diffusion barriers in many other sites. They also form barriers within the plasma membrane, preventing the diffusion of membrane components, e.g. from the apical surface of a cell to its more basal region. In this way, specialized regions of membrane can be maintained in an appropriate position, e.g. the secretory surface of a gland cell or the ion-transporting surface of a kidney tubule cell (see Simons & Fuller 1985).

The junctio communicans (communicating 'gap' or electrical junction, nexus or *macula communicans*) resembles occluding junctions in sections but apposed membranes are separated by an apparent gap of 3 nm, which is traversed by numerous dense beads arranged in hexagonal arrays on the two surfaces (1.14,15B). Such junctions form limited attachment plaques (Goodenough & Revel 1970) rather than continuous zones, thereby allowing free passage of substances along the cleft between cells. They occur in numerous tissues including the liver, epidermis, connective tissues, cardiac muscle and non-striated muscle (see the review by Hertzberg et al 1981); they are also common in embryonic tissues. In the central nervous system (Staehelin 1974) they are found in the ependyma, in neuroglia, and they form electrical synapses between some types of neurons (see p. 888).

Communicating junctions form channels for the diffusion of ions and larger particles (up to a relative molecular mass (*M*r) of about 1000) *from one cell to the next*. Thus, in some excitable tissues (e.g. cardiac and non-striated muscle), one cell can affect another by electrotonic current flow without the intervention of a chemical transmitter, in contrast to the usual mode of synaptic transmission. Elsewhere their functions are not certain; experimentally they have been shown to be permeable to various dyes and to form pathways with low resistance to the flow of ionic current. Communicating junctions probably permit metabolic cooperation between adjacent cells or groups of cells. Thus, in embryonic life, such junctions may aid the establishment of pattern and the coordinated differentiation of the whole blastula, within and between germ layers, or of more localized tissues (Fraser 1985). This may involve the movement of regulatory substances involved in gene blocking or gene repression and derepression diffusing freely or creating morphogenetic gradients (see p. 109). Communicating junctions may also assist in the

control of cell division since in damaged tissues they disappear, while cells undergo repair by mitosis, to reappear when regeneration ceases (Bennett 1973, Fusijawa et al 1976).

Freeze-fracturing and -etching methods (Staehelin 1974) and recently, computer-aided high resolution electron microscopy (Unwin & Ennis 1984) show hexagonal arrays of membrane particles on both sides of communicating junctions, each particle (or 'connection') composed of six protein subunits surrounding a central channel (cf. 1.10,14) which, when apposed to a similar unit in an adjacent cell, forms a small communicating passage between the two. Such particles may also exist in smaller numbers, or singly, elsewhere on the cell, so that intercellular communication may not be restricted to special junctional *areas*. Changes in pH and calcium ion concentrations, etc. can cause narrowing or closure of such channels, so intercellular communication can change with the metabolic alterations in the participating cells (Unwin & Zampighi 1980).

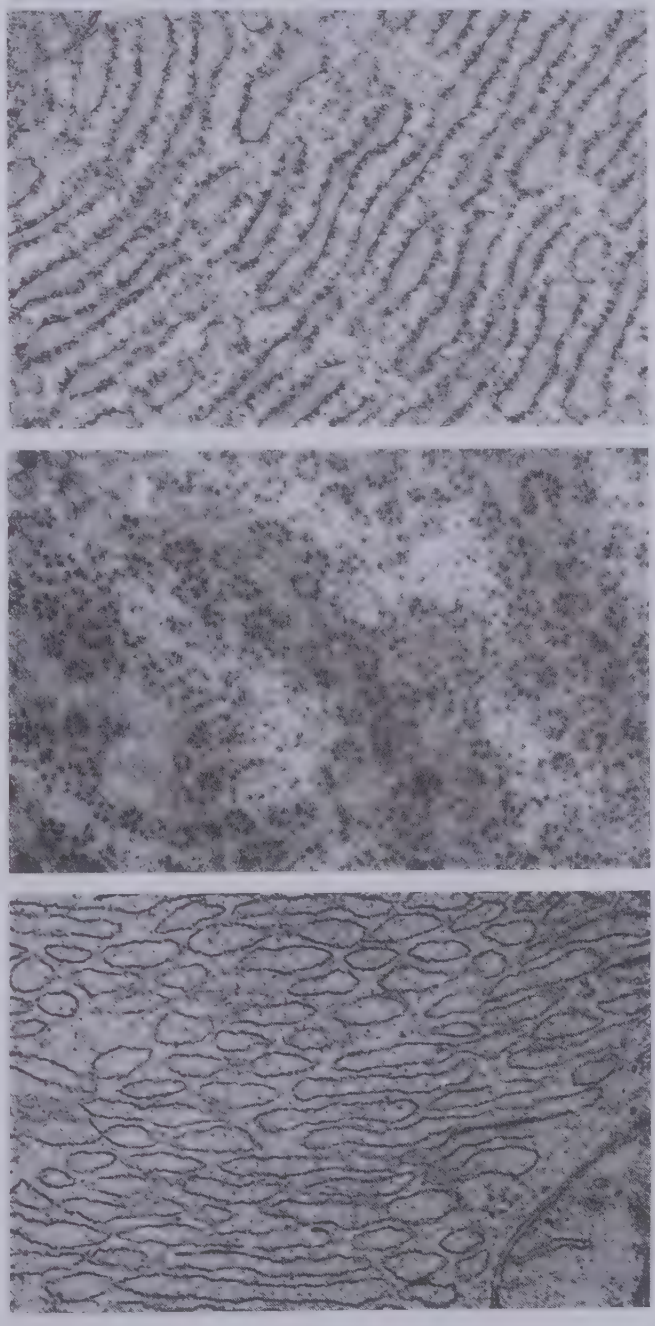
Junctional complexes are present at the apex of epithelial cells (Farquhar & Palade 1963), where a combination of a zonula occludens, zonula adherens and macula adherens (desmosome) is a regular feature (1.13,14). This array corresponds partly to the *terminal bar* of light microscopy.

Synapses and *neuromuscular junctions* are specialized areas providing interneuronal and nerve–muscle transmission, and will be described under these headings in a later chapter.

With these two exceptions, all intercellular junctions are labile, being resorbed or reformed in suitable circumstances and so permit slow migration and division of cells and the passage of other cells along intercellular clefts (e.g. leucocytes between endothelial cells).

Other specializations of the plasma membrane include various extensions—microvilli, filopodia, microspikes, cilia and flagella; and less regular, often rounded or leaf-like extensions—'blebs', pseudopodia and ruffled membranes. Indentations include endocytic and pinocytotic vesicles associated with the uptake of materials by the cell and exocytic vesicles involved in the outward transport of materials. These various structures will be discussed below.

ENDOPLASMIC RETICULUM



This is the system of interconnecting membrane-lined channels (Palade 1975) within the cytoplasm (1.5,8,16). These channels take various forms, including cisternae (flattened sacs), tubules and vesicles. The membranes divide the cytoplasm into two major compartments: that inside the channel system, the *vacuoloplasm*; and that outside, the *hyaloplasm* or *cytosol*. The former constitutes the space in which secretory products are stored or transported to the Golgi complex and cell exterior; the latter is made up of the colloidal proteins such as enzymes, carbohydrates and small molecules, together with ribosomes and ribonucleic acid.

Structurally, the channel system can be divided into *granular (rough) endoplasmic reticulum* (1.16A,B), to the exterior of which ribosomes are attached, and *agranular (smooth) endoplasmic reticulum* (1.16C), lacking ribosomes. When cells are disrupted and centrifuged, both endoplasmic reticula break up into vesicles respectively termed *granular* and *agranular microsomes*.

The granular endoplasmic reticulum can synthesize proteins, because of its attached ribosomes. Such proteins are passed *through* the membranes to which the ribosomes are bound and accumulate within the cisternae of this system; thereafter they remain in membrane-bound bodies such as lysosomes or else are secreted to the exterior of the cell. Some carbohydrates are also synthesized by enzymes within the cavities of the granular endoplasmic reticulum and may be attached to newly-formed protein (glycosylation). *Agranular endoplasmic reticulum* is associated with carbohydrate metabolism and many other metabolic processes, including detoxification and synthesis of lipids and of cholesterol and other steroids. The membranes of the agranular endoplasmic reticulum serve as convenient surfaces for the attachment of many enzyme systems (e.g. important detoxification mechanisms involving the enzyme cytochrome P_{450}) which are thus accessible to the substrates in solution within the cell. They also cooperate with the granular endoplasmic reticulum and Golgi apparatus to elaborate new membranes, the protein, carbohydrate and lipid components being added in different regions.

Highly specialized types of endoplasmic reticulum are present in some cells. In striated muscle cells the agranular endoplasmic reticulum (*sarcoplasmic reticulum*) stores calcium ions, which are liberated to initiate contraction on appropriate stimulation (p. 551).

In embryonic cells, endoplasmic reticulum is scant and ribosome clusters lie mostly unattached in the hyaloplasm. During differentiation, membranes usually increase greatly and ribosomes may become attached to form granular endoplasmic reticulum.

1.16 Ultrastructural details of the endoplasmic reticulum: A. rough endoplasmic reticulum; B. polysome groups attached to obliquely sectioned cisternae showing 'rosette' configuration; C. smooth endoplasmic reticulum. B provided by D R Turner, Guy's Hospital Medical School. Magnification × 30 000.

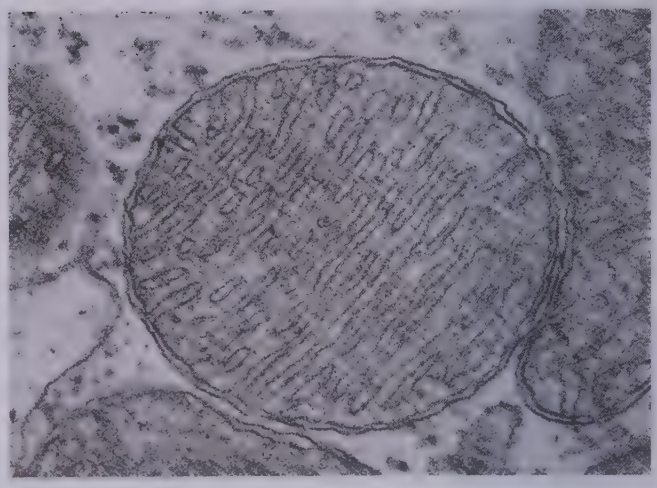
RIBOSOMES

Ribosomes (ribonucleoprotein particles) are granules about 15 nm across (1.16A,B), composed of equal parts, by weight, of protein and (ribosomal) RNA; they are responsible for the synthesis of proteins from amino acids (Palade 1955, Siekevitz & Palade 1960). Each ribosome is made of two subunits (Lake 1981), one slightly larger than the other, sedimenting in the centrifuge at different rates (in nucleated cells mainly at 60S and 40S, where S = the Svedberg unit of sedimentation rate, a function of density, shape, etc.; the whole ribosome sediments at 80S). The subunits can be further dissociated into about 73 different proteins (40 in the large subunit and 33 in the small), with structural and enzymatic functions. Three small RNA strands (28, 5.8 and 5S), highly convoluted, lie in the large subunit, and one in the small subunit (18S). Most of these RNA molecules are derived from the nucleolus (p. 40). The large and small subunits are separate from each other when not engaged in protein synthesis.

Ribosomes may be solitary, relatively inactive *monosomes*, or form groups (*polyribosomes* or *polysomes*) attached to messenger RNA which they translate during protein synthesis (1.33). Polysomes can be attached to membranes, constituting granular endoplasmic reticulum (vide supra) or may lie free in the hyaloplasm where they synthesize proteins for use outside the channel system, including enzymes of the hyaloplasm, structural proteins of the cell (e.g. actin, tubulin) and haemoglobin in erythroblasts.

In a mature polysome all the attachment sites of the messenger RNA are occupied as ribosomes move along it, synthesizing protein according to its instructions, so the number of ribosomes in a polysome indicates the length of the messenger RNA molecule and hence the size of the protein being made.

The two major subunits have separate roles in protein synthesis. The smaller is the site of attachment and translation of messenger RNA; the larger is responsible for the release of the new protein and, where appropriate, attachment to the endoplasmic reticulum, directing the protein through its membrane into the cisternal cavity.



Subunit proteins of the ribosomes themselves are synthesized in the cytoplasm by other ribosomes. They then apparently enter the nucleus where they bind to ribosomal RNA from the nucleolus to form the two major subunits; these then pass separately back into the cytoplasm and only associate to form a complete ribosome when they attach themselves to a messenger RNA molecule (Nomura 1984). When protein synthesis is over, the two subunits dissociate but may serve more than once.

Mitochondrial ribosomes differ from those of the general cytoplasm, being somewhat smaller (55S). They will be discussed later (see mitochondria, vide infra). The ribosomes of fungi and prokaryote organisms such as bacteria are also smaller than those of the nucleated cells of animals (and plants), which may perhaps reflect the less complex regulatory mechanisms of these relatively primitive species.

MITOCHONDRIA

Mitochondria are membrane-bound organelles of great metabolic significance (Ernster & Schatz 1981, Fawcett 1981, Tzagoloff 1982) producing energy from the oxidative breakdown of large molecules and carrying out various other chemical processes. They were first observed with the light microscope as thread-like, spherical or ellipsoidal bodies in the cytoplasm of most cells, particularly those with a high metabolic rate such as secretory cells in exocrine glands. In living cells, when viewed by bright field, phase contrast or interference microscopy, they have been seen to move, change size and shape and to divide. In size most mitochondria range from 0.5–2.0 μm long; those of cardiac muscle are particularly large.

Each mitochondrion is lined by an outer and an inner membrane, separated by a variable gap (1.17). The outer is smooth and sometimes attached to other organelles (e.g. microtubules); the inner membrane is deeply folded to form incomplete transverse or longitudinal septa or tubular invaginations, *cristae mitochondriales*, which thus create a relatively large surface area of

1.17 Electron micrograph showing details of mitochondrial structure: the outer membrane, the inner membrane folded to form cristae and their related intra-mitochondrial spaces are visible. Magnification × 30 000.

membrane. Cristae are more numerous and complex in cells with a high metabolic rate than in relatively inactive ones; in heart muscle, for instance, they are numerous and show complex pleats. In mitochondria of the lipocytes of brown fat, cristae are particularly conspicuous and their chemical activities are diverted to the direct production of heat rather than ATP (see p. 62). Cristae of cells in the adrenal cortex are typically tubular. The significance of these different arrangements is not clear.

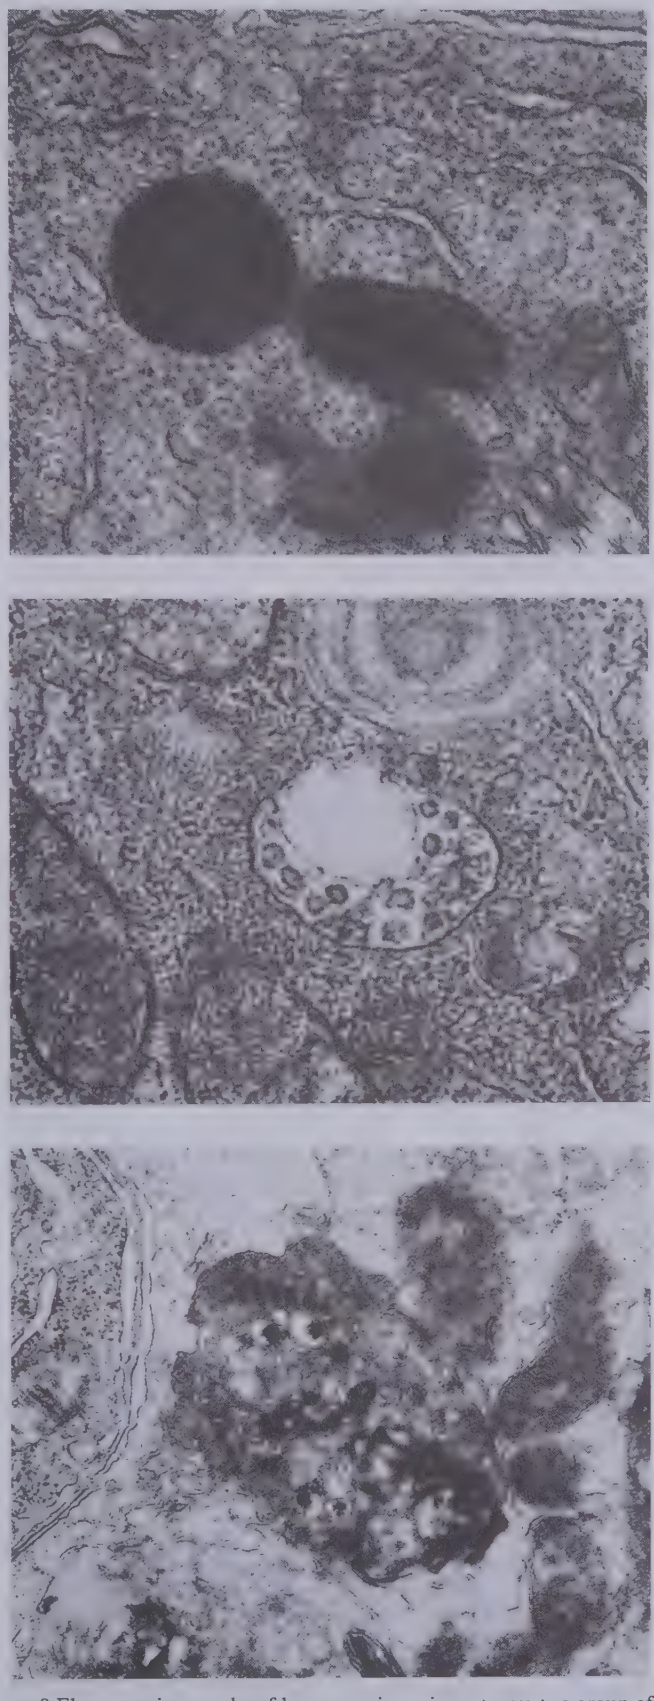
In the inner lumen of the mitochondrion lies the finely granular *matrix*, of variable density. Within the matrix are many soluble enzymes and a variety of inclusions have also been described, including calcium salts, organic crystals, glycogen, some ribosomes and the nucleic acids RNA and DNA. The ribosomes are smaller and quite distinct from those of the rest of the cell. The DNA thread forms a complete ring and has a ratio between its nitrogen bases different from that of chromosomal DNA. There are also chemical differences in the RNA types and the precise genetic code used in protein synthesis (Grivell 1983). Mitochondria are able to multiply by division during interphase, some of the inner mitochondrial membrane components being specified by the mitochondrial DNA. To some extent, therefore, this is an example of *cytoplasmic inheritance*. It follows from this that all mitochondria in the body are in effect descended from those in the cytoplasm of the fertilized ovum. Further, it has recently been shown that these are entirely of maternal origin, so that mitochondria (and any of their genetic variants) are passed only through the female line; the mitochondrion of the sperm is not incorporated into the ovum at fertilization. The ribosomes and nucleic acids are, interestingly, similar to those of bacteria, suggesting the origin of mitochondria in the far distant past as symbiotic bacteria which lost their ability to lead an independent existence (see Margulis 1981).

Mitochondria are the principal site of a number of enzyme systems, particularly those of oxidative phosphorylation associated with the tricarboxylic acid (Kreb's) cycle and the cytochrome electron transport sequences of respiration. They are the chief sites where chemical energy is derived from breakdown of organic compounds in respiration to form high-energy organic phosphate compounds (particularly adenosine triphosphate, ATP, and guanosine triphosphate, GTP) by an unusual chemical mechanism, the chemi-osmotic process, which involves the pumping of hydrogen ions out of the mitochondria to drive the synthesis of ATP (Mitchell 1961). These energy-rich compounds pass to other parts of the cell where they fuel energy-consuming reactions. The various enzymes of the Kreb's cycle occur in the mitochondrial matrix, while those of the cytochrome system and oxidative phosphorylation are localized chiefly in the inner mitochondrial membrane. Some of these ATPases form an enzyme assembly (ATP-synthetase) which, when mitochondria are hypotonically disrupted and negatively stained, become

visible as minute spheres about 9 nm across, supported by stalks projecting from the inner membrane (*elementary, submitochondrial* or *stalked particles*). Fatty acid metabolism, calcium concentration and various other chemical activities are also carried out in mitochondria.

It is interesting that these organelles are distributed within the cell according to regional energy requirements, e.g. near the bases of cilia in certain epithelia and at the base of the cells of proximal convoluted renal tubules, where considerable active transport occurs. Estimates of mitochondrial numbers in cells also show variability; in mammalian hepatocytes they number about 1000–2000 per cell; in lymphocytes only a few may be present.

Various syndromes are known in which patients have defective mitochondrial enzyme systems, affecting, e.g. the efficiency of muscles, kidney and neural function, etc. (Morgan-Hughes 1986).



LYSOSOMES

Lysosomes are membrane-bound, spheroidal or ellipsoidal bodies, 0.08–0.8 μm in diameter (1.8,18), which contain hydrolases capable of degrading a wide variety of substances (de Duve 1965, Holtzman 1976, Bainton 1981, Brachet 1985). They occur in all cells except mature erythrocytes and are essential to cellular catabolism (degradative activities), being particularly numerous in cells with a rapid metabolism and in phagocytes. So far, more than 40 lysosomal enzymes are known including many varieties of proteases, lipases, carbohydrases, esterases and nucleases. They are maintained at a low pH, mainly conjugated to carbohydrates. Cytochemically, the enzyme acid phosphatase (β-glycerylphosphatase) has been widely used as a marker of lysosomes for light and electron microscopy, though it is not invariably present.

Lysosomes have a complex life history, each stage being structurally distinct, and several forms may appear in the same cell. Their proteins are first formed in the granular endoplasmic reticulum where carbohydrate is also added to the enzymes; then they are passed to the Golgi complex for packaging in vesicular form and final processing. Enzyme retention within lysosomes rather than immediate secretion depends on the presence of a specific carbohydrate group added to the enzyme in the granular endoplasmic reticulum. When first released as *primary lysosomes* they are relatively small but may fuse to form larger primary lysosomes up to 0.8 μm across, typically dense and granular within. Primary lysosomes can be used either to degrade materials taken into the cell by endocytosis (*heterophagy*) or to degrade worn out, damaged or 'unwanted' organelles in the cell (*autophagy*). In heterophagy, phagocytic vacuoles (*phagosomes*), containing objects such as bacteria, fuse with one or many primary lysosomes to form *secondary lysosomes* which show signs of digestion—membranous whorls, fibrillar debris, etc. The term *phagolysosome* is given to a phagosome in the process of fusing with a lysosome. Smaller pinocytotic and endocytic vesicles, containing fluids or small particles, fuse with primary lysosomes to form *multivesicular bodies* (1.18B), another form of secondary lysosome. In both heterophagy and autophagy, lysosomes become smaller and denser as digestion proceeds; the final *residual bodies*, containing insoluble remains, may be ejected from the cell by exocytosis or may remain within the cell (*'storage excretion'*). In non-dividing cells such as neurons, residual bodies (1.18C) may fuse to form much larger aggregates, retained permanently, becoming conspicuous in old age in the form of the lipid-rich pigment lipofuscin (*'senility pigment'*) within the nervous system.

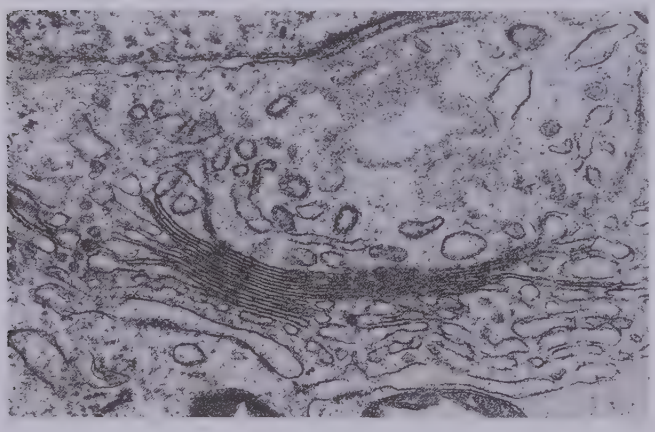
In some cells, lysosomes are a dominant feature, as in neutrophil leucocytes, where the primary granules are lysosomes which assist in killing phagocytosed bacteria. Lysosomal enzymes may also be expelled to damage neighbouring foreign organisms or alter extracellular materials; the erosion of bone is in part caused by such lysosomal action from osteoclasts (see p. 295). Abnormal release of enzymes can cause tissue damage, as in certain types of arthritis. Enzymes released to the exterior can also be taken up by other cells and incorporated into their own lysosomes.

Lysosomal membranes, normally impermeable to their enclosed enzymes, may allow the enzymes to leak. When exposed to ionizing radiations, some carcinogens, silica or asbestos

1.18 Electron micrographs of lysosomes in various stages: A. a group of lysosomes in an olfactory receptor cell showing small primary lysosomes (left), and larger secondary lysosomes containing lamellar débris; B. a multivesicular body with which endocytic vesicles are in the process of fusing; C. a residual body, the end stage of lysosomal hydrolysis of engulfed cellular organelles. All magnifications × 30 000.

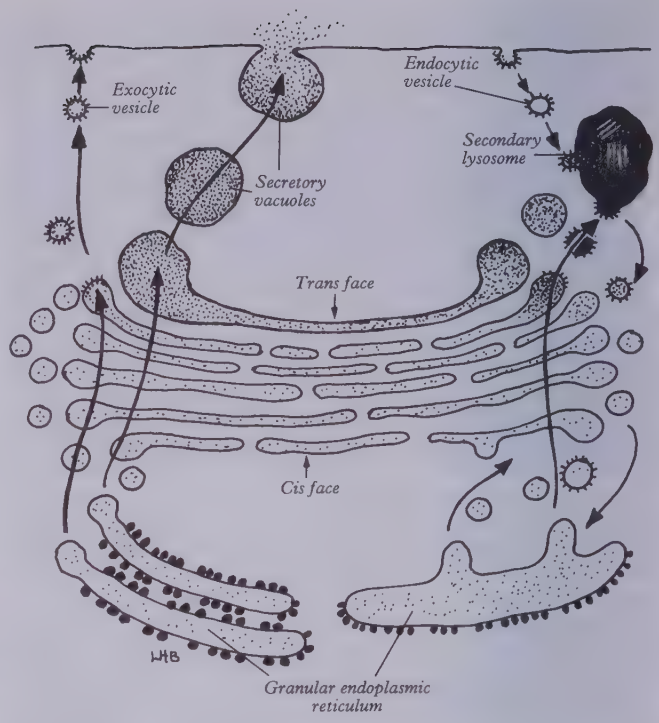
particles, anoxia, heat and many drugs cause such effects, with consequent cellular damage or death or, if the genes are affected, perhaps neoplastic transformation. Conversely, some drugs, e.g. cortisone, can stabilize lysosomal membranes and may therefore inhibit their fusion with phagocytic vesicles. Lysosomal leakage may also be involved in the *programmed death* of redundant cells during embryonic growth or in facilitating their removal once dead (see also p. 103).

By their involvement in breakdown processes in metabolism, defects in lysosomal enzymes can cause profound morphogenetic changes; a wide range of genetic disorders (*lysosomal storage diseases*) has also been described, e.g. Tay-Sachs' disease in which a faulty carbohydrase leads to the accumulation of glycolipid in the central nervous system, with consequent early death, and Hurler's syndrome, where failure to metabolize certain glycosaminoglycans (mucosubstances) causes abnormalities in the formation of connective tissues.



PEROXISOMES

Peroxisomes (microbodies) are membrane-bound vacuoles (1.8), about 0.5–0.15 μm across, often with dense cores or crystalline interiors (de Duve 1973, 1983, Tolbert & Essner 1981). Large (0.5 μm) peroxisomes are found, e.g. in hepatocytes and kidney tubule cells, where they appear to detoxify various substances including ethanol by oxidizing them with molecular oxygen. Oxidation of a wide variety of compounds also occurs in smaller peroxisomes, which probably occur in all nucleated cells and form a vital system for detoxification of materials produced by or taken into cells. The oxidative enzyme *catalase* is particularly important in these processes, breaking down hydrogen peroxide produced by other peroxisomal enzymes, e.g. D-amino acid oxidase and urate oxidase which are also characteristically present. Some fatty acid breakdown also occurs in peroxisomes.



GOLGI COMPLEX (GOLGI APPARATUS OR DICTYOSOME)

Beginning with the Italian Camillo Golgi, optical microscopists of the nineteenth and early twentieth centuries recognized a distinct cytoplasmic region near the nucleus, particularly prominent in secretory cells and staining well with metallic salts. This was long considered an artefact by many but with the advent of electron microscopy it was authenticated as a genuine cellular organelle of great importance (see Farquhar & Palade 1981, Brachet 1985, Farquhar 1985).

The Golgi complex consists of one or more zones of smooth endoplasmic reticulum (1.5,19,20) arranged as stacks of flattened interconnected cisternae; small vesicles are found clustered at their borders. In glandular cells with an apical secretory zone, the Golgi complex is positioned between the secretory surface and the nucleus; in fibroblasts, where secretory activity is more general,

1.19 Electron micrograph of a Golgi apparatus in a spermatocyte showing the central multilamellar cisternae and clusters of peripheral vesicles. Magnification × 15 000.

1.20 Some of the main routes of intracellular transport associated with the Golgi complex. The arrows indicate (lower picture) the origin of proteins from the granular endoplasmic reticulum and (left) their passage through the Golgi cisternae to the cell surface, either via exocytic vesicles as surface molecules (e.g. receptors for cholesterol) or as larger vacuoles for secretion. On the right, pathways involving lysosomes are shown: primary lysosomes in the form of small or larger vesicles are budded off from the *trans* face of the Golgi complex and fuse with material to be degraded as secondary lysosomes. Vesicles derived from lysosomes also pass back to the Golgi cisternae which in turn can recycle membrane between its cisternae and also back to the endoplasmic reticulum.

there are two or more groups of flattened vesicles and in liver cells up to 50.

The Golgi complex is often cup-shaped, usually with the convex side nearest the nucleus. Biochemical and autoradiographic studies have shown that the organelle is a metabolically active region where secretory products and lysosomal enzymes are accumulated by fusion of *transport vesicles*. These coalesce with one (usually convex) surface of the complex, termed the '*forming surface*, or *cis* aspect and, after their contents have moved through the pile of cisternae, other vesicles are budded off at the other (usually the concave) surface, the *condensing* or *trans* surface, as secretory or storage vacuoles (*condensing vacuoles*). The forming surface is usually on the side closer to the nucleus (Jamieson & Palade 1967). In traversing the complex, substances can be altered by various processes including addition of carbohydrates and fatty acids, sulphation and by selective removal of amino acids. In mucus-secreting cells, for instance, the proteins synthesized in the rough endoplasmic reticulum are concentrated in the condensing vacuoles by subtraction of water, and carbohydrates rich in sulphur are added. In other cells, too, much of the carbohydrate in their secretions is added at the Golgi complex, whose membranes bear enzymes associated with carbohydrate synthesis, such as glycosyl-transferase, particularly within the cisternae of the *trans* aspect. The enzyme thiamine pyrophosphatase is also a valuable histochemical marker of Golgi complex activity. It has also been proposed that, by selecting and passing on only purified proteins from the cis to the *trans* surfaces, successive cisternae act collectively rather like a molecular distillation apparatus to concentrate specific proteins free of contaminants (Rothman 1981).

The Golgi complex is also active in primary lysosome production (vide supra) which in neurons and other cells may occur in a special region, the Golgi-endoplasmic reticulum-lysosome

complex *(G.E.R.L.)* (see Novikoff 1973). The synthesis of cell membranes and glycocalyx also involves this organelle. Various types of modification and sorting of different substances for appropriate destinations may also occur simultaneously in different regions of the same complex.

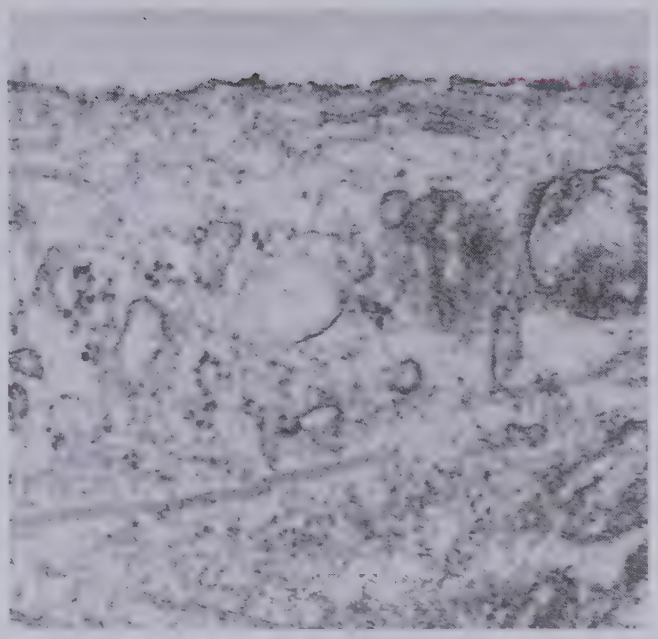
ANNULATED LAMELLAE

Annulated lamellae are arrays of parallel cisternae which sometimes appear in the cytoplasm and occasionally nuclei of cells undergoing rapid protein synthesis (Kessel 1968), e.g. oöcytes, some embryonic and neoplastic cells. Adjacent membranes fuse at intermittent sites where they are punctuated by structures closely resembling nuclear pores (p. 34), reflecting their origin from the outer nuclear membrane. They may serve as attachments for stored RNA but are otherwise obscure.

INTRACELLULAR VESICLES

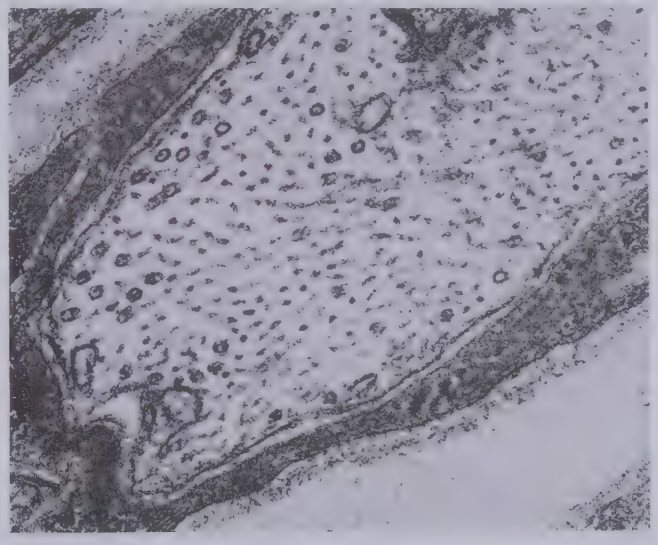
These include membrane-bound vacuoles, usually less than 0.1 μm in diameter, involved in the movement of fluids and particles into, out of and within the cell. The process of uptake is *endocytosis* and the passage of materials in vesicles to the cell surface and their release, *exocytosis*. Endocytosis involves different types of vesicle; *phagocytic vesicles* take in relatively large particles, e.g. bacteria, by an energy-using process. Smaller particles, including macromolecules, can be endocytosed in *coated vesicles* without the use of direct energy. Macromolecules binding to surface receptors trigger attachment of tetrahedral assemblies of the protein *clathrin* to the inner face of the plasma membrane, forming a *coated pit*, then a *coated vesicle* (Pearse and Bretscher 1981) which passes into the cytoplasm, to fuse with other organelles (e.g. lysosomes, golgi complexes) after removal of the clathrin coat. Membrane can then be returned to the cell surface in vesicular form. Small vesicles are also used extensively by cells to shuttle substances internally between organelles (*transport vesicles*). *Pinocytosis* involves the bulk uptake of fluid into large, complex vesicles.

Exocytic vesicles, carrying materials out of cells, vary greatly in size and may only be distinguished from endocytic vesicles experimentally by using extracellular tracers, which will enter the latter but not the former (see p. 50). Vesicles of these various types are present in all cells, but are particularly numerous where rapid exchange of materials between the cell and its environment is occurring, e.g. endothelial cells, synaptic terminals of neurons and in secretory cells.



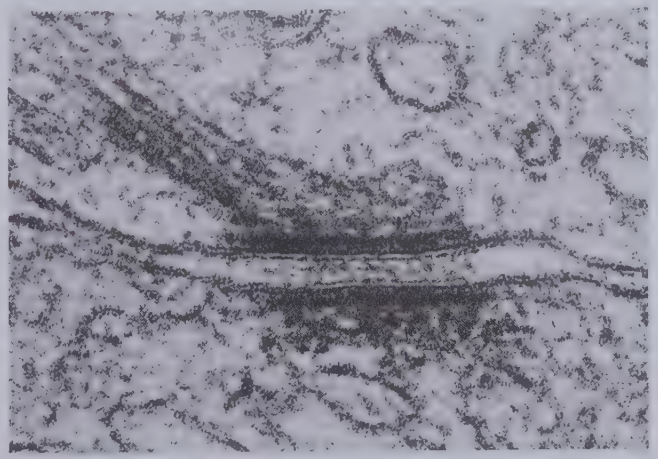
THE CYTOSKELETON

This term is commonly used to denote a heterogeneous collection of filamentous structures which play important roles in maintaining or altering cell shape, generating motion within cells and promoting movement relative to their external environment, i.e. they form the cell's skeleton which, like that of the whole body, performs supportive and motile functions. The components of the cytoskeleton include several types of proteinaceous assemblies, all of them deployed within the cytosolic regions of the cytoplasm lying outside the system of membrane-lined compartments, although they are often attached to them. The way in which movements are created by these structures and their importance both in the daily lives of cells and in more complex processes of development will be considered later (p. 49); here we will give a brief account of their form and composition (see also the reviews by Alberts et al 1983, Brachet 1985, Schliwa 1986, Lackie 1986).



The roll-call of cytoskeletal structures is lengthening rapidly as electron microscopy combined with immunocytochemistry and classic protein chemistry continues to define new forms. Those which we know best are the *microtubules*, *microfilaments* and *intermediate filaments*; other important structures are *myosin filaments* and there is also a galaxy of minor components involved in linking the foregoing structures together or regulating their activities in some way (see e.g. Weber and Osborn 1985).

Microtubules



These are elongated cylinders about 24 nm in diameter (**1**.5,22B),

1.21A Electron micrograph of microtubules and microfilaments in a tangential section through a fibroblast. Magnification × 50 000.

1.21B Microtubules and neurofilaments in a transverse/oblique section of part of a small nerve fibre. The microtubules have a circular cross-section whereas the smaller neurofilaments appear solid. Magnification × 50 000.

1.21C Intermediate filaments associated with a desmosome (macula adherens) between two epithelial cells. Magnification × 100 000.

of varying length (up to some 70 μm in spermatozoan flagella) and made of protein. They are frequent components of most cell types but are abundant in neurons, leucocytes, blood platelets and in the mitotic spindles of dividing cells. They also form part of the structure of cilia, flagella and centrioles (vide infra). Helical microtubules occur in Schwann cells and oligodendrocytes (pp. 893, 901). Massed parallel bundles of inter-connected microtubules are found in the pillar cells supporting the sensory cells of the cochlea. Microtubules rarely show acute bends, indicating a degree of stiffness.

These structures are composed of two proteins, *tubulins* α and β, arranged as dimers (see e.g. Soifer 1986) with a combined *Mr* of 100 000 (50 000 each). Each protein subunit is about 5 nm across and microtubules in transverse section are made up of a ring of 12 or 13 such globular subunits which are arranged in long columns ('protofilaments') of alternating tubulins α and β, forming the wall of a cylinder. Each column is slightly shifted on its neighbour, so that a spiral pattern of alternating α and β subunits is also generated (Amos & Klug 1974). Microtubules are formed by the simple polymerization of the tubulin dimers and there is in some cells an equilibrium between polymerized and unpolymerized tubulin, so that some types of microtubule may break down and reform rapidly, although stability varies. Consequently, chemicals which bind to tubulin cause the equilibrium to shift, bringing about the depolymerization of microtubules; the drugs colchicine, colcemide, vinblastin and griseofulvin are well known as anti-microtubule agents acting in this manner.

Formation of microtubules can take place by addition to pre-existing microtubules, or formation de novo in, as yet, poorly understood *microtubular organizing centres* such as those surrounding (and including) centrioles, around which spindle microtubules polymerize during cell division (Pickett-Heaps 1975) and from which cilia can grow (see p. 31). In other instances such centres have no obvious structural basis, thus centrioles are not always essential to microtubule formation.

Because tubulin dimers are asymmetrical, microtubules themselves are also asymmetrical, i.e. they have an integral *direction*, one end being chemically different from the other. It is therefore possible to add tubulin at one end while removing it at the other (a phenomenon called 'treadmilling', see also p. 51).

Attached to the walls of the microtubules are other minor components known as *microtubule-associated proteins (MAPs)*, which are important in linking microtubules to each other or to membranous organelles (e.g. mitochondria) or otherwise modifying microtubule functions. In the case of cilia, some of their microtubules have projecting arms whose movements cause sliding between neighbouring microtubules and thus ciliary beating; a protein (kinesin) associated with the walls of other microtubules appears to create the flow of cytoplasm along their surfaces, e.g. in the movements of substances along neuronal axons (for further details see p. 881).

Microfilaments

These are thinner (6–8 nm) than microtubules and appear solid (1.21,22B); they are prominent components of all cells except mature erythrocytes and are intimately involved in cell motility (Wessels et al 1971). They are composed of the protein *actin*, of which the 6 nm subunits of globular *g-actin* (*Mr*:43 000) are arranged in a staggered helical form to form filamentous *f-actin*. A number of different varieties of actin are known, some of them forming long relatively stable microfilaments, others assembling into shorter and more transient ones. Some types are primarily associated with cell plasma membranes; others lie deeper within the cytosol. Muscle cells contain particularly robust forms of microfilament (p. 550). Actin binds to the protein *myosin* when an energy source (ATP) is available and when appropriately organized. This leads to various types of shearing movement which can produce cell motility of different kinds, including muscular contraction (p. 550). Actin microfilaments can be detected electron microscopically by incubating cells, made permeable to proteins, with heavy meromyosin which binds to actin and decorates the filaments with arrowhead formations. Actin can also be readily detected by labelling with anti-actin antibodies conjugated to a fluorescent dye for light microscopy; (see 1.22A) or to an electron-dense marker (e.g. colloidal gold) for electron microscopy. It also binds the fungal derivative phalloidin which can be fluorescently labelled, too. The cytochalasins (fungal products) cause depolymerization of some actin microfilaments (see Spudich & Lin 1972), and therefore provide a valuable experimental tool in research into their functions. Often associated with actin microfilaments are a number of other proteins (e.g. troponin, tropomyosin B, actinin) which assist in various motile activities of these organelles (Lazarides 1976). In cells they are often linked together by shorter filaments, e.g. of the *actin bundling protein, fodrin*, or to cell membranes by such molecules as *vinculin* (in fibroblasts) or *ankyrin* (in erythrocytes, see p. 664).

Intermediate Filaments

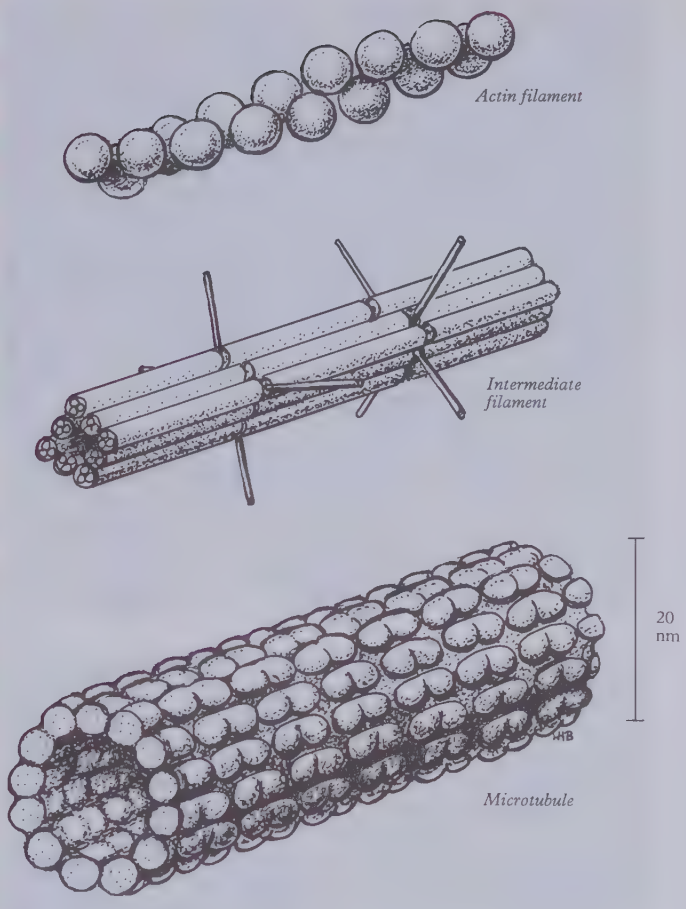
These include a family of protein filaments about 10 nm thick, found in different cell types and often present in large numbers where structural strength is needed (1.8,22). Recently it has been shown by immunochemical and other means that several types of intermediate filament occur, all with similar though not identical chemical structure. These include *keratin* filaments of epithelial cells, *vimentin* filaments of connective tissue cells, *desmin* filaments of muscle cells, *neurofilaments* of nerve cells and *glial fibrillary acidic protein* filaments of neuroglial cells.

All have diameters of about 10 nm and are composed of filamentous subunit proteins in the 50 000–100 000 daltons molecular weight range. They tend to form bundles linked together by lateral extensions which appear to be an integral part of each filament.

Keratin filaments include many subtypes with different roles, according to developmental and functional status of the cells containing them. Best known structurally are those of epidermal keratinocytes. In these cells, keratin filaments are at first arranged in bundles forming a network within the cytoplasm and anchored to desmosomes at the cell surface. As the cells mature, the filaments aggregate in flattened layers to give the now scale-like cells considerable strength (see p. 74). However, studies with specific monoclonal antibodies have distinguished many varieties of such filaments, even within keratinocytes; it is possible to discern a changing pattern of keratin chemistry as cells mature. Likewise, in other epithelial tissues, keratin chemistry is equally complex but this diversity is proving of great advantage in detecting pathological changes and in diagnosing the origins of epithelial carcinomas when these have spread from their parent tissue (for a review, see Clausen et al 1986).

Intermediate filaments also occur in the nucleus of the cell, attached to the inner nuclear membrane and providing mechanical strength to the nuclear wall. They form a complex interlacing network or *nuclear membrane skeleton*, which supports the pore complexes (p. 34) and help to determine nuclear shape.

MICROVILLI



These are finger-like extensions of cell surfaces (1.5,8,23) usually about 0.1 μm in diameter and up to about 5 μm long. When arranged in a regular parallel series, they constitute a *striated border*, as at the absorptive surfaces of the epithelial cells of the small intestine; when less regular, as in the gall-bladder epithelium, the term *brush border* is applied.

Internally bundles of actin microfilaments support them (see Mooseker 1985); these are implanted within the apical cytoplasm of the cell amongst other transversely running filaments to create a meshwork, the *terminal web*, which forms a sheet of filaments across the apical cytoplasm, anchored peripherally to the zonula adhaerens. The protein myosin also occurs in the terminal web and is thought to bind to the actin to stiffen this part of the cell. In vitro this meshwork can be stimulated to contract, experimentally. The microfilaments are attached to the membrane of each microvillus by finer lateral filaments along the margins and are inserted apically into a dense mass of the protein α-actinin (Mooseker & Tilney 1975).

Microvilli greatly multiply the area of surface (up to 40 times, in striated borders) and are found at sites of active absorption, such as in the proximal and distal convoluted tubules of the

1.22A Intermediate filaments, in this case composed of glial fibrillary acidic protein (GFAP), demonstrated in cultured retinal astrocytes with anti-GFAP antibodies coupled to rhodamine. Provided by Caroline Wigley, UMDS, Guy's Campus, London. Magnification × 5000.

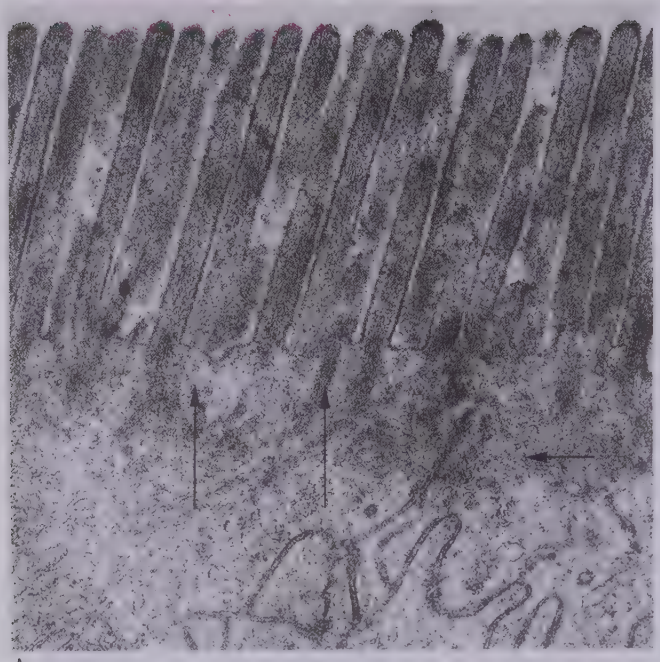
1.22B The substructure of some major cytoskeletal components, including (top) an actin microfilament formed by polymerization of globular actin monomers; (middle) an intermediate filament composed in this example (e.g. vimentin) of eight sub-filaments, each containing two or three paired acidic and basic polypeptide chains, some extending laterally as side-arms; and (below) a microtubule composed of assemblies of tubulin dimers arranged in a tight helix.

kidney. In the small intestine absorptive cells bear microvilli which have a thick glycocalyx, probably of great importance in providing a site for activity of digestive enzymes. Several enzyme systems associated with active transport across membranes have been localized within striated borders.

Irregular microvilli, or *filopodia*, are also found on the surfaces of many types of cell, particularly free macrophages and fibroblasts. Again, these may be associated with transport processes, particularly phagocytosis, and with cell motility.

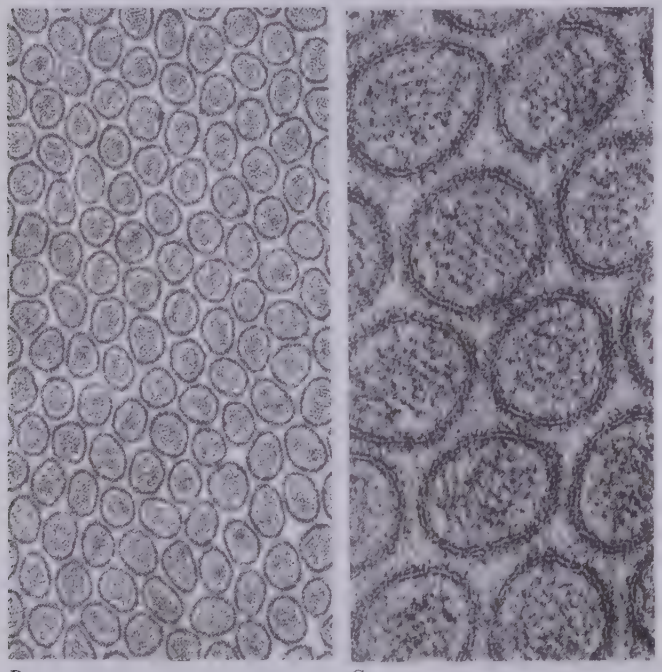
Large, regular microvilli (*stereocilia*) occur at some sensory surfaces, e.g. on cochlear and vestibular receptor cells and in the absorptive epithelium of the epididymis.

Transient microvillus-like structures found on developing or motile cells include elongate '*microspikes*' and *ruffled membranes* (see p. 49, also 1.48).



CILIA AND FLAGELLA

These are, typically, motile hair-like (cilium = eyelash) and whip-like (flagellum = whip) projections of the cell surface, which create currents in the surrounding fluid or movements of the cell to which they are attached. Cilia occur on many internal surfaces, particularly the epithelia of most of the respiratory tract and parts of the male and female reproductive tracts, the ependyma lining the central canal of the spinal cord and ventricles of the brain and the mesothelia of the peritoneal and pleural cavities. They also occur at olfactory receptor and vestibular hair cell endings and, modified, as portions of the rods and cones of the retina; cilia are, in addition, present on many dividing tissue cells. Many cilia may be present on a single cell, as in bronchial epithelium, or only one or two as with some mesothelial cells. Each male gamete possesses a single flagellum about 70 μm long.



By electron microscopy (1.24,25) each cilium or flagellum is seen to consist of a *shaft*, constituting most of its length, with a diameter of about 0.25 μm, a tapering *tip* and, within the surface cytoplasm of the cell, a *kinetosome (basal body, basal granule* or *blepharoplast)* about 1 μm long (Gibbons & Grimstone 1960). The whole structure is bounded, except at its base, by an extension of the plasma membrane. In freeze-fracture preparations chain-like groups of characteristic membrane particles, the *ciliary necklace*, surround the proximal end of the cilium (Gilula & Satir 1972). These particles may assist the control of ciliary beating. Within the membrane lies a cylinder of nine double microtubules (the *axoneme*), surrounding a central pair of single microtubules.

At the *base* of the cilium each microtubule doublet, the two parts of which are designated the A and B subfibres, are twisted through 40 degrees (1.24) and another microtubule, the C subfibre, is added. The central pair sometimes end above the cell surface in a dense sphere or *axosome*, beneath which lies a transverse partition or *basal plate*. Associated with the kinetosome are often one or more cross-banded filamentous *rootlets* and a plate-like *basal foot*, which probably help to anchor the cilium into the cytoplasm.

At the *apical end*, the various microtubular elements do not all continue to the tip; the A subfibres are shortest, then the B

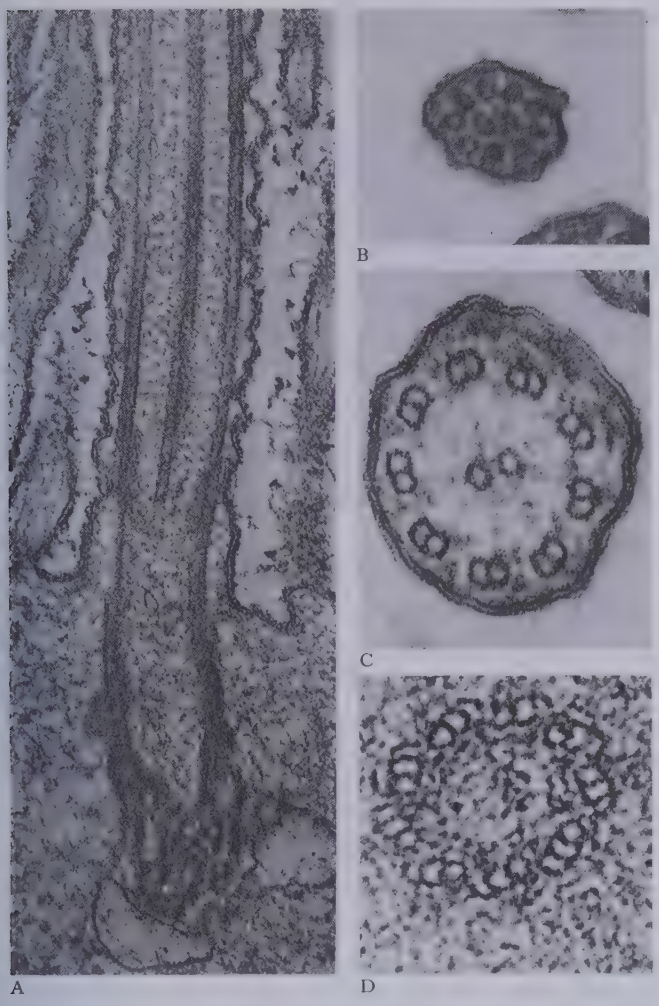
1.23D Scanning electron micrograph of a striated border from the small intestine showing numerous microvilli. The epithelium has been cut vertically to allow the microvilli to be viewed from the side as well as from above. Magnification × 6000.

subfibres and finally the central pair terminate. Within the shaft lie several filamentous structures associated with the microtubules, such as radial spokes which extend inwards from the outer microtubules towards the central pair. The outer doublet microtubules bear two rows of tangential *dynein arms* attached to the A subfibre of one doublet, pointing towards the B subfibre of the adjacent doublet. Adjacent doublets are also linked by thin filaments. Other filaments partially encircle the central pair of microtubules, which are also united by ladder-like spokes. Because of the 9+2 pattern of tubules, there is a plane of symmetry which passes perpendicular to a line joining the central pair and corresponds to the direction of bending.



Movements of cilia and flagella (see Sleigh 1974,1977), are similar in broad outline (1.26). Flagella move by rapid undulation passing from the attached to the free end. In human spermatozoa there is a helical component in this motion, although the precise form is hydrodynamically complex (see e.g. Brokaw 1975).

In cilia, the beating is planar, but asymmetrical. In the *effective stroke*, the cilium remains stiff except at the base where it bends to produce an oar-like stroke. Then follows the *recovery stroke* during which the bend passes from base to tip returning the cilium to its initial position for the next cycle. The activity of groups of cilia is usually coupled so that the bending of one is rapidly followed by the bending of the next and so on, resulting in long travelling or *metachronal* waves (see also p. 1276). These pass over the tissue surface in the same direction as the effective stroke. Mechanical coupling of adjacent cilia is caused by their viscous interaction, the bending of one initiating beating of the next.

The basic mechanism is still not clear; when a cilium bends, the microtubules do not change in length but slide on one another (Warner & Satir 1974). The 'arms' of peripheral doublets are made of a protein 'dynein' and slant towards the cilium base from their attached ends. Dynein has an ATPase activity, stimulated by magnesium ions, and appears to cause mutual sliding of adjacent doublets by first attaching to the next at its free end, then swinging upwards towards the tip of the cilium. The radial spokes and various other substructures appear to modify the form of the ciliary bending (Warner & Mitchell 1980).

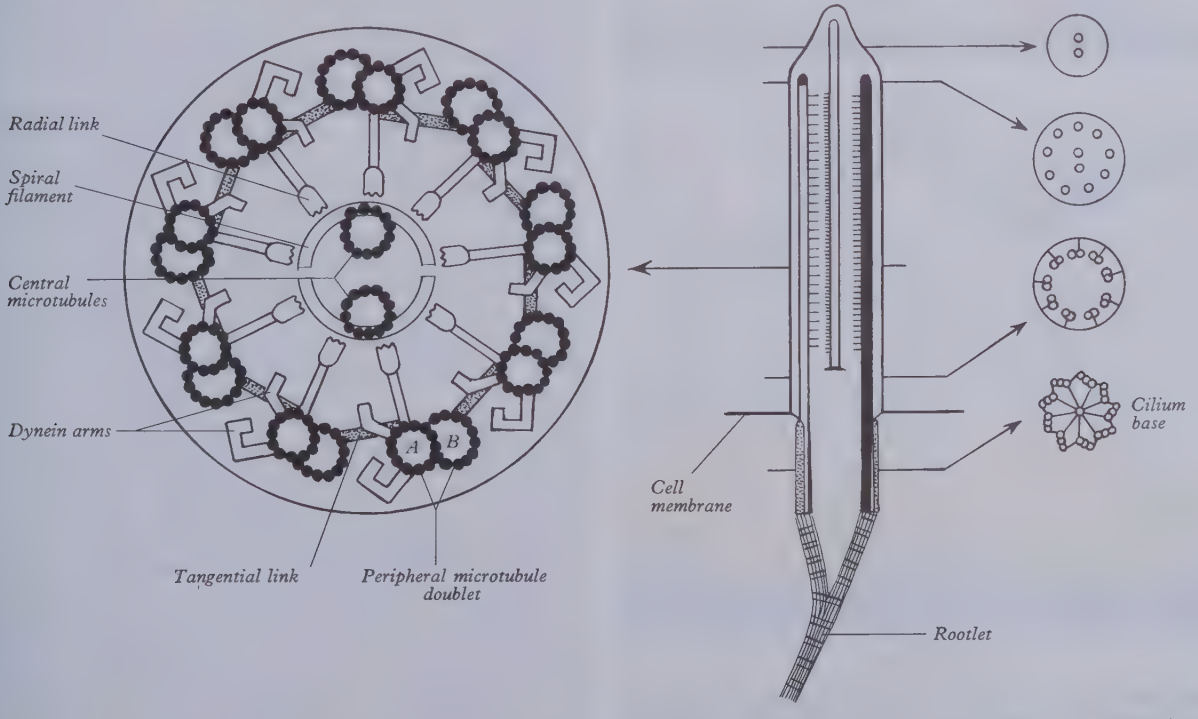
The cilia of olfactory receptors (p. 1173) show the typical '9+2' arrangement of subfibres; the cilium segment of retinal rods and cones, however, lacks the central pair (p. 1199). Dividing cells of many tissues (e.g. the adrenal cortex) also show a small number of cilia which protrude from the cell surfaces into the intercellular spaces. Their function is unknown but they may represent some unavoidable, functionless by-product of cell division processes.

Cilia and flagella are formed by the polymerization of tubulin on centrioles, which are synthesized deep in the cell and then move to lie immediately beneath the cell membrane before the cilia begin to sprout (Sorokin 1968, Staprans & Dirksen 1974). Once initiated, they grow by the addition of tubulin and other materials to the distal end.

1.24 Electron micrographs of cilia cut (A) longitudinally, and (B, C, D) through the tip, shaft and base respectively. Magnifications: A × 50 000; B–D × 110 000.

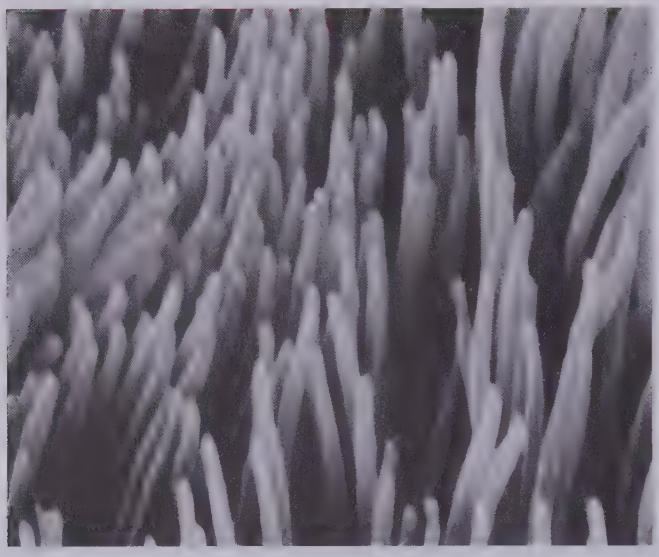
CENTRIOLES

Centrioles are microtubular cylinders about 1μm long by 0.25 μm in diameter (Peterson 1980, Wheatley 1982), identical in structure with the bases of cilia (vide supra) but lying free in the cytoplasm (1.5,27). At least two centrioles occur in all cells capable of division, usually lying close and at right angles to each other, together often termed a *diplosome*, within a somewhat dense region of cytoplasm, the *centrosome*. Various filamentous or granular structures (*centriolar satellites* or *pericentriolar bodies*) surround them.



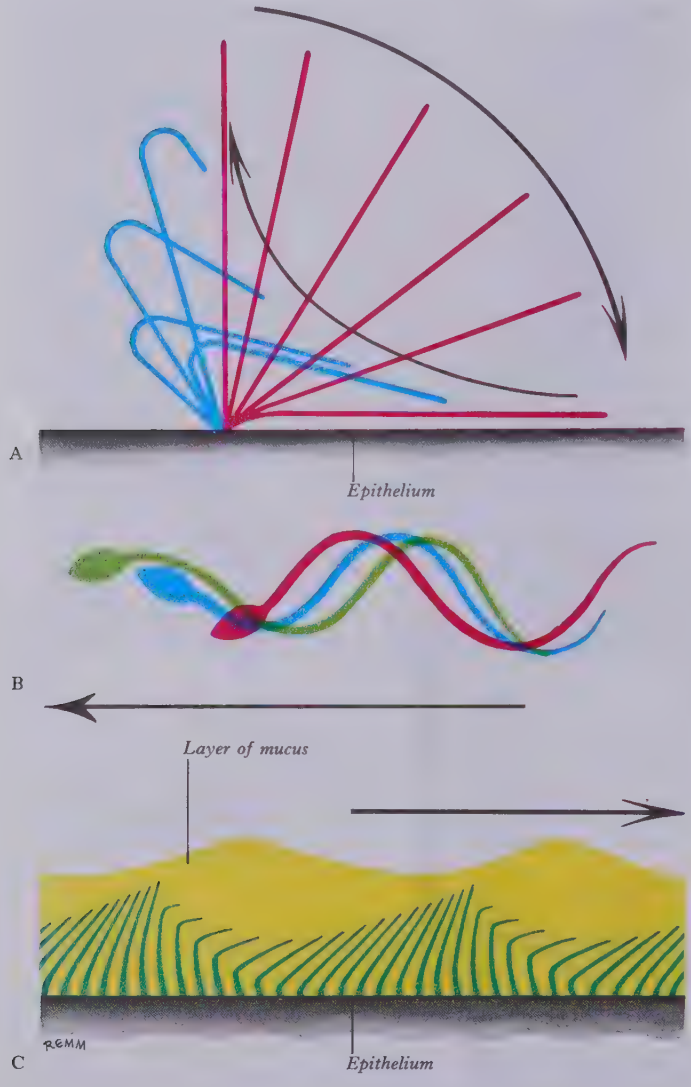
This centriolar complex is a centre for microtubule assembly, e.g. in the generation of the spindle and aster microtubules during cell division, the sprouting of cilia and the provision of axonal and dendritic microtubules in developing neurons. Prior to cell division a new centriole forms near each old one and the resulting pairs are passed on to the two new cells (Rattner & Phillips 1973).

Although the microtubules of cilia are assembled directly on the ends of centrioles, spindle microtobules grow from the surrounding centriolar satellites rather than centrioles themselves. The nature of this organizing capacity is not certain; in flowering plants spindle microtubules are formed without centrioles, so they may not be essential to this process.



The Nucleus

The nucleus is usually spherical or ellipsoidal, often indented, 4–10 μm in diameter, and separated from the cytoplasm by a membranous nuclear envelope. It stains deeply with basic dyes such as haematoxylin, by virtue of the nucleic acids in its chromosomes (deoxyribonucleic acid, DNA) and its nucleoli (ribonucleic acid, RNA). DNA is also responsible for the strong positive reaction with the Feulgen method. Basic proteins (histones) and some acidic proteins are also present in the nucleus.



Many experimental investigations of the functions of the nucleus have been carried out to determine its role in cellular life. These involved various approaches, e.g. transplantation of nuclei between different species of protozoa, removal of the nucleus and the fusion of dissimilar cells from different species after prior treatment with viruses or other agents (Harris 1970). Such experiments and many other observations, e.g. on the role of the gamete

1.24E The internal structure of a cilium in longitudinal section (centre), the disposition of microtubules at various levels (right), and the detailed cross-sectional appearance of the shaft of the cilium (left). In the latter, hook-like dynein arms extend from the peripheral doublets and radial links with expanded heads project towards the central pair of microtubules. A filamentous spiral encircles the central pair. Adjacent peripheral doublet microtubules are also connected by tangential links. Redrawn from Sleigh (1977).

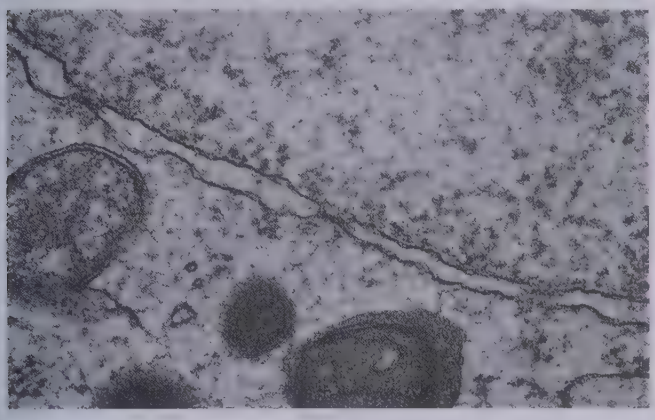
1.27 Transmission electron micrograph of a group of centrioles in a developing nerve cell dendrite. Provided by A Cuschieri. Magnification × 25 000.

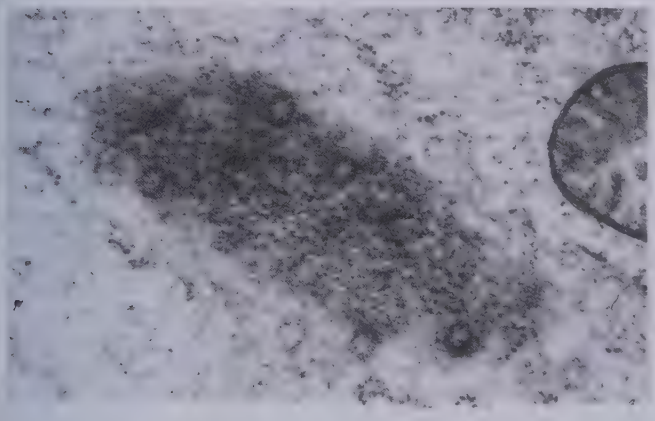
nuclei in transmitting inheritable traits, show that the nucleus contains the inheritable instructions (genes) for the direction of the cell's activities so that, although the cytoplasm can survive for a limited time without a nucleus, protein synthesis ceases and the cell soon dies.

Many of the characteristics of intact cells in culture, such as division rate and motility, seem primarily determined by the nucleus. Isotopic labelling also shows a constant exchange of materials between nucleus and cytoplasm (see p. 39).

NUCLEAR ENVELOPE



This is a flattened sac formed by the membranes of the innermost two layers of the cytoplasmic membrane system, separated by a distance of about 20 nm (1.5,28). The outer membrane is part of the endoplasmic reticulum proper and often bears ribosomes; products of protein synthesis may accumulate between the two membranes. The inner membrane is quite distinct from other cell membranes, being the attachment site for the ends of chromosomes, which often adhere to this surface as a dense coating of chromatin during interphase. This membrane is also reinforced with a network of 10 nm filaments (p. 30) which, with other proteinaceous material, forms a dense *nuclear lamina* lining the inner surface of the nuclear envelope.



The envelope membranes show scattered zones of annular fusion to form *nuclear pores*. Each of these creates an aperture in the nuclear envelope, about 80 nm across and surrounded by a ring of eight groups of granules; a diaphragm partly covers the aperture and another granule occupies its central region, so that only particles less than 9 nm across can traverse the pore. The whole apparatus is the *pore complex* (Franke et al 1981). There are from 3000–4000 pores in a typical nucleus, providing diffusion channels for smaller proteins, messenger RNA, etc, while retaining the chromosomes within the nucleus and excluding potentially destructive organelles, e.g. lysosomes.

Chromosomes

Within the nucleus most of the nucleic acid is deoxyribonucleic acid (DNA) associated with protein as *chromatin*, in the form of elongated threads, the *chromosomes*. Between cell divisions, these are highly extended to create, collectively, a diffuse network which may be dispersed as weakly staining *euchromatin* or more folded as more densely staining *heterochromatin* (1.29). These two states are associated, respectively, with high and low degrees of RNA synthesis (vide infra). It has also been found that replication of DNA during S phase takes place later in heterochromatin than euchromatin. Euchromatic nuclei are known as *open-faced* and are larger than heterochromatic, *closed-face* nuclei. When heterochromatin takes the form of thick threads, as seen by light microscopy, it is said to be *leptochromatic* (e.g. in resting

lymphocytes). In moribund cells, the nuclei are often small and stain densely (*pyknotic nuclei*) or may disintegrate into vesicles (*karyorrhexis*). Pathological nuclei (e.g. in neoplastic cells) may be highly irregular in shape and take on a variety of appearances (*pleomorphic nuclei*), reflecting disturbances in their chromosomal organization.

1.29 Photomicrograph showing the configuration of chromatin in 'closed-face', heterochromatic nuclei of lymphocytes (small cells) and 'open-face', euchromatic nuclei of larger reticular cells. The section is stained with methyl green-pyronin stain which also gives the characteristic red colour to the nucleolus and cytoplasm of the larger cells, denoting the presence of much RNA. Magnification × 1000.

In most somatic cells both states of chromatin co-exist; heterochromatin typically lies mainly against the inside of the nuclear envelope, leaving gaps at the nuclear pores; euchromatin occupies the more central region of the nucleus. It must be added that the terms euchromatin and heterochromatin are used in a different sense in the discipline of cytogenetics, to denote specific configurations of chromatin in dividing cells (see p. 42).

During cell division chromosomes shorten very considerably; each cell is then seen to contain a fixed number of chromosomes characteristic for that species. In human somatic cells this number is 46, the *diploid* number; in gametes and their immediate precursors the number is half this (the *haploid* number, p. 42). When fertilization occurs, fusion of two haploid sets, one from each gamete, restores the diploid number. The number of sets is the *ploidy*. If more than two sets are present the cell is *polyploid*.

Each chromosome in a haploid set is unique in size and shape; in a diploid set there are two of each type of chromosome (*homologous* pairs), one each from the ovum and the spermatozoön. However, the chromosomes of one pair are not always identical with each other; these are the *sex chromosomes*, which in humans are distinct from the remaining 22 pairs of chromosomes (*autosomes*). In the female (the *homogametic sex*) the sex chromosomes are identical X *chromosomes*, so giving 44 autosomes + 2 X sex chromosomes. In the male (the *heterogametic sex*) there is one X and an unequal Y *chromosome* giving a diploid complement of 44 autosomes + X and Y sex chromosomes.

During gametogenesis homologous chromosomes separate, one to each gamete. Hence in the male, there are equal numbers of gametes with X or Y sex chromosomes whereas, in the female, all ova contain an X chromosome. At fertilization there is therefore an equal chance of a male (XY) or a female (XX) zygote being formed, although at birth there is a slight predominance of females because of a higher prenatal mortality in male embryos.

CHROMOSOMAL STRUCTURE

Chromosomes are most clearly observed during cell division, when they are shortest and thickest; then each pair of homologous chromosomes has a characteristic common basic structure. Each consists of two parallel and identical *chromatids* (1.30–32), joined together at a narrowed region, the *primary constriction*, within which is a pale-staining *centromere* or *kinetochore*; this is attached to the spindle fibres during cell division.

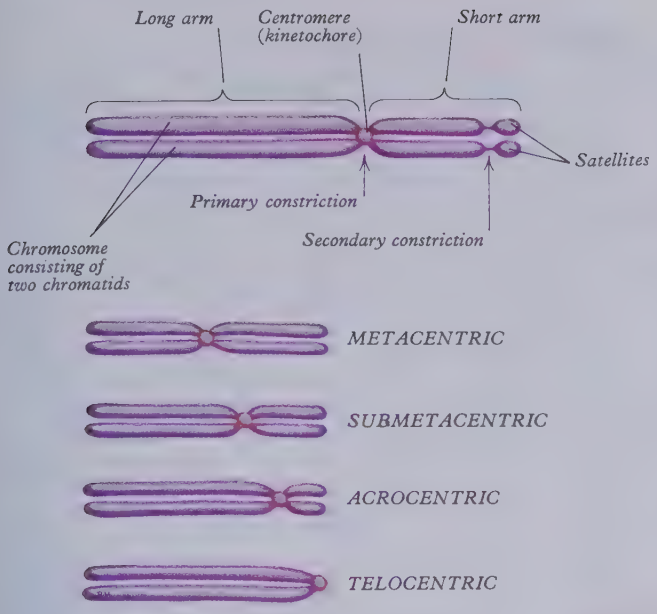
Each chromatid is divided by the centromere into two *arms*. The centromere may be close to the middle of the chromosome (*metacentric*) or placed somewhat away from the middle

1.30 A possible model for the organization of DNA and protein in chromosomes during early metaphase in mitosis. Each chromosome consists of two chromatids united at the primary constriction where the centromere is also sited. In the exposed region of the DNA molecule, the chemical groups of the 'backbone' of each helix—S (sugar) P(phosphate)—and the bases—A(adenine), T(thymine), C (cytosine) and G(guanine)—are represented. Several nucleosomes are also depicted (see text).

(*submetacentric*) or near one end (*acrocentric*). In some mammals the centromere may be placed at the extreme end (the *telocentric* condition). In certain chromosomes there is a *secondary constriction* near one end of each chromatid, dividing off terminal *satellite bodies*. These constrictions are believed to be associated with the formation of nucleoli (*nucleolar organizing centres*), which are attached to this region in interphase. The classification of human chromosomes on the basis of such characteristics will be considered later (p. 47).

Each complete diploid set of chromosomes contains the cell's hereditary instructions, or *genome*, and each cell in the body, apart from the germ cells, has an identical genetic complement. Chromosomal threads bearing these instructions are *chromonemata* (singular: *chromenema*). Each chromosome bears a linear sequence of *genes* (units of inheritance), each at a characteristic position (*gene locus*), which together determine the inheritable characters of the organism.

During interphase, each chromosome retains its integrity and the sequence of genes is thus preserved. Although this arrangement is highly stable, permanent, inheritable changes (*mutations*) can be caused by external agents such as ionizing radiation and exposure to certain chemicals. When the affected region is restricted these are called *gene mutations*. When whole arms or relatively large segments are involved, they are *chromosomal mutations*. Such changes are some of the principal causes of inheritable *biological variation* which all populations show (but see also meiotic cell division, p. 44). Within members of such a population, homologous chromosomes may determine a number of alternative characters by carrying mutant genes; such alternative genes are termed *alleles*.



In any genome homologous chromosomes may possess, at a particular locus, identical alleles (the *homozygous* condition) or non-identical ones (the *heterozygous* condition). During gametogenesis the homologous chromosomes are segregated into haploid sets and so their alleles are also segregated. The various types of recombination of these which occur at fertilization, and their expression in the resulting organism, are the substance of the basic laws of inheritance, first propounded by Gregor Mendel, forming the basis of classical genetics.

COMPOSITION AND ACTIVITIES OF CHROMOSOMES

Chromosomes are made of filaments of the nucleic acid DNA (1.30,33) each associated with various nucleoproteins. Human diploid somatic cell nuclei each contain about 5.6×10^{-12}g of DNA (Rudkin 1967). The identification of DNA as the hereditary

1.32 The major structural features of chromosomes seen in mitotic metaphase; the terminology of the different chromosomal regions is given together with the various major categories of chromosome, classified according to differences in the position of the primary constriction.

material has a long history, dating from the characterization of nucleic acids by Miescher in the 1860s, the recognition of the role of nuclei in fertilization and the cytological events in mitotic and meiotic divisions, and their correlation with the laws propounded by Mendel in 1865 and rediscovered in 1900. Further milestones were the analysis of the chemistry and distribution of nucleic acids in cells including bacteria, the investigation of viruses, which are largely composed of either RNA or DNA, and the resolution of DNA structure by X-ray diffraction crystallography. The latter led to the 'double helix' model of DNA (Watson & Crick 1953 a,b), which opened a new era of molecular biology. Since that time the nature of the genetic store and its mode of action have been studied more intensively, perhaps, than any other biological theme and, in the recent development of the science of molecular genetics, promises to transform many areas of medical research and clinical practice.

DNA and RNA are long molecules which bear coded information directing the activities of each cell and therefore the structure and metabolism of the whole organism (1.33). DNA is the central molecule, since its 'code' is handed on unaltered from parent cell to all of its descendants in the individual organism, and, by its germ cells, to subsequent generations. RNA is the transient intermediary, translating coded information from chromosomal DNA into the structure of enzymes and other proteins which determine the morphology and chemistry of the cell. This flow of information has been termed 'the central dogma' of molecular biology, i.e. DNA→RNA→protein. At each step chemical energy is expended and the mediation of previously existing enzymes is necessary.

All three of these compounds (DNA, RNA and proteins) have one characteristic in common: their molecules are all linear sequences of subunits. Proteins are long polymers of 20 types of amino acid arranged in different order. They vary in length, each arrangement determining the precise nature of a particular protein, e.g. the way in which its chain folds into more complex shapes, as in the macromolecules of globular proteins, and its catalytic activity in enzymes. Likewise, DNA is a long linear molecule, with a direct correspondence between the arrangement of its chemical groups and those of the protein for which it codes. Transfer of information from DNA to RNA by synthesis of the latter alongside the former is *transcription* and the final decoding of the RNA message into the amino acid sequence in a protein is *translation*. The other activity, the exact duplication of the DNA code to provide each derived cell with identical gene sequences, is *replication*.

THE CELL CYCLE

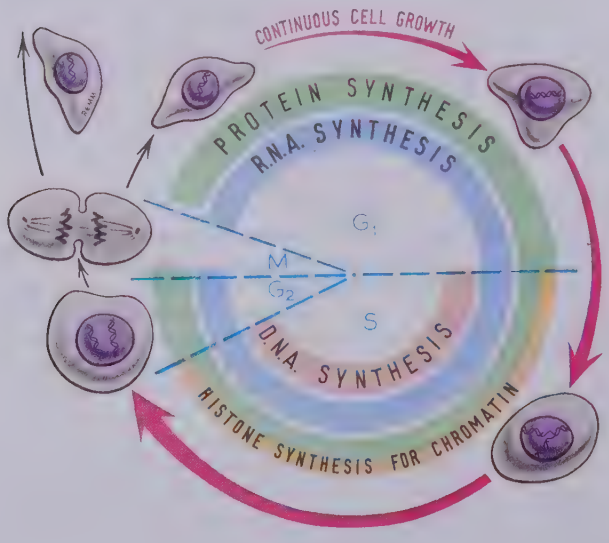
Synthetic activity in a cell is not uniformly continuous: e.g. appreciable protein or DNA synthesis does not occur during mitosis. Likewise in interphase, DNA synthesis is restricted mainly to a short period of the cell cycle, whereas protein synthesis occurs throughout it(Mitchison 1971). Accordingly, interphase can be divided into a G_1 *(first gap)*, *S (synthetic)* and G_2 *(second gap)* stage (1.34). DNA replication occurs in the S phase and manufacture of proteins for mitosis takes place in G_2. The duration of the cycle and its stages varies greatly between cell types. G_1 may last from a few hours to many years or it may be absent, as in the rapidly dividing blastomeres of the early embryo. The S stage usually lasts about seven hours and the G_2 stage up to five hours. Mitosis in human cells is complete in approximately one hour.

Some cells, once formed, do not enter the S phase, being unable to divide and are then said to be in G_0, e.g. neurons.

DNA STRUCTURE

In the Watson–Crick model of DNA structure, now amply confirmed, DNA consists of two parallel molecular chains running in opposite directions as a double helix, 2.5 nm in diameter, repeating every 3.4 nm (see 1.30,33). Each chain is composed of a 'backbone' of pentose sugar (deoxyribose) groups, linked by phosphoric acid bridges in such a way that they confer directionality. Each sugar group bears a nitrogen-carbon ring base, directed sideways towards a corresponding group on the opposite helix, and is linked to it by hydrogen bonds. There are four bases: *adenine* and *guanine* (purines), and cytosine and thymine (pyrimidines). These are dissimilar in shape; the space between the two helices and the type of bonding available dictate that adenine on one side always pairs with thymine on the other, and guanine with cytosine. The rigid complementary nature of this pairing is the basis of the genetic code, written in terms of three-letter 'words', each made up of three bases in a row and corresponding to a single amino acid in the final protein. Multiples of such triplets encode a single polypeptide and such a sequence corresponds to a *structural gene*, or *cistron*, of classic genetics. Some triplets do not code for amino acids but initiate or end the formation of polypeptides, like punctuation in a sentence. Often several functionally related proteins, e.g. an interdependent system of enzymes, are encoded by a series of genes which may be controlled as a unit, a *supergene* or *polycistron*.

ORGANIZATION OF CHROMOSOMAL DNA



In all eukaryotes the DNA of each chromosome forms a single continuous duplex thread (i.e. consisting of one long double helical molecule) before the S phase, when DNA is duplicated and thereafter, or until cell division, two double helices, lying parallel to each other (vide supra). Each nucleus contains a total DNA length of about 170 cm and the longest human chromosomes are each as much as 7 cm if fully extended (Du Praw 1968).

Chromatin

In the nucleus, proteins are bound intimately to the DNA threads, in a 1:1 ratio by mass, to form a molecular *chromatin*. The proteins carry out various vital functions, including regulation of genetic expression and stabilizing the structure of the whole chromosome. The proteins include two major classes, histones and non-histone proteins. Histones carry net positive charges (i.e. they are basic) and form the great majority of nuclear proteins. In structure they vary little in animals and plants, being highly conserved, a fact pointing to a fundamental role in living processes (although they are absent in bacteria). Most of the histones are aggregated in spheroidal particles, each about 10 nm across, strung like beads along the DNA duplex strand, which is coiled around each particle to form a complex, the *nucleosome*, then passes to the next particle. The whole thread is then a *chromonema*. The intervening length of DNA (linker DNA) is considered to be part of the nucleosome complex (Olins et al 1976, Kornberg & Klug 1981). Nucleosome proteins are grouped

1.33 The processes occurring during DNA replication and protein synthesis. The processes of DNA replication (on left) and transcription (middle, right) are indicated; abbreviations are the same as those used in 1.30, with the addition of U = uridine.

1.34 The major events occurring during the cell cycle of a growing and mitotically active cell to show the major stages: G_1 or 'first gap' phase; *S* or 'synthetic' phase; G_2 or 'second gap' phase; *M* or 'mitotic' phase.

eightfold, comprising pairs of four proteins, H2A, H2B, H3 and H4. Another histone, H1, acts as a link between adjacent nucleosomes and is responsible for aggregating these structures in more complex assemblies which e.g. generate the 30 nm diameter coiled form of chromatin. It has also been suggested that the nucleosomes may be able to move along the DNA or to become detached when the DNA is perhaps active in transcription. Non-histone proteins are present in much smaller amounts. They include important regulatory molecules, enzymes for replicating and transcribing and repairing DNA and many others needed for appropriate gene activity. Some of these (e.g. RNA polymerase) can be detected structurally as 5 nm granules attached to DNA threads.

Folding of Chromatin within Chromosomes

Much of the DNA exists in a highly folded state, a condition most extreme in heads of mature spermatozoa (p. 119). The narrowest chromatin threads are 10 nm wide (the diameter of the nucleosomes) but 30 nm threads are also abundant, consisting of spiral clusters of nucleosomes (the '*solenoid*' configuration). Further folding and looping may also occur, depending on functional status; chromatin which is active in transcription (during protein synthesis) is most extended (euchromatin), while inactive chromatin is highly folded (heterochromatin). DNA synthesis during S phase (p. 37) is completed earlier in euchromatin than in heterochromatin. Chromatin is most folded during cell division

(at metaphase) and, in active cells, least folded in interphase. However, some DNA is permanently folded and heterochromatic; this includes DNA which at some phase of early development was active but later becomes inactive (*facultative heterochromatin*, see Brown 1966), e.g. the inactive X chromosome in human females. Other chromosomal regions which appear permanently heterochromatic (*constitutive heterochromatin*) lie at the primary constrictions of some, and perhaps all, chromosomes and in the satellites of acrocentric chromosomes (p. 37) (Hsu & Arrighi 1971) amongst other sites. The significance of this chromatin is not clear although it may have some intrinsic role in maintaining chromosome stability. The coiled structure of chromatin can also vary locally with different sequences of nucleotides which alter the geometry of the duplex. Such regions may have special properties in causing specific types of folding or in promoting (or preventing) attachment of molecules involved in gene regulation.

Analyses of DNA show that a small proportion consists of highly *repetitive sequences of bases* and is therefore separable from the bulk of nuclear DNA by centrifugation; this is *satellite DNA*. Its functions are unknown, but generally constitutive heterochromatin seems to be identical with satellite DNA (Jones 1970). Satellite DNA is thought to be non-coding; it can be detected with special stains in mitotic chromosomes at their centromeric and terminal (telomeric) regions, including satellites (a coincidence in terminology) where these are present (p. 47). Amounts of repetitive DNA vary widely in different, even closely related, species so there is no obvious significance in its presence.

TRANSCRIPTION

In transcription the two helical strands of DNA separate locally to expose a particular cistron on one of them, the coding *strand* (the other being complementary). Upon this template, a single strand of RNA is constructed with the aid of an RNA polymerase and ATP. RNA is similar to DNA in composition but it is single stranded, contains ribose instead of deoxyribose and has the base uracil in place of thymine. The same type of base pairing now takes place so that a chain of RNA is formed alongside the DNA coding strand. The DNA triplets are thus transcribed into complementary triplets or *codons* of RNA. When the complete cistron has been transcribed, the codon-bearing RNA separates and moves to the cytoplasm, being therefore known as *messenger* RNA (mRNA). This eventually attaches to the small subunit of a ribosome which, with other chemical factors, acts as a complex enzyme. Another class of nucleic acid called *transfer* RNA (tRNA) recognizes specific cytoplasmic amino acids and matches them with the triplet codons of the mRNA. There exist a large number of specific tRNA molecules in the cytoplasm, each able to bind at the same time to a single mRNA codon and a corresponding amino acid. Recognition of codons again occurs by complementary base-pairing and the relevant part of the tRNA molecule involved is called the tRNA *anticodon*. Recognition of the specific amino acid is less well understood; it may not involve the amino acid directly but, rather, an intermediary specific enzyme involved in its linkage to the growing polypeptide chain.

Each ribosome moves along the mRNA strand, 'reading' its code, so that a corresponding sequence of amino acids is formed, each linked to the next by a peptide bond; this process is termed *translation*. Many ribosomes may be reading the mRNA strand at a given time, so forming polysome rosettes or helices. When decoding is complete, the ribosome detaches itself and both mRNA and protein are released.

Introns and Exons

During the last few years it has also been shown that the relatively simple mechanism described here has fundamental modifications in most cases so far studied. In the synthesis of many proteins, messenger RNA formed by DNA transcription is altered in the nucleus, being initially quite long (*heterogeneous RNA*, or *hnRNA*), and is later cut by enzymes, present in *small ribonucleoprotein particles* abundant in the nucleus, into shorter lengths, some of which are then spliced together, the others being destroyed. Thus the final sequence of bases in the final mRNA represents only a fraction of the total DNA used in encoding it. DNA sequences which are ultimately translated into proteins are termed *exons* and those portions not expressed are *introns*. This mechanism allows a single length of DNA, consisting, in effect, of overlapping genes, to be used to synthesize more than one type of protein, by bringing together various sequences of triplet codons in their corresponding mRNAs (Darnell 1985). This arrangement is economical and also has the evolutionary potential of generating novel proteins after mutation (a rare event of course).

REGULATION OF GENE EXPRESSION

Since each nucleus contains the whole complement of genetic information for an individual, the expression of this must be subject to complex interlocking control mechanisms for any directed action to occur. These permit only a small fraction of the total to be transcribed at any moment, depending on demands made on the cell and its role in the economy of the total organism.

Jacob & Monod (1961) proposed a twofold mechanism of gene control on the basis of bacterial experiments, involving a hierarchial system of three gene types. In the first type of control, *regulation by induction*, each group of structural genes is closely linked to a controlling *operator gene*, together forming an *operon*. The operator gene is normally repressed by a protein, the *repressor*, produced by a *regulator gene* (not necessarily on the same chromosome) and so prevents RNA polymerase from transcribing the structural genes by binding tightly to a particular gene region, the operator. A metabolite of the cell which induces protein transcription does so by combining with the repressor, which then cannot repress the operator gene, so allowing transcription. Alternatively, a metabolite may inhibit protein synthesis—*regulation by repression*. This second scheme is similar to the first, except that the repressor can only inhibit the operator gene after combining with the inducer substance, which thus prevents transcription by the structural genes.

In higher organisms, gene regulation, although basically similar to that of prokaryotes, has important differences. In multicellular animals the cells of the body, while carrying identical genes, express them in a wide variety of different ways, so that in any cell most genes are inactive and only those few which are relevant to general maintenance and to its specialist functions are expressed. DNA appears to be maintained in the repressed state by its close association with *histones*, the major basic nucleoproteins of chromatin (von Holt 1985, and also p. 37). There are only a few classes of histones and these are very similar in a wide range of animals; they are hence unlikely to be related to any particular pattern of genes, unlike repressor substances in bacteria (vide supra, and p. 108).

Regulation of gene expression in eukaryotes is still not well understood but a number of different mechanisms appear to operate in this process. Genes in eukaryotes can be activated by *non-histone proteins* which interact with specific genes. Many such proteins are known and these vary widely in different cells and species. They probably operate by first disengaging the histones from their close association with a particular gene sequence and then attach to DNA to promote the co-attachment of a molecule of RNA polymerase which proceeds to transcribe the gene or group of genes. Such activities have been studied extensively in the interaction of hormones with specific 'target' cells. Sometimes, as in the action of progesterone (a steroid of low molecular weight) on the uterine epithelium, the hormone enters the cytoplasm and combines with specific receptor proteins; then, in this complexed form, it moves to the nucleus to combine further with an appropriate region of DNA through its associated histones, resulting in its transcription and the formation of proteins for cell growth (King & Mainwaring 1974, O'Malley & Schrader 1976). In other examples a hormone too large in molecular size to traverse the plasma membrane (e.g. adrenocorticotrophic hormone, ACTH) may instead stimulate an enzyme, adenyl cyclase, present in the plasma membrane, to release an intracellular 'second order messenger' which, by a complex train of events, eventually activates the relevant genes as do other hormones (Stein et al 1975). The sensitivity of a target cell to its stimulatory hormone presumably depends on its ability to synthesize appropriate receptor molecules and the relative susceptibility of

its gene sequences to derepression. However, various other factors may affect transcription by DNA, including local chemical modification of its related histones, its degree of coiling and other variations in local geometry. Specific DNA sequences exist which are known to play important roles in the regulation of gene expression, including initiation of RNA transcription (e.g. the sequence of bases: TATA, where T is thymidine and A is adenine), frequency of transcription and enhancement of the rate of this process. The establishment of such patterns of gene regulation in a particular cell and its coordination are poorly understood at present, although this process, *cellular differentiation*, is known to be dependent on many factors both inside and outside the differentiating cell. In the Britten–Davidson model (1969), it is envisaged that small numbers of repetitive nucleotide sequences synthesize 'activator' molecules of some kind, when suitably stimulated, and that these switch on groups of many related genes ('batteries'). Although there is some evidence that repetitive DNA may in certain cases act in this way, this model remains unproved (see Davidson et al 1983, Klug & Cummings 1986).

CELLULAR DIFFERENTIATION

As development of an organism proceeds, its cells pass through a series of changes in gene expression, reflected in alterations of cell structure and behaviour (see also pp. 107–9). Initially, all cells possess rather similar properties but, as embryogenesis gathers momentum, they begin to diversify, first separating into broad categories (e.g. the principal germ layers, etc.) and then into narrower categories (tissue and subtypes of tissues) until finally they mature into the '*end cells*' of their particular lineage (Gurdon 1973). Some cells which are capable of giving rise to others throughout life *(stem cells)* never proceed to the ultimate point of this progression and retain some embryonic characteristics (p. 678) but in all cases there is a *sequential pattern of gene expression* which changes and limits the cell to a particular specialized range of activities. We can detect such changes as alterations in cell structure and biochemical properties, particularly in the types of proteins which are synthesized. At the level of the gene, differentiation of this kind must be based on a change in the pattern of repression and activation of the DNA sequences transcribing the specific proteins of that stage of development; in the lifetime of a particular cell lineage, many such changes will take place (see, e.g. the development of haemal cells, p. 678). It appears that the selection of a pattern of gene activity occurs some while before its expression in protein synthesis. Thus, a cell may be *committed* to a particular line of specialization without manifesting its commitment until later; once 'switched' in this way, cells are not usually able to revert to an earlier stage of development, so that an irreversible repression of some gene sequences must have occurred. *Stem cells* may remain permanently at a level of partial differentiation, although some of their offspring will be committed to full differentiation. In general, as the degree of differentiation progresses, cell division becomes less frequent (e.g. erythroblasts, p. 679), although some structurally specialized cells such as Schwann cells (p. 891) and certain glandular cells, when suitably stimulated, may undergo repeated mitotic divisions.

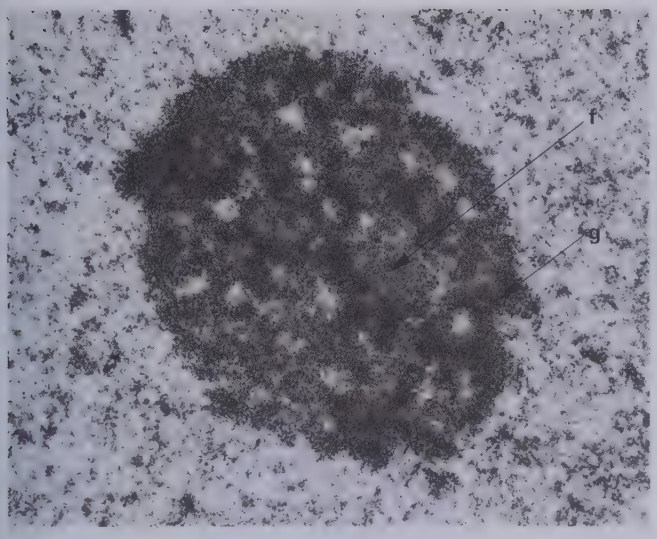
What constitutes the appropriate stimulus for a cell line to differentiate at successive stages in development is one of the most fascinating of biological problems and one which also lies at the heart of many pathological transformations including carcinogenesis. In the embryo, differentiation depends upon a wide variety of circumstances (see pp. 107–9), although in most cases chemical interactions between cells or between different regions of the same cell are thought to be of primary significance. The initiation of a particular pathway of cellular development may, however, also depend upon complex, competitive interactions between cells or upon the position which a cell occupies within a cell group (see discussion on 'positional information' on pp. 110, 111). In addition, differentiation may also depend upon some temporal sequence such as the number of previous cell divisions (pp. 104, 108). Even in mature tissues in which cell turnover occurs, similar mechanisms appear to ensure the final differentiation to a functional end cell. In some cases this is linked to the presence of a physiological stimulus as, e.g. in the case of the 'B' lymphocytes which respond to exposure to an appropriate antigen by differentiating into plasma cells which secrete a neutralizing antibody. In other cases, particularly where a cell is part of a highly organized system, more subtle mechanisms must be present.

REPLICATION

Replication requires the separation of the two intertwined DNA chains (1.33) and the manufacture of complementary chains alongside each of the originals which act as templates for the exact copying of the sequence of bases. Thus, in each of the two resulting double helices, one chain of the original double helix is conserved, so that replication is *semi-conservative* (Taylor 1958). During replication DNA is synthesized by a DNA polymerase from nucleotide precursors, so that if radioactive thymidine, a precursor of the specific DNA base thymine, is added to a cell, it is incorporated into the chromosome and can be detected autoradiographically. Using this method it has been shown that DNA synthesis during the S phase occurs simultaneously along many short stretches of DNA, beginning at a series of *initiation points* where DNA polymerase molecules can attach and then move along the chromonema to synthesize new DNA chains. Synthesis spreads in both directions from the initiation points, forming *replication forks* which can also be visualized by autoradiography (Cairns 1966, Taylor & Hozier 1976), until the whole chromosome is replicated.

Each type of chromosome has its own pattern of DNA synthesis; permanently heterochromatic regions replicate later than the rest and the inactive heterochromatic X chromosome in females replicates later than the other chromosomes (German 1964).

While most of the chromosomal DNA synthesis is confined to the S phase, there is also a constant low level synthesis of DNA for the *repair* of minor chromosomal damage resulting, e.g. from ultraviolet radiation of epidermal cells. Various enzymes are needed for repair, including *endonucleases* which recognize damaged DNA strands and begin to cut them, *exonucleases* which excise damaged regions, a *DNA polymerase* which synthesizes new DNA alongside the unaffected chain and a *ligase* to join the new portion to cut ends of the old. These enzymes can be separated from bacterial cells, and are now widely employed to insert genes isolated from animal or human cells for their further analysis or to make specific proteins (i.e. for genetic engineering). In diseases where DNA repair mechanisms are faulty, the body may be very sensitive to mutagens, e.g. in *xeroderma pigmentosum*, where skin is easily damaged by ultraviolet light.



Limited DNA synthesis also occurs in the first meiotic prophase in gametogenesis (Stern & Hotta 1969) and this may be concerned with exchange of genetic material between homologous chromosomes (p. 44).

It is now known that a single DNA thread lies within a single chromatid. After DNA synthesis the two chromonemata separate into two distinct chromatids so that each cell now possesses the tetraploid amount of DNA (i.e. each *chromosome* contains two DNA strands and there are *two* of each type of chromosome in each somatic cell). At mitotic division (vide infra) the content in each cell is reduced to the diploid amount, to be doubled again in the following interphase.

It is interesting that wide variations of DNA content occur in the cells of different species, even though closely related, suggesting that segments of DNA may be repeated many times. It is possible that in some cases many copies of each gene exist so that, when activated, large-scale transcription can be initiated rapidly, as in the case of the nucleolar genes, of which there are multiple copies. However it appears that much of the repetitive DNA is not active in transcription and its function remains an enigma.

NUCLEOLI

Each nucleus possesses a number of spheroidal nucleoli, dense bodies which take up basic dyes strongly; the human number varies (one or several may occur) and collectively they are considered to consist of five pairs of nucleolar fragments related to

1.35 Electron micrograph of a nucleolus from a highly active cell, showing the pars filamentosa (f) enclosed in the darker pars granulosa (g). Magnification × 25 000.

particular chromosomes (vide infra). Nucleoli vary in size up to about 4 μm in diameter (1.5,6,35). Each is a heterogeneous mass of fine granules and fibrils set in a less dense matrix, the whole agglomeration often containing cavities or channels continuous with the surrounding nucleoplasm, so that with the light microscope it may have the appearance of a folded thread (*nucleolonema*). By electron microscopy, four structural elements can be detected: an inner region of dense filaments (*pars filamentosa*), an outer granular zone (*pars granulosa*), both embedded in an apparently structureless matrix, the *pars amorpha*; while centrally lies a series of somewhat less dense elongate DNA-rich regions, constituting the *pars chromosoma*. These parts can be correlated with the synthetic pathway of ribosomal RNA much of which is transcribed on the nucleolar organizing genes of certain chromosomes, in the pars chromosoma. Newly synthesized ribosomal RNA is exceptionally long, forming the basis of the fibrils in the pars filamentosa, but is later broken into fragments and combined with ribosomal proteins to form ribosome subunits. These accumulate in the pars granulosa, from which point they pass to the cytoplasm through the nuclear pores, eventually assembling into mature ribosomes.

In humans *nucleolar organizing centres* are present on those chromosomes with *secondary constrictions* (acrocentric chromosomes, with satellites; chromosomes numbers 13–15,21,22) and within a single nucleolus several such centres may be active. Each consists of many tandemly repeated DNA sequences which code for ribosomal RNA and which can therefore generate large quantities of this material very rapidly—a necessity if enough ribosomes are to be formed prior to active synthesis of other proteins. In some lower vertebrates there are large numbers of such organizing regions and in their oöcytes hundreds of nucleoli are formed; regions of such chromosomes synthesizing nucleolar RNA form lateral loops giving the whole chromosome a bristly appearance (*lampbrush chromosomes*) and these, under the electron microscope, are seen to be festooned with RNA strands in the process of being transcribed (Mott & Callan 1975).

Cells with a high rate of protein synthesis, and thus a large demand for ribosomes, have large nucleoli, e.g. large neurons with extensive axons and dendrites, active embryonic cells and the cells of malignant neoplasms.

During cell division, when protein synthesis is suspended, the nucleoli disintegrate and their chromosomal portions are drawn back into the main mass of their parent chromosomes; at the end of division nucleoli are rapidly reformed.

OTHER NUCLEAR INCLUSIONS

Other less prominent structures present in all nuclei (Wischnitzer 1973) including *granules*, some of which are associated with chromatin margins (*perichromatin granules*) about 40 nm across, and others lying between the chromatin masses (*interchromatin granules*) about 20 nm across; the significance of these is unknown. *Perichromatin fibres* also occur at the margins of the chromatin. In addition, many other nuclear inclusions have been described as constant features of some cells or occurring occasionally, including fibrillar material, membranous structures and larger granules. Many though not all of these have been shown to be non-pathogenic viruses which abound in the cells of the human body.

In the prophase of the first meiotic division, long, fibrillar *synaptonemal complexes* connect adjacent chromosomes (p. 44). Other structures which have been reported in different types of cell include membranous vesicles and lamellae, bundles of filaments, crystals and further varieties of granule. Some of these may represent symbiotic C viruses, common inhabitants of mammalian nuclei. The nature of the other inclusions is obscure. The nucleoplasm also contains numerous enzymes, nucleotide precursors and proteins, only identifiable by cytochemical or biochemical means; these are, of course, involved in nuclear metabolism.

REPRODUCTION OF CELLS

During prenatal development most cells undergo repeated division as the body grows in size and complexity. As cells mature they differentiate in structure and function and may finally lose the ability to divide, as do neurons, or may persist permanently as stem cells capable of dividing throughout life, as in the haemopoietic tissue of bone marrow.

Rates of cell division vary considerably in different tissues (see e.g. Potten et al 1979, Lewin 1980, Lloyd et al 1982); in many epithelia subject to mechanical stress, the replacement of damaged cells by division of stem cells may be rapid, as in crypts between intestinal villi; it may also vary according to demand, as in healing of wounded skin, where cell proliferation rises to a peak and then returns to the normal replacement level. The rate of cell division is therefore tightly coupled to the demand for growth and replacement; where this coupling is faulty, tissues either fail to grow, or replace their cells, or else they overgrow, giving rise to neoplasms.

The mechanism of normal control is poorly understood (see the reviews by Yanishevsky & Stein 1981, Alberts et al 1983, Brachet 1985). During early embryonic life, control appears to be local, involving the diffusion of metabolites from one cell group to another, so stimulating or inhibiting division of cells. At later stages, endocrine control is also involved. Several hormones affect cell division rates either generally (e.g. somatotrophic hormone) or locally (e.g. progesterone). Some hormones may act on division by affecting general metabolic rates (thyroid hormones) or protein synthesis (some corticosteroids and somatotrophic hormone). At least some of these effects may be mediated by the intracellular release of cyclic adenosine monophosphate (cyclic AMP) which inhibits synthesis of new DNA during the S phase.

In adult tissues, local control of cell division is an important factor in wound healing. A class of compounds termed *chalones*, which inhibit cell division, has been isolated from normal tissue cells. A possible model for their action is that normal cells produce chalones which inhibit division of the cells in their locality; when some cells are damaged or destroyed, the concentration of chalones drops allowing cell division to occur until the normal levels are restored, when division is again inhibited.

The Mechanism of Cell Division

Two distinct events occur in cell division: division of the nucleus (*karyokinesis*) and of the cytoplasm (*cytokinesis*); they are usually, but not always, coupled. For reviews of these processes, consult Prescott (1976), Lewin (1980), Inoué (1981), Zimmerman & Forer (1981), Alberts et al (1983) and Brachet (1985).

Nuclear division can occur in three ways. In the first, termed *amitotic* or *direct division*, nuclear material is distributed at random to the resultant cells. (This process, once thought to be common, is in fact restricted to pathological conditions.) In the other two modes of nuclear division, complex chromosomal manoeuvres take place (*indirect division*, comprising *mitosis* and *meiosis*).

Mitosis (1.36–8) occurs in most somatic cells and results in the distribution of identical copies of the parent cell's genome to the resulting cells. In *meiosis*, occurring in the divisions immediately before final production of gametes, the number of chromosomes is halved to the haploid number, so that at fertilization the diploid number is restored; some exchange of genetic material also occurs between homologous chromosomes, a *reassortment* of genes (see e.g. Klug & Cummings 1983). This leads to further genetic variability in a population, the essence of evolution (see also p. 44).

Mitosis and meiosis are alike in many respects, differing chiefly in chromosomal behaviour during early stages of cell division. In meiosis two divisions occur in quick succession; the first of them is unlike mitosis (*meiosis I, heterotypical* division) but the second more like mitosis (*meiosis II, homotypical* division).

MITOSIS

As already stated, new DNA is synthesized during the S phase of interphase, so that in diploid cells the *amount* of DNA has doubled by the onset of mitosis to the tetraploid value, although the chromosome *number* is still diploid. During mitosis, this amount is halved between the two resulting cells, so that DNA quantity and chromosome number are now diploid in both. The nuclear changes which achieve this distribution can be divided into four phases: prophase, metaphase, anaphase and telophase (1.36,37).

Prophase

The strands of chromatin, highly extended during interphase, begin to shorten, thicken and resolve themselves into recognizable chromosomes, each made up of two chromatids joined at the centromere. Outside the nucleus centrioles begin to separate, moving to opposite poles of the cell; parallel microtubules are synthesized between them to create the *central spindle* and others radiate to form the *astral rays*, collectively termed asters. The spindle and two asters together constitute the *achromatic figure* or *diaster* (amphiaster).

As prophase proceeds, the nucleoli disappear and finally the nuclear envelope suddenly disintegrates into small vesicles to release the chromosomes. This event marks the end of prophase.

Metaphase

As the nuclear envelope disappears, the spindle microtubules invade the central region of the cell and the chromosomes move towards the equator of the spindle (*prometaphase*). Once they have arrived at this imaginary plane (the *metaphase* or *equatorial plate*), the chromosomes attach by their centromeres to spindle microtubules and are so arranged in a star-like ring when viewed from either pole of the cell.

Anaphase

The centromere in metaphase is a double structure; its halves now separate both carrying an attached chromatid, so that the original chromosome has, in effect, split lengthwise into two new chromosomes. These move apart, one towards each pole. It is not yet known how this is achieved, but spindle microtubules are necessary for movement to occur. The two halves of each centromere may become attached to separate categories of microtubules (McIntosh et al 1979) which would then move towards their respective poles, possibly by sliding interaction with other stationary microtubules, pulling the chromosomes. Alternatively the progressive disintegration and reassembly of microtubules might generate similar movements by addition of tubulin at the equator and removal at the poles (Inoué & Sato 1967).

Telophase

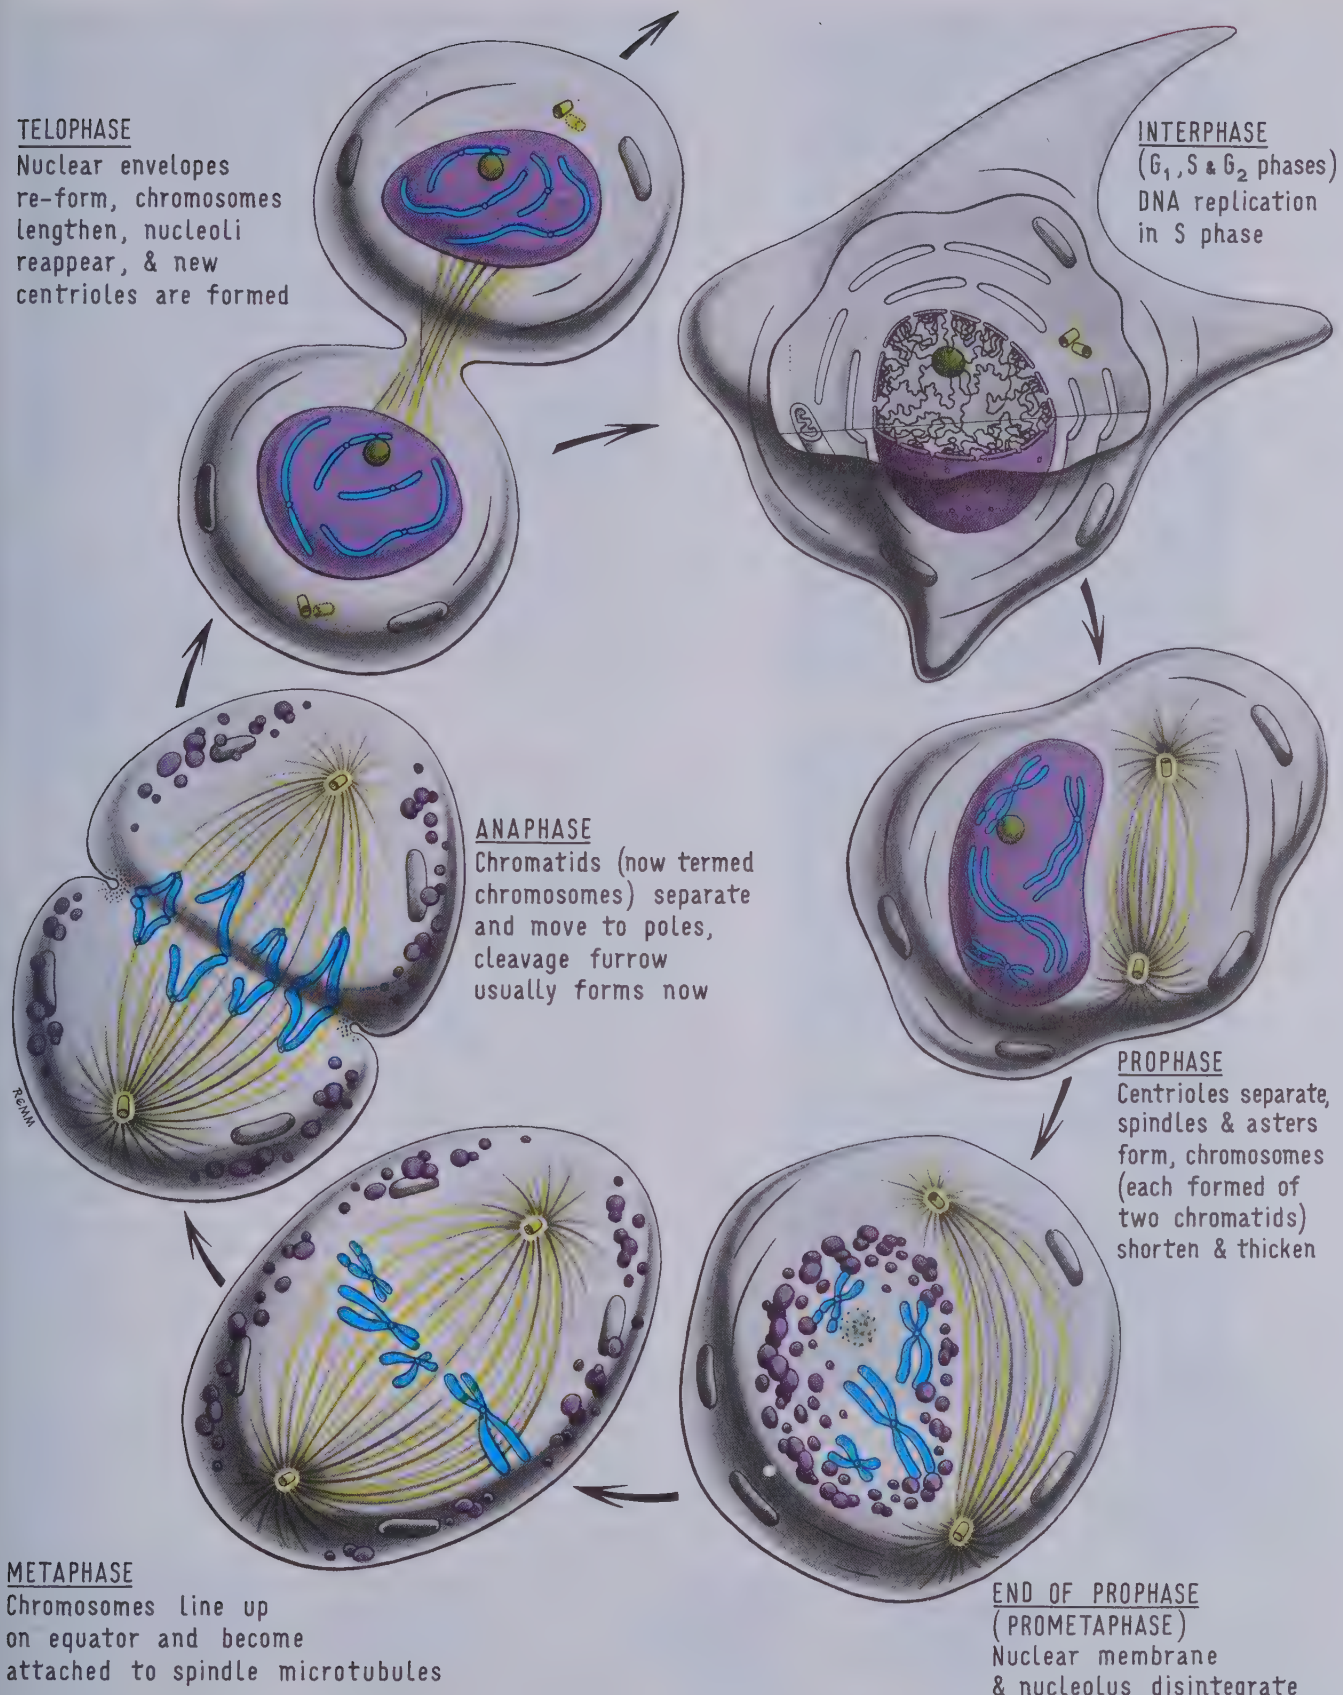
At the end of anaphase the chromosomes are grouped at each end of the cell, both aggregations being diploid in number. The chromosomes now re-extend and the nuclear envelope reappears, beginning as membranous vesicles at the ends of the chromosomes. Nucleoli also reappear.

Meanwhile, cytoplasmic division, which usually begins in early anaphase, is progressing. This process is accompanied at late metaphase by cytoplasmic movements involving the equal distribution of mitochondria and other organelles around the cell periphery. In anaphase an infolding of the cell equator begins and deepens as the *cleavage furrow* (Schroeder 1973). Small vacuoles form in the cytoplasm along the plane of cleavage and eventually the furrow divides the cell into two. Where the constriction meets the remains of the spindle, a dense region of cytoplasm, the *mid-body*, is visible but eventually the new cells separate, each with its derived nucleus. The spindle remnant now disintegrates. While the cleavage furrow is active, a peripheral band of actin and myosin appears in the constricting zone and the contraction of this is probably responsible for furrow formation. During telophase the filaments of the cleavage furrow contract down on the remaining spindle microtubules to form the dense mid-body which finally disappears.

Failure of *disjunction* and *'lagging'* of chromatids may sometimes occur, so that paired chromatids pass to the same pole. Of the two new cells, one will have more and the other less chromosomes than the diploid number. Exposure to ionizing radiation promotes such events and may, by chromosomal damage, inhibit mitosis altogether. A typical symptom of *radiation sickness* is the failure of epithelia to replace lost cells, with consequent ulceration of the skin and mucous membranes.

Mitosis can also be disrupted by several chemical agents, particularly colchicine and its derivatives colcemide, podophyllin and podophyllotoxin, and by viniblastine. These compounds inhibit or reverse spindle microtubule formation, so that mitosis is arrested in metaphase. This is useful in cytogenetic studies, since chromosomes are most easily examined in the metaphase condition, and also forms the rationale for attacking multiplying tumour cells with many types of cytotoxic drugs.

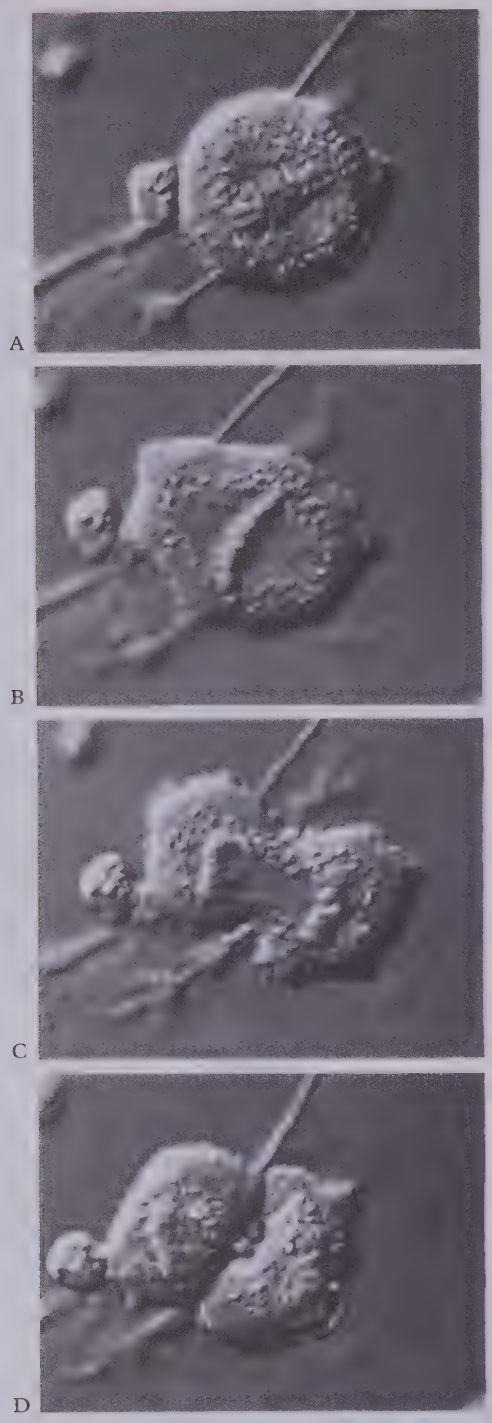
MEIOSIS



During meiosis (1.39–42) there are two cell divisions; in the interphase prior to the first division DNA is replicated in the usual manner, resulting in the tetraploid amount of DNA, the chromosomal number being diploid. During *meiosis I* the DNA is reduced to the diploid *amount* in each resultant cell, although the chromosome *number* is halved to the haploid value; in *meiosis II*, the DNA in each new cell formed is reduced to the haploid amount, the chromosome number remaining haploid.

Prophase I

This long and complex phase differs considerably from mitotic prophase and is customarily divided into five substages: the leptotene, zygotene, pachytene and diplotene stages and diakinesis (for details see Comings & Okada 1972, Whitehouse 1973, Moens 1974, Brachet 1985).



Leptotene stage. Chromosomes appear as individual threads attached at one end to the nuclear envelope and show characteristic beads (*chromomeres*) throughout their length.

Zygotene stage. Chromosomes have come together side by side in homologous pairs (a process which may already have occurred as early as telophase of the previous mitotic division). The homologous chromosomes pair point for point progressively,

1.36 The main stages of the mitotic cycle of a somatic cell.

beginning at the attachment point to the nuclear envelope (Moens 1974), so that corresponding regions lie in contact. This process is *synapsis*, *conjugation* or *pairing*. Each pair is now a *bivalent*. In the case of the unequal X and Y sex chromosomes, which during zygotene and pachytene are sequestered in a secluded zone of the nucleus, the *sex vesicle* (Solari & Tres 1967), only limited *pairing segments* are homologous and these pair end to end (1.40); the remaining parts are *differential segments*. By electron microscopy,

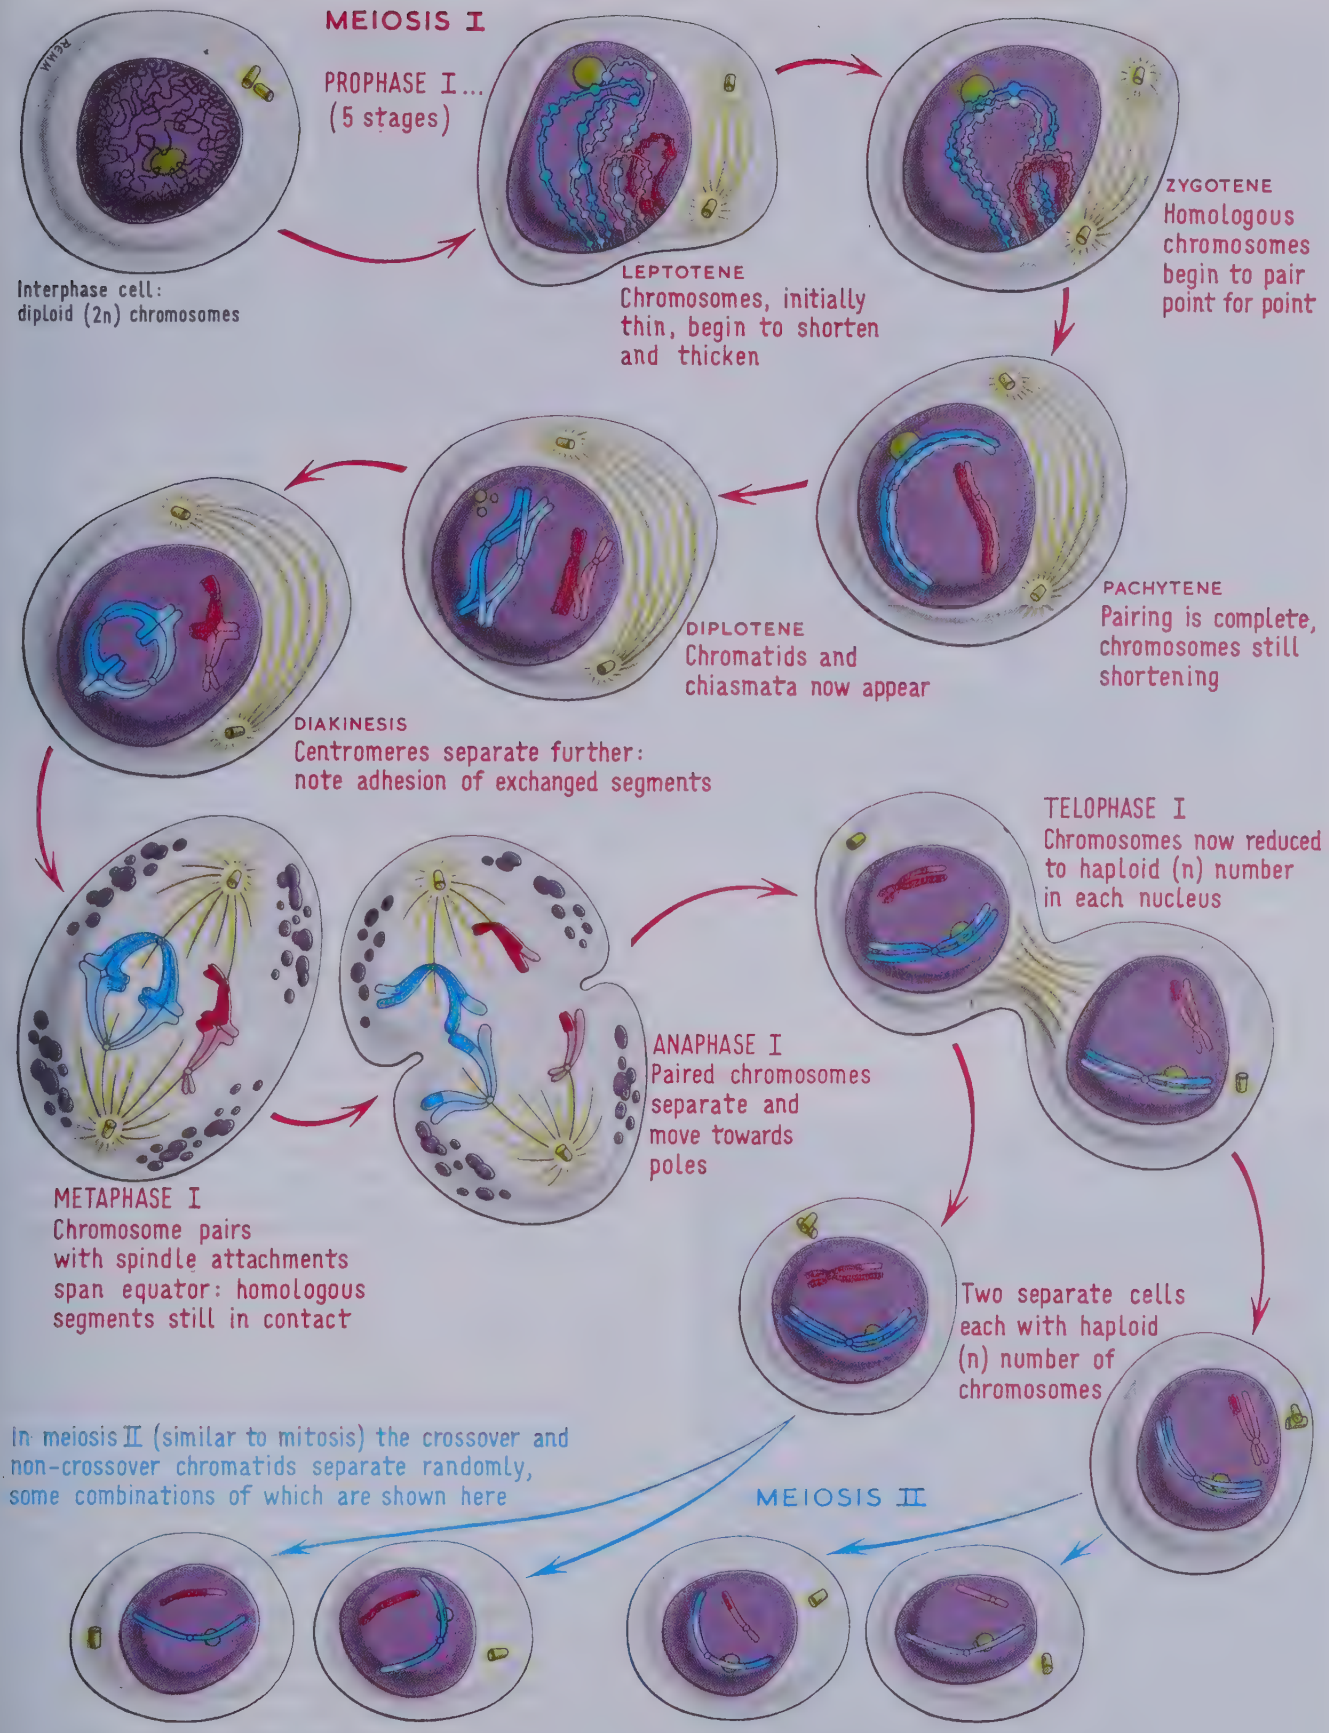
homologous chromosomes appear held together by a highly structured fibrillar band, the *synaptonemal complex* (1.42), which occupies the space (about 100 nm wide) between them (von Wettstein et al 1984, see also p. 44).

Pachytene stage. Spiralized shortening and thickening of each chromosome progresses and its two chromatids, joined at the centromere, become visible. Each bivalent pair therefore consists of four chromatids, forming a *tetrad*. Two chromatids, one from each bivalent chromosome, partially coil round each other, and during this stage it is probable that exchange of DNA (*crossing over* or *decussation*) occurs by breaking and rejoining, perhaps facilitated by the synaptonemal complex. Within the latter structure, regions of DNA exchange are marked by the presence of dense proteinaceous masses about 90 nm in diameter (*recombination nodules*) in which the processes of cutting and rejoining the adjacent DNA strands may occur.

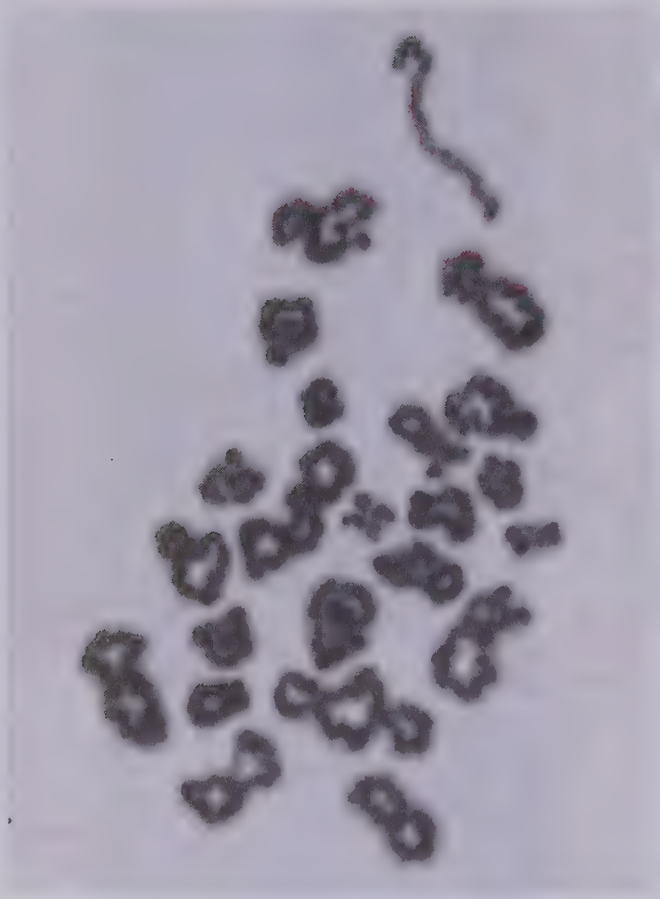
Diplotene stage. Homologous pairs, now much shortened, separate except where crossing over has occurred (*chiasmata*). Sometimes chiasmata appear to move towards the ends of the chromatids (*terminalization*); at least one chiasma forms between each homologous pair and up to five have been observed (even up to 10 in some species). In human ovaries, primary oöcytes become diplotene by the fifth month in utero and each remains in this stage until the period prior to ovulation (some for decades, and even up to 50 years).

Diakinesis. Remaining chiasmata finally resolve and the chromosomes, still as bivalents, become even shorter and thicker; they disperse, as bivalents, to lie against the nuclear envelope.



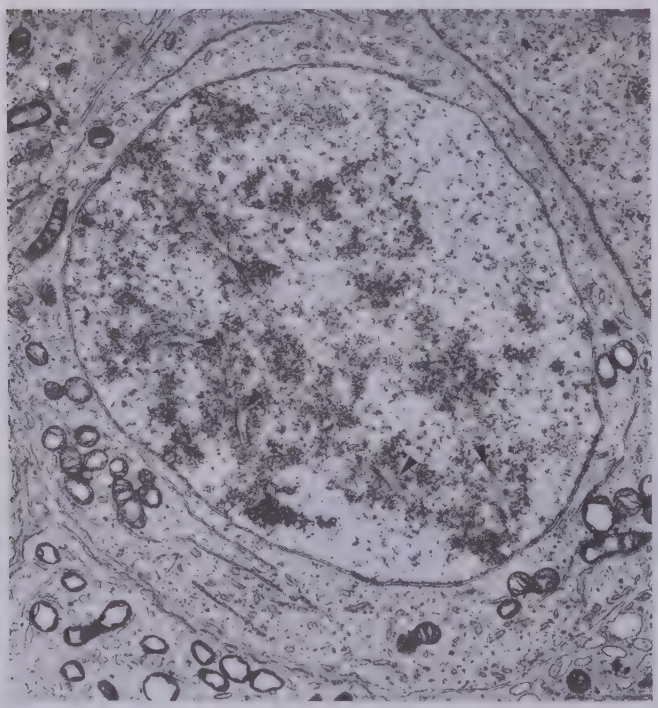
During prophase the nucleoli have disappeared and the spindle and asters have formed as in mitosis. At the end of prophase the nuclear envelope disappears and bivalent chromosomes move towards the equatorial plate (*prometaphase*).

Decussation. Exchange of genes between homologous chromosomes involves extraordinary precision whereby the DNA, at exactly corresponding positions on both, is severed and rejoined to the DNA of its corresponding partner. How this is achieved is not certain, although it has been proposed that the DNA double chains of the two exchanging chromatid segments are exchanged one at a time, perhaps with some remodelling of redundant DNA chains by partial dissolution and resynthesis in the correct position (Holliday 1964, Whitehouse & Hastings 1965). Such exchanges may occur during late zygotene and early pachytene (Whitehouse 1973), when there is some DNA synthesis; it is likely that the synaptonemal complex is an important mediator of genetic exchange.

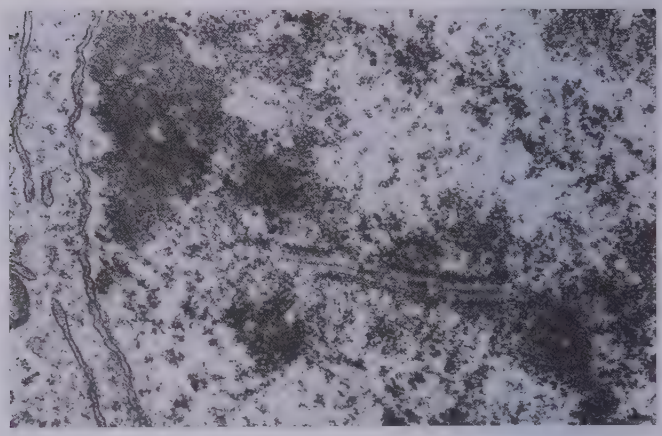


Once segments of chromatid are exchanged and the chromosomes begin to separate, regions where crossing over has taken place become visible as *chiasmata*; these therefore represent a *past event* and chiasma formation is *not* synonymous with genetic recombination. After diakinesis the paired chromatids of a given chromosome adhere to each other more strongly than those of homologous chromosomes, even when exchange has occurred, producing the curious configurations which chromosomes adopt in metaphase of meiosis I (1.39).

Metaphase I



This resembles mitotic metaphase except that the bodies attaching to the spindle microtubules are bivalents, not single chromosomes. These become arranged so that the homologous pairs lie parallel to the equatorial plate with one member on either side.



1.39 Chief stages in the meiotic cycle (male). For clarity only four chromosomes out of the total 46 are shown. Please note that the detailed movements of chromosomes during different stages of Meiosis II are not shown in this figure.

1.42 Detail of a synaptonemal complex in a cell similar to that shown in 1.41. Note the masses of heterochromatin and the fibrillar core of the synaptonemal complex. Magnification × 20 000.

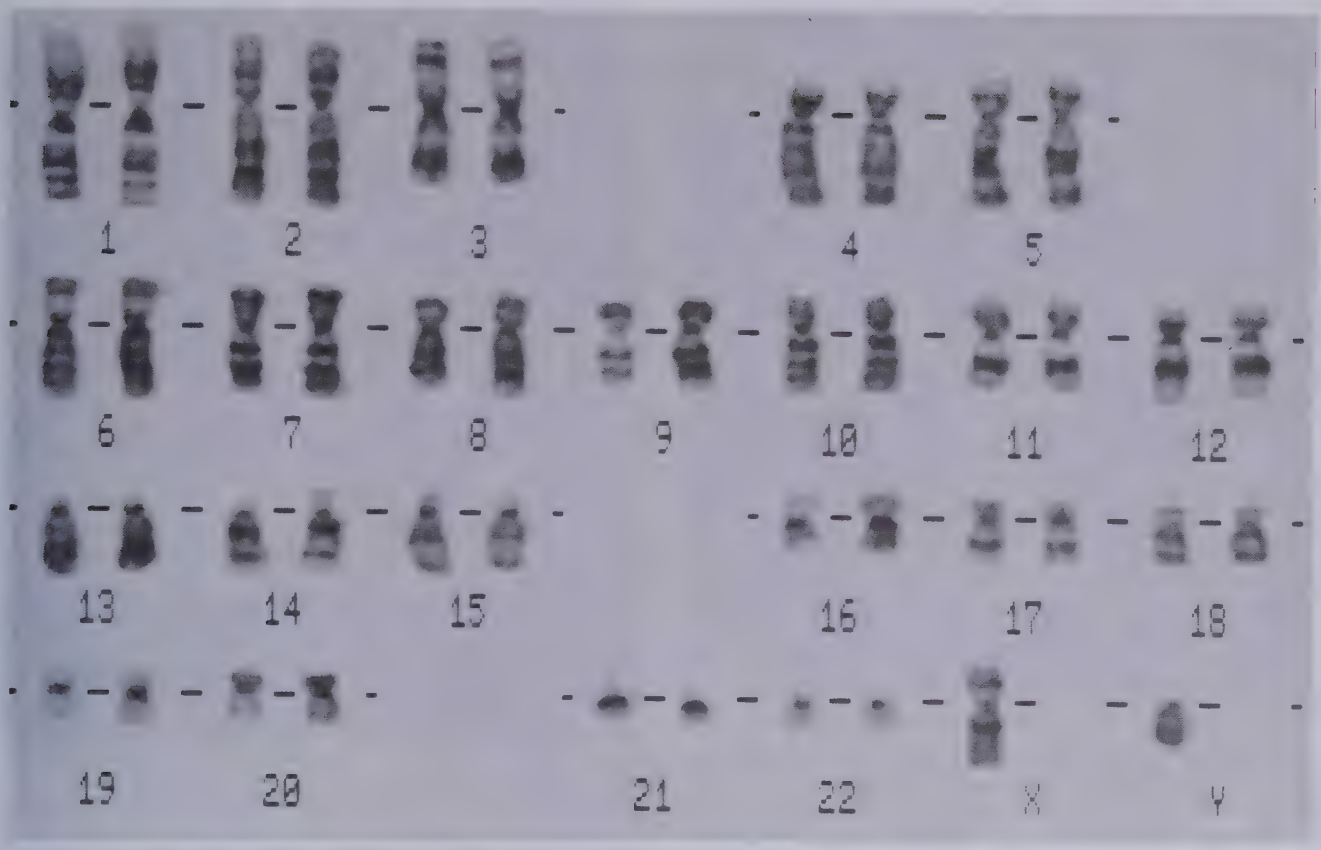
Anaphase and Telophase I

These also occur as in mitosis, except that in anaphase the centromeres do not split; thus, instead of the paired chromatids separating to move towards the poles, whole homologous chromosomes made up of two joined chromatids depart to opposite poles. Since positioning of bivalent pairs is random, assortment of maternal and paternal chromosomes in each telophase nucleus is also random.

During meiosis I, cytoplasmic division occurs as in mitosis to produce two new cells.

Meiosis II

This commences after only a short interval during which no DNA synthesis occurs. This second division is more like mitosis, with separation of chromatids during anaphase; but in contrast to mitosis, the separating chromatids are genetically dissimilar. Cytoplasmic division also occurs and thus *four* cells result from meiosis I and II.



If cytoplasmic division fails during meiosis I, gametes with the diploid number of chromosomes result and thus give, at fertilization, a triploid zygote.

Other abnormalities, some of them viable, are produced by *non-disjunction* of chromosomes, or by the *lagging* of individual chromosomes, during anaphase. These will be discussed later (p. 48). There is much evidence that, as maternal age increases, so does the frequency of such abnormalities.

CLASSIFICATION OF HUMAN CHROMOSOMES

Since a number of genetic abnormalities can be directly related to the chromosomal pattern, the characterization or *karyotyping* of chromosomes is of considerable diagnostic importance. Their identifying features are most easily seen during metaphase, although recently prophase chromosomes have also been used for more detailed analysis (vide infra).

As a source of chromosomes, lymphocytes can be separated from blood samples or cells taken from other sources. For diagnosis of fetal chromosome patterns, samples of amniotic fluid, containing fetal cells, can be aspirated from the uterus (amniocentesis) or, as is now often preferred, a small piece of a chorionic villus (p. 145) removed from the placenta. Whatever their origin, the cells are cultured in vitro and stimulated to divide by treatment with phytohaemagglutinin or other chemicals. Mitosis is later interrupted at metaphase with spindle inhibitors (see p. 42) and chromosomes dispersed by swelling the cells in hypotonic solutions followed by air drying, or squashing, to rupture the cells and flatten the chromosomes. These can then be stained to allow the identification of individual chromosomes by their

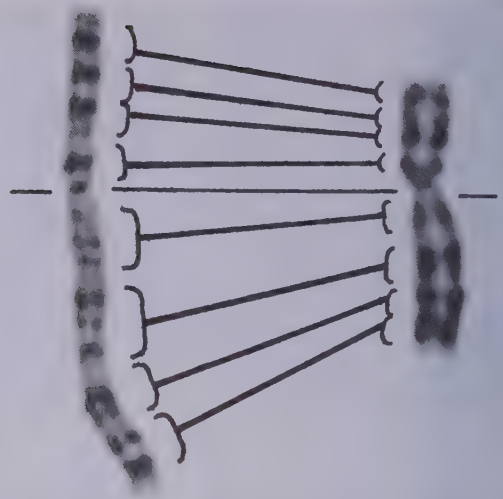
1.43A Human karyotype, stained with the Giemsa banding method. This micrograph was prepared with the assistance of computer analysis to assemble and enhance the appearance of the chromosomal banding. Provided by the Paediatric Research Unit, Guy's Hospital Medical School. Magnification × 2500.

size, shape and distribution of stain. When large numbers of cells have to be examined for clinical purposes, automatic scanning light microscopy with computer control and analysis can greatly facilitate the identification of chromosomes and any abnormalities (1.43–45). Methods include: *general techniques* to show the obvious landmarks, e.g. length of arms, position of primary and secondary constrictions; and *banding techniques* to demonstrate differential staining patterns, characteristic for each chromosome type. Since the introduction of the first banding methods (Caspersson et al 1968), several others have been developed, such as fluorescence staining with quinacrine mustard and related compounds (Q bands) (1.46), Giemsa staining after treatment with alkali (G bands), 'reverse-Giemsa' staining in which the light and dark areas are reversed (R bands) and the staining of constitutive heterochromatin with silver salts (C-banding); T-banding methods stain the ends (telomeres) of chromosomes and other techniques can be used to demonstrate nucleolar organizing centres. In *high resolution banding*, chromosomes arrested in prophase are used, even greater detail being discernible in these more elongated forms (Yunis et al 1978).

By such methods, chromosomes can be classified by length, positions of primary and secondary constrictions, presence of satellites, number and positions of the transverse bands and the distribution of constitutive heterochromatin. A system of numbering autosomal pairs of chromosomes in order of decreasing size, from 1 to 22, has been adopted according to the conventions agreed in London (1960) and Chicago (1964). Before the introduction of banding, some chromosomes were difficult to distinguish and thus were grouped together in seven categories (A–G) according to size and detailed shape and updated more recently (ISCN 1985). However, the later methods allow unambiguous identification and a classification agreed first in Paris (1972) is now generally accepted. A summary of the major classes of chromosomes is given in the table below.

Major Categories of Human Chromosomes

Group 1 – 3 (A) Large metacentric chromosomes
4 – 5 (B) Large submetacentric chromosomes
6 – 12 + X (C) Metacentrics of medium size
13 – 15 (D) Medium-sized acrocentrics with satellites (and nucleolar organizing centres)
16 – 18 (E) Shorter metacentrics (No. 16) or submetacentrics (Nos. 17 and 18)
19 – 20 (F) Shortest metacentrics
21 - 22 + Y (G) Short acrocentrics, 21 and 22 with satellites (and nucleolar organizing centres), Y without satellites.



These advances have also much improved the recognition of *abnormal chromosome patterns*, since the origins of extra chromosomes, or the fragments, can often be identified. Another means of identification exploits variations in the *time* of DNA synthesis during the S phase in different chromosomes, which is shown by pulse-labelling the replicating chromosomes with ^{3}H-thymidine at specific times during the S phase, followed by autoradiography of chromosomes during the ensuing metaphase (Gianelli 1970). They can also be pulse-labelled with an analogue of thymidine, bromo-deoxyuridine (BrDU), which stains differently from normal DNA (Pain et al 1976). For example, the inactive X chromosome replicates particularly late (p. 48) and extra X chromosomes can easily be detected by such techniques.

SEX CHROMATIN

The interphase nuclei of female mammals differ from those of males in that a heterochromatic body is usually present on the

1.43B Human (male) metaphase spread stained with the C-banding method to show constitutive heterochromatin (dark spots) mainly centromeric in position. The arrow indicates the Y chromosome in which heterochromatin is situated terminally in the long arm. Provided by the Paediatric Research Unit, Guy's Hospital Medical School. Magnification × 1300.

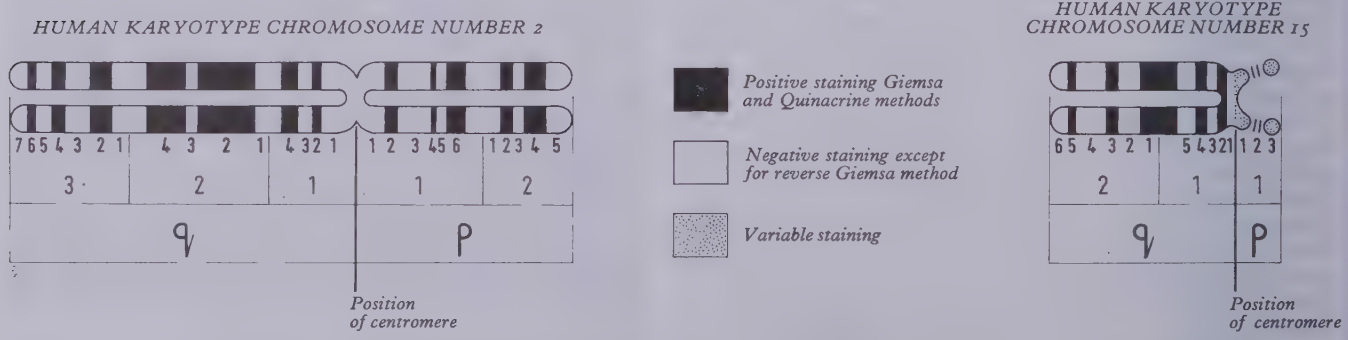
inner face of the nuclear envelope in females (1.47). This structure, the *sex chromatin* or *Barr body* (Barr & Bertram 1949), may protrude from the surface of polymorphic nuclei (as a 'drumstick'). It is now regarded as one of the X chromosomes which is synthetically inert and thus heterochromatic, its euchromatic partner carrying out all necessary functions in RNA synthesis (Lyon 1962). The inert X chromosome also replicates later during interphase than its homologue.



CHROMOSOME ABNORMALITIES

As already stated, aberrations in mitotic and meiotic cell divisions cause chromosomal abnormalities. Extreme examples such as formation of more than the doublet (diploid) set of chromosomes to form *polyploid genomes* (triploid, tetraploid, octoploid, etc.) occur in some organisms, but are lethal in higher forms.

Failure of equal segregation of chromosomes in anaphase can result in more or less than the normal compliment. If this takes place in gametogenesis, the resulting offspring will also possess an altered number of either autosomes or sex chromosomes.

Where, instead of a pair, three homologous chromosomes are present (*trisomy*), the additional chromosome can be readily identified as may unpaired chromosomes (*monosomy*). Trisomy of chromosome 21 (one of the smallest in the set) is found in Down's Syndrome ('mongolism'), giving a total of 47 chromosomes in the karyotype. However, the same syndrome is also found in individuals with 46 chromosomes, as a result of *translocation*, in which a segment of the extra chromosome 21 is attached to another chromosome (usually number 18). Other abnormalities of chromosome structure include *fragile sites*, seen as gaps in the staining patterns of some chromosomes. Many such examples have been described but, although inherited, they do not appear to result in any defect in their carriers. However, when X chromosomes are affected, mental retardation and various skeletal or other abnormalities may occur (*fragile X Syndrome* or *Martin-Bell Syndrome*; see Sutherland 1984, Pembrey et al 1986).

Anomalies of the sex chromosome complement are also well known. In the trisomy of Klinefelter's syndrome the cell contains an additional X chromosome (44 autosomes + XXY); these cases are male in character (phenotypically male) but the testes remain small and spermatogenesis fails to occur. On the other hand, in Turner's syndrome there is only a single X chromosome (44 autosomes + XO); the subject is feminine but the ovaries are rudimentary and, although the embryonic ovary may appear normal with plentiful oögonia, oögenesis is not completed. Higher

multiples (e.g. 44 autosomes + XXXXY) have also been described.

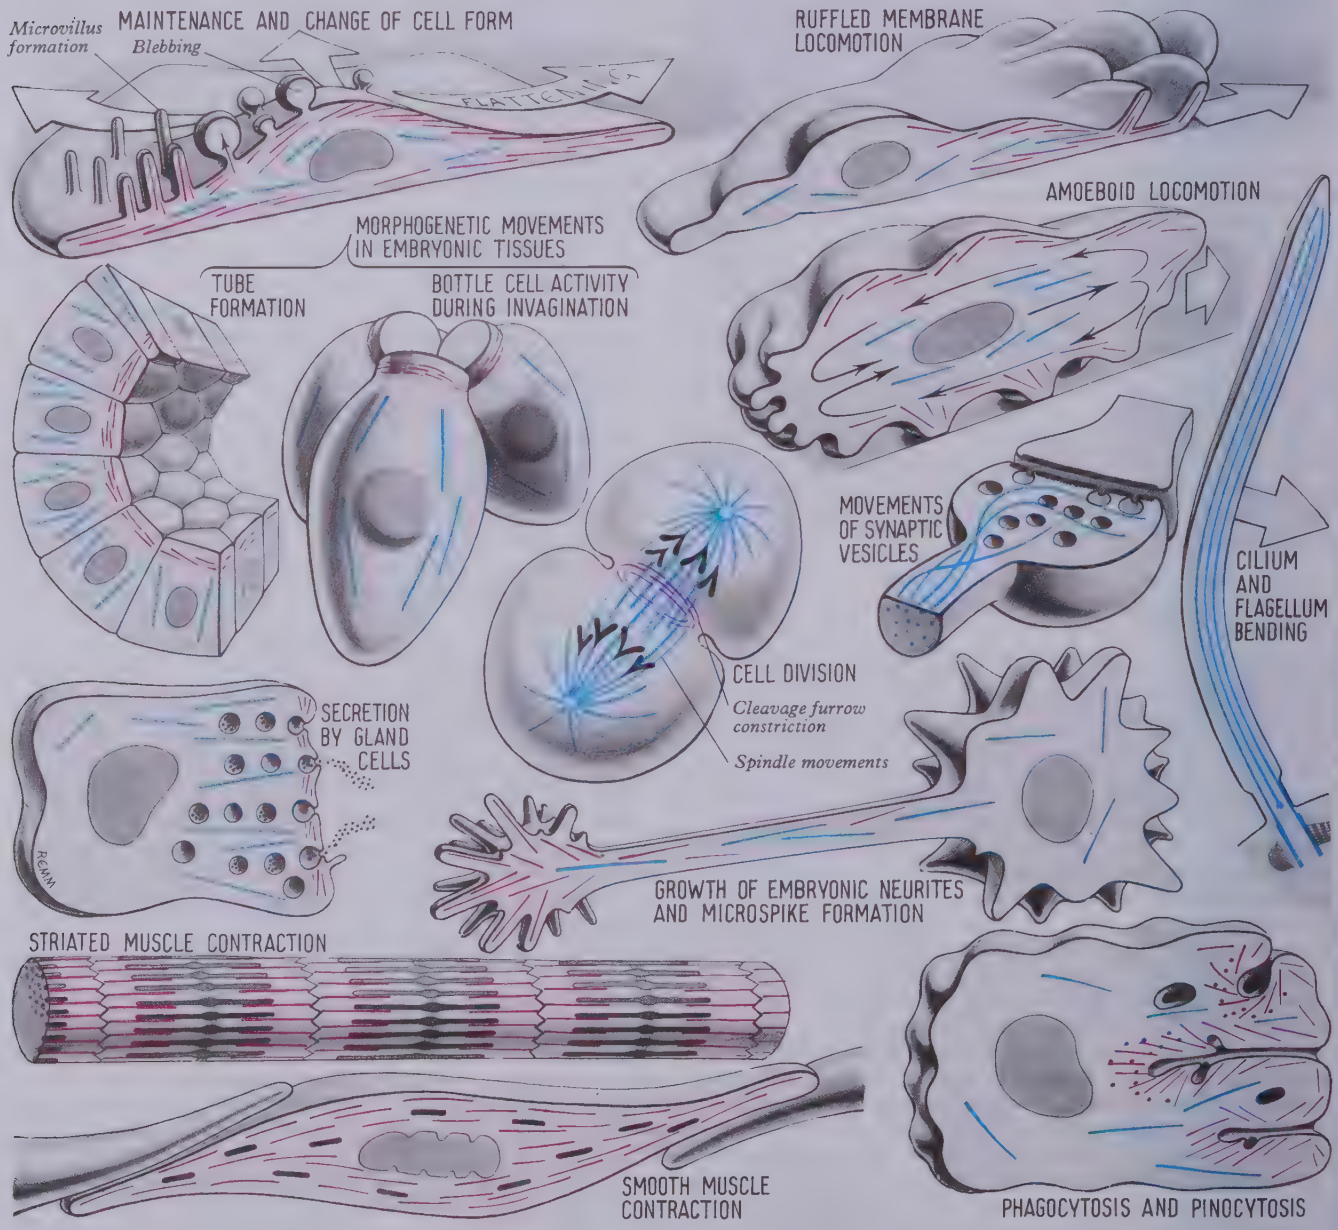
Human chromosomal abnormalities and triploidy are quite common (about 0.6% of all conceptions) and sometimes are compatible with survival to birth. However, many such abnormalities are lethal in embryonic life, accounting for their rarity among survivors at birth; 20–30% of spontaneously aborted individuals are chromosomally abnormal.

Cell Motility

All cells, except perhaps erythrocytes, exhibit some form of motility ranging from the minute streaming of cytoplasm, characteristic of all nucleated cells, to the powerful contractions of muscle cells. The types of motility vary widely; in most tissues there are constant modulations of cell shape and detailed surface topography, including rounding prior to mitosis, flattening or elongation, e.g. in developing neuroblasts of the neural tube, and the formation of microvilli and pseudopodia at the cell surface (1.48). Such changes in shape are prominent in embryonic development and in the repair of damaged tissues; many morphogenetic movements of cell layers also result from such motility (p. 110), e.g. the rolling up of the neural tube, brought about by transformation of columnar cells of the neural plate into wedge-shaped elements or the formation of depressions by apical contraction of 'bottle cells' (1.48). Changes of shape caused by cytoplasmic movement occur in the locomotion of many cells. In amoeboid movement, typical of neutrophil and some other migratory cells, the central cytoplasm streams into pseudopodia at the advancing edge and is withdrawn at the rear. In other cells, e.g. macrophages, the leading edge shows delicate undulations, creating a much folded, thin *ruffled membrane* or, as in the growth cones of the neurites of nerve cells, long narrow *microspikes*, which are constantly formed and resorbed as the cone advances. Some cells carry motile cilia and flagella which generate fluid movements at their surfaces, either to move mucus on the surface (e.g. of the respiratory tract) or to move the entire cell, in spermatozoa. Muscle cells and myoepithelial cells are extreme examples of motility, although their activities have much in common with those of less specialized cells (see Bretscher 1987).

Cytoplasmic streaming within cells moves metabolites and organelles much more rapidly than simple diffusion. Such streaming is often restricted to certain specific pathways, so that there is a rapid and directed flow of highly fluid cytoplasm through a landscape of relatively immobile organelles. Cytoplasmic streaming is well developed in extensive cells such as neurons, where metabolites may be conveyed for distances of a metre or more to the extremities of axons and dendrites, some materials then retracing the route back to the cell soma. Speeds of up to 25 mm/day have been recorded for the centrifugal *axoplasmic flow* in peripheral nerves.

Other internal movements include: passage of secretory vacuoles to the surface of glandular cells, with subsequent release of the secretory product; intake of materials at the cell surface (endocytosis, phagocytosis, and pinocytosis; see p. 29) and their movement into the cytoplasm; and the movements of chromosomes during mitosis and meiosis.



The mechanisms of many of these appear to be fundamentally similar, depending on the presence of actin, myosin and, depending on location, various other types of molecule, e.g. tropomyosin, tubulin. Motility has been investigated most thoroughly in the highly organized cytoplasm of striated muscle fibres whose orderliness has facilitated structural, biochemical and biophysical analyses (p. 556). Muscle contraction involves the energy-dependent sliding interaction of filaments of actin and myosin, and these two proteins are also present in a less organized form in nearly all other cells, including myoepitheliocytes, endothelial cells, fibroblasts, macrophages, platelets, etc. Actin is present in its polymerized form (*f-actin*) as microfilaments which are thought to exist in more than one state, some relatively stable but others highly labile, being assembled or dispersed in a few seconds (Wessels et al 1971). F-actin is in equilibrium with an intracellular pool of actin monomer (g-actin); agents which disturb this equilibrium either cause the formation, or the dismantling, of at least some classes of microfilament. Cell membranes often form sites of attachment for microfilaments by way of other proteins (see p. 30). Myosin, more difficult to demonstrate

structurally, is probably present as small molecular groups of two or more in most cells; it is only in specialized contractile cells that larger assemblies are permanently present. In fibroblasts, small aggregates of myosin may form sliding cross-links between adjacent microfilaments, thus generating forces which cause the network of microfilaments to extend or contract. If the actin filaments were attached to the plasma membrane, such movements would affect the whole cell, flattening or rounding it according to the direction of sliding. Localized extensions of the actin network could form microvilli or, if directed by the presence of aligned bundles of microtubules or intermediate filaments to which actin may also be attached, could produce some types of locomotion. Contraction of bundles of actin filaments by sliding interaction with myosin probably also causes cytoplasmic cleavage during cell division (p. 42).

Certain very transient structures, including microspikes and ruffled membranes, are created by rapid conversion of g-actin into a network of filaments, then stabilized by interaction with myosin into finger-like processes or ridges. Such structures can be easily dismantled by depolymerization, their presence or absence depending upon local fluxes of certain ions or cell metabolites. Actin-myosin interactions also probably accompany some types of endocytosis, such as pinocytosis and phagocytosis, where major cell surface movements occur. Cytochalasins, which depolymerize some though probably not all actin filaments, severely impair many cell movements so that, e.g. multinucleate cells are formed because the cleavage furrow fails to separate cells during mitosis.

A number of regulatory proteins accompany actin and myosin both in muscle and non-muscle cells, including tropomyosin, troponin and α-actinin; these can be demonstrated clearly, often in strikingly beautiful networks, by immunofluorescent labelling with antibodies evoked specifically against these proteins (see e.g. Lazarides 1976).

Another major protein associated with movement is tubulin, which polymerizes to form microtubules (p. 29). As the major component of mitotic spindles, these are vital for the anaphase movements of chromosomes during cell divisions. They are also involved in the movement of neurotransmitter vesicles in synaptic endings, in axoplasmic flow, in movements of cilia, flagella and in secretion by some glandular cells. Some microtubules can be disassembled by colchicine and other drugs which bind to the

1.48 Diagram summarizing some major examples of cell motility associated with actin filaments (red) and microtubules (blue).

cytoplasmic pool of dimers and thus shift the equilibrium away from the polymeric form. Under these conditions motility is often affected (see e.g. Dustin 1980, Roberts & Hyams 1979). In cilia and flagella motility is achieved by the sliding interaction between adjacent microtubule pairs through the mediation of another protein, dynein (p. 32), which causes bending movements. In other sites it is probable that vesicles and other organelles or colloids may be able to slide along the outside of microtubules by means of interacting, temporary protein links by substances such as the protein *kinesin*, recently shown to be involved in vesicle movements along microtubule arrays. to produce directed movements and perhaps some types of cytoplasmic streaming (1.48). Other types of movement may involve growth by the extension of the ends of axonal microtubules as tubulin is added at that point and also possibly the progressive assembly and disassembly of microtubules as in 'treadmilling'.

Finally, there are a number of other movements which probably operate by different mechanisms. These include the transport of various transport vesicles within the cytoplasm vesicles and the formation of 'coated' endocytotic vesicles (see p. 29).

The patterns of control of cell movements are also of great significance, particularly in the study of morphogenesis, teratogenesis and various pathological states in the adult. Ionic fluxes, perhaps associated in some cases with the release of such metabolites as cyclic adenosine monophosphate (cyclic AMP) and other 'second messengers' (p. 18) within the cell, are associated with many types of motile control, often involving the phosphorylation of 'motile' proteins.

THE TISSUES

EPITHELIUM

The term *epithelium* is applied to the layer or layers of cells covering body surfaces. Strangely, this term originally referred to the cellular covering of the nipple (*thelos*) but has been extended to include the cellular linings of all cavities as well as the exterior of the body. Embryologically, epithelia are derived from all three major cell layers; those lining or continuous with external surfaces (the integument, alimentary tract and the distal parts of the urogenital tracts) arise from ectoderm and endoderm. Those lining internal cavities and the proximal parts of the urogenital tract stem from mesoderm and are variously known as *mesothelia* (lining the pericardial, pleural and peritoneal cavities), *endothelia* (lining vascular channels) and *epithelia* in urogenital passages.

Most glands are epithelial, since they arise as diverticula of the body surfaces. The largest is the liver.

Epithelia function generally as selective barriers, aiding or preventing materials traversing the surfaces which they cover; some also protect underlying tissues against dehydration, chemical and mechanical damage; some elaborate and secrete materials into the spaces which they bound; others function as sensory surfaces. Indeed, many features of nervous tissue can be regarded as those of a modified epithelium.

Mesothelia and endothelia are often classified as distinct from epithelia, as they are derived from mesenchymal cells rather than ectodermal or endodermal elements, and have some characteristic mesenchyme-derived features, e.g. their cytoskeletal intermediate filaments (p. 30) are of the connective tissue type (vimentin) rather than the keratin filaments found in epithelia proper. Pathological changes are also more typical of mesenchyme-derived tissues.

Structure of Epithelia

Epithelia (1.49) are predominantly cellular, i.e. they possess little extracellular material. Their cells rest on a mucopolysaccharide *basement membrane* (see p. 67) and the 20 nm intercellular gaps between adjacent cells are occupied by glycoproteins. Intercellular junctions (p. 22) are usually numerous. Cell shape, typically polygonal, is partly determined by their cytoplasmic contents and partly by pressure from surrounding tissues, among other factors.

Epithelia can also regenerate when injured, as seen most dramatically in the liver, which can replace excised portions rapidly. Continuous replacement is also important where abrasion occurs and most epithelia covering external surfaces show a steady rate of cell division, which offsets loss of cells due to this cause. Perhaps because of this ability, tumours of epithelial origin (papillomata and carcinomata) are common.

Usually, blood vessels do not penetrate epithelia, diffusion from capillaries of neighbouring tissues providing nutrition. This limits the maximum thickness of living cell layers. Epithelia with their supporting connective tissue can often be removed surgically as one 'layer', collectively known as a *membrane*. Where the surface is moistened by mucous glands it is a *mucous membrane* and, if covered with a film of serum-like fluid, a *serous membrane*.

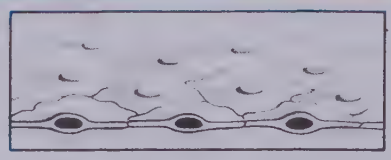
Classification of Epithelia (1.49)

They can be grouped into unilaminar (*simple*) epithelia—single layers of cells resting on a basement membrane; and multilaminar epithelia—more than one cell thick. The latter includes: *replacing* or *stratified squamous* epithelia, in which superficial cells are constantly replaced from the basal layers; *urothelium (transitional epithelium)* serving special functions in the genito-urinary tract; and other multilaminar epithelia which, like urothelium, are replaced only very slowly under normal conditions.

Unilaminar (Simple) Epithelia

This group may be further subdivided according to the shape of its cells into squamous, cuboidal, columnar and pseudostratified types. Cell shape is largely related to cell volume; where little cytoplasm is present, denoting few organelles and therefore a low metabolic activity, cells are squamous or low cuboidal. Highly active cells, e.g. ciliated and secretory forms, contain abundant mitochondria and endoplasmic reticulum and are typically tall cuboidal or columnar.

Unilaminar epithelia can also be subdivided into those which have special functions, i.e. those with cilia, microvilli (brush and striated borders), secretory vacuoles (in mucous and serous glandular cells) or sensory features. *Myoepitheliocytes*, which are contractile, occur as isolated cells associated with glandular structures, e.g. salivary glands (p. 1296).



SQUAMOUS (PAVEMENT) EPITHELIUM

This is composed of flattened, interlocking, polygonal cells (*squames*). The cytoplasm may in places be only 0.1 μm thick and the nucleus usually bulges into the overlying space (1.49,50). These cells line the alveoli of the lungs, renal corpuscles, the thin segments of the nephric tubules and various parts of the inner ear. The structurally similar *mesothelium* forms the surfaces of the pericardial, pleural and peritoneal cavities, each cell possessing one or more cilia. *Endothelium* lines the blood vascular and

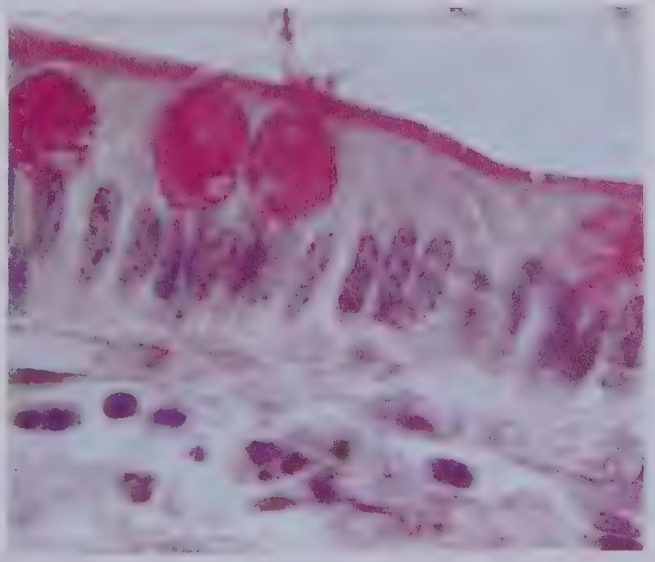
lymphatic channels (p. 684) and this term (i.e. endothelium) is also used for the layer of cells lining the inner surface of the cornea.

Simple squamous epithelia may also be *tessellated*, the cells having sinuous interlocking borders rather than straight boundaries as shown in **6.11**.

Although mesothelia and vascular endothelia resemble ordinary squamous epithelia structurally, there are some important differences in their composition, e.g. they contain vimentin filaments rather than epithelial keratin filaments; they also show characteristic pathological reactions and can form distinctive neoplasms.

Because it is so thin, squamous epithelium allows rapid diffusion of gases and water but may also engage in active transport, as indicated by the numerous endocytic vesicles often seen in such cells. Occluding junctions between adjacent cells (see Staehelin 1975) ensure that materials pass primarily *through* cells rather than between them, except where punctuated by holes, as in the fenestrated endothelia of the renal glomeruli and elsewhere (see p. 1401).

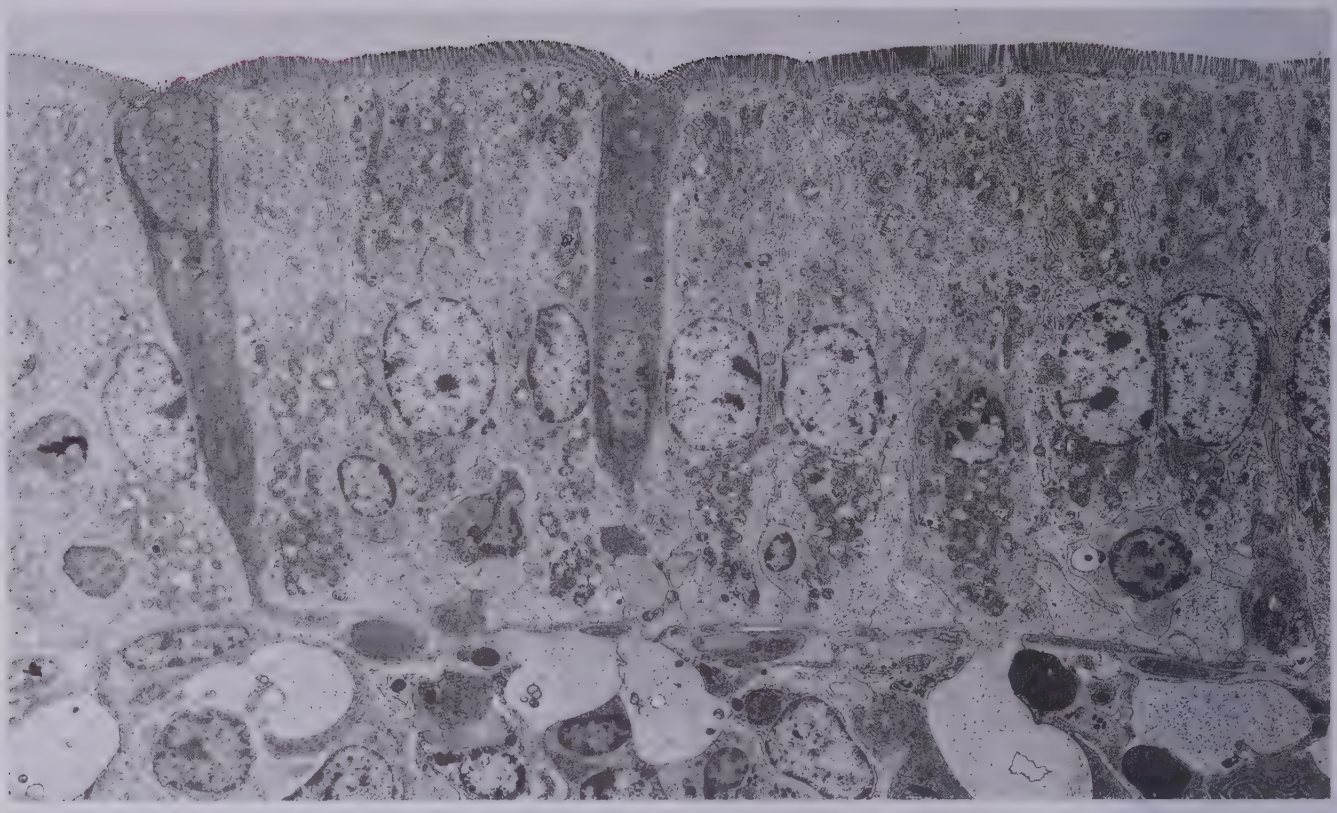
CUBOIDAL AND COLUMNAR EPITHELIA



These consist of regular rows of cylindrical cells (**1.51–56**). Cuboidal cells are square in vertical section, whereas columnar cells are taller than their diameter, and both are polygonal when sectioned horizontally. Commonly, microvilli are found on their free surfaces, providing a large absorptive area (p. 30), e.g. the epithelium of the small intestine (columnar cells with a striated border), the gallbladder (columnar cells with a brush border) and proximal and distal convoluted tubules of the kidney (large cuboidal cells with brush borders). Ciliated columnar epithelium lines most of the respiratory tract (**1.54–56**) as far as the respiratory bronchioles (excepting the lower pharynx and vocal folds), some of the tympanic cavity and auditory tube, the uterine tube and patches in the cavity of the infantile uterus and efferent ductules of the testis.

Mucous glands also line the respiratory tract and cilia sweep a layer of viscous fluid and trapped dust particles, etc. from the lung towards the pharynx (the *muco-ciliary rejection current*), clearing the respiratory passages of inhaled particles. In the uterine tube, cilia may assist the passage of ova from the peritoneal cavity to the uterus.

Some columnar cells are glandular, their apices containing mucus or proteinaceous vacuoles, e.g. mucin-secreting and chief cells of the gastric epithelium. Often mucous cells lie among non-secretory ones, allowing expansion of the secretory apices to give a shape characteristic of these, the *goblet*, *chalice* or *calciform* cells (**1.52,53**) e.g. in the intestinal epithelium.



Mucus is a viscous suspension of complex glycoproteins of various kinds, as well as many other secretory products of adjacent epithelial cells. All mucous glycoproteins (*mucins*) consist of filamentous *core proteins* to which are attached carbohydrate chains, usually branched, standing out from the core protein like bristles in a bottle brush; up to 600 such chains occur in human salivary mucus, so that the entire molecule is quite huge. Furthermore, such glycoproteins typically are linked by sulphydryl groups into tetramers, with molecular weights of 2 million or more. Carbohydrate residues include glucose, fucose, galactose and the negatively charged N-acetylglucosamine (sialic acid), particularly near the free ends of the chains. The terminals of some carbohydrate chains are identical with the blood group antigens of the ABO (ABH) group in about 80% of the population ('secretors', bearing the *secretor gene* S^e) and can be detected in salivary mucus with appropriate clinical tests. There is an interesting correlation between the absence of these antigens in mucus and proneness to gastric ulcers and it is possible that they confer protective properties to gastric and perhaps other types of mucus. The long polymeric carbohydrate chains bind water and so protect surfaces against drying; when in dilute suspension, their molecules can slide over one another with ease, providing good lubricating properties, and their negative charges also bind cations such as Na^+. In more concentrated states, they form viscous layers which protect the underlying tissues against damage.

Mucus is synthesized in a stepwise fashion (Peterson & Leblond

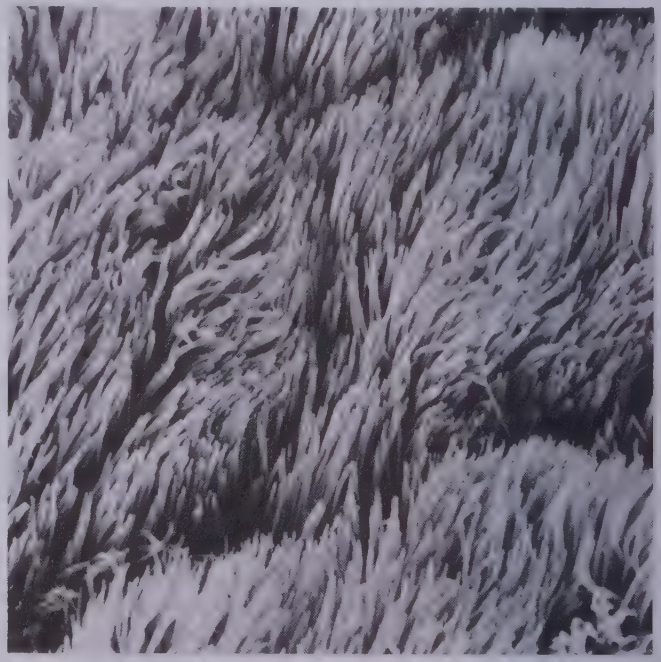
1964); protein synthesized in the granular endoplasmic reticulum is passed to the Golgi complex, where it is first conjugated with sulphated carbohydrates to form the glycoprotein, *mucinogen*, then exported in small dense vesicles which swell as they approach the cell surface and finally fuse with it to release the mucus.

PSEUDOSTRATIFIED EPITHELIUM



This is a simple columnar epithelium in which nuclei lie at different levels in a vertical section (1.49,57). Not all cells extend through the whole thickness of the epithelium, some constituting a basal cell layer, often mitotic and able to replace damaged mature cells. Migrating lymphocytes within columnar epithelia may also give a pseudostratified appearance because their nuclei are placed at different depths. Much of the ciliated lining of the respiratory tract is of the pseudostratified type.

contain sensory cells surrounded by supportive, non-receptive cells. Olfactory receptors are modified neurons, their axons passing directly to the brain, but the other types are specialized epithelial cells synapsing with terminals of afferent (and sometimes efferent) nerve fibres (see Section 7 Neurology).

MYOEPITHELIOCYTES

Also sometimes termed *basket cells*, these are fusiform or stellate in shape, containing actin and myosin filaments; they contract when stimulated by nervous or neurohormonal signals (Abe et al 1981). They surround the secretory portions and ducts of some glands, e.g. mammary, lacrimal, salivary and sweat glands (Nagato et al 1980), lying within the basal laminae at the surface of these structures. Their contraction assists the initial flow of secretion into larger channels. Myoepitheliocytes are ultrastructurally similar to non-striated muscle cells (p. 559) in the arrangement of their actin and myosin but they originate from ecto- and endoderm.

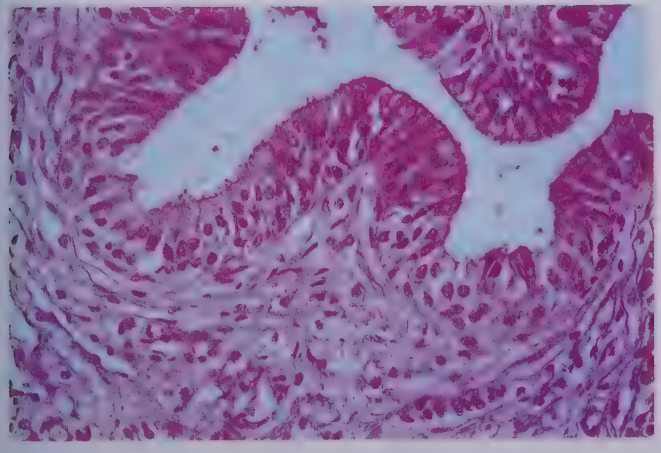
Multilaminar Epithelia

These are found at surfaces subjected to mechanical wear and tear. They can be divided into those which continue to replace their surface cells from deeper layers (stratified squamous epithelia) and others where replacement is extremely slow except when injured.

STRATIFIED SQUAMOUS EPITHELIA

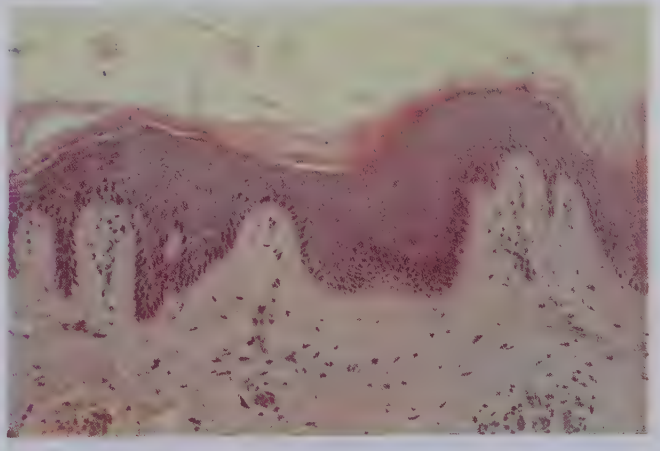
These are multilayered tissues in which there is a constant formation, maturation and loss of cells. Formed mitotically in the most basal layers, their cells move more superficially, changing from a cuboidal or columnar shape to a more flattened form, and eventually being shed from the surface. These epithelia occur in sites exposed to mechanical stresses and provide for a constant protection of the underlying tissues against mechanical, microbial and chemical damage. Typically, the cells are held together by numerous desmosomes to form strong continuous cellular sheets. The two major types of these epithelia are *keratinized* and *non-keratinized stratified squamous epithelia*.

Keratinized Epithelium



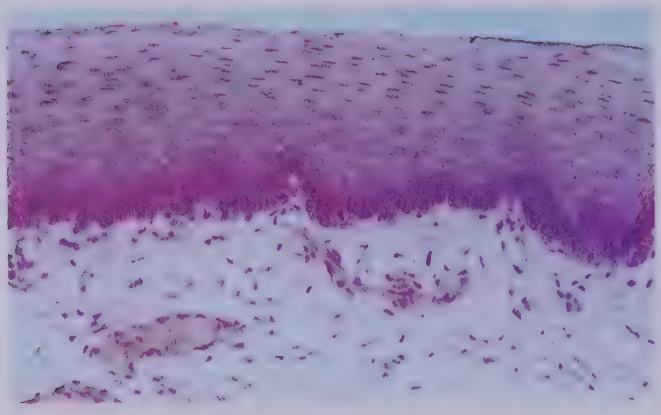
This is found at surfaces which are subject to drying as well as mechanical stresses (1.58). These include the entire epidermis, the mucocutaneous junctions of the lips, nostrils, distal anal canal and the outer surface of the tympanic membrane. Their cells, *keratinocytes*, are formed by the mitosis of basally-sited stem cells (the *stratum basale*) and gradually pass towards the surface in a column of moving cells. When newly formed, keratinocytes contain many ribosomes, mitochondria and other metabolically active organelles and have an extensive cytoskeleton of keratin filament bundles (tonofibrils), anchored into the plasma membrane at desmosomal contacts with neighbouring cells. The most basal layer of cells is also anchored to the basal lamina by hemidesmosomes (p. 24). As keratinocytes move away from the base, the cell surfaces become highly folded, tightly interlocking with those of adjacent cells to present a spiny appearance. These cells (*prickle cells*) together comprise the *stratum spinosum*. As they move more superficially they begin to flatten and synthesize other substances including a dense, basophilic protein, keratohyalin, which mingles with the keratin filaments and gives the cells of this layer (the *stratum granulosum*) a granular appearance. Simultaneously, the cells synthesize and secrete a glycolipid which coats the cell surface, forming a thick, adhesive, water-resistant lipidic cement between the flattened cells. At this stage the cells lose their nuclei, the keratin filaments become firmly embedded in the matrix protein and the cells are now dead, flattened plates (squames), forming the final layer, the *stratum corneum*. They eventually flake off from the surface.

This unusual combination of strongly coherent layers of living cells and more superficial strata made of plates of inert, mechanically robust protein complexes, interleaved with water-resistant lipid, makes this type of epithelium an excellent barrier against different types of injury.



Further details of this tissue are given on p. 73 with the skin.

Non-keratinizing Epithelium



This is present at surfaces subject to abrasion but protected from drying (1.59), including the buccal cavity, oro- and laryngopharynx, oesophagus, part of the anal canal, vagina, distal uterine cervix, distal urethra, the conjunctiva and cornea, inner surfaces of eyelids and vestibule of the nasal cavities. Characteristically,

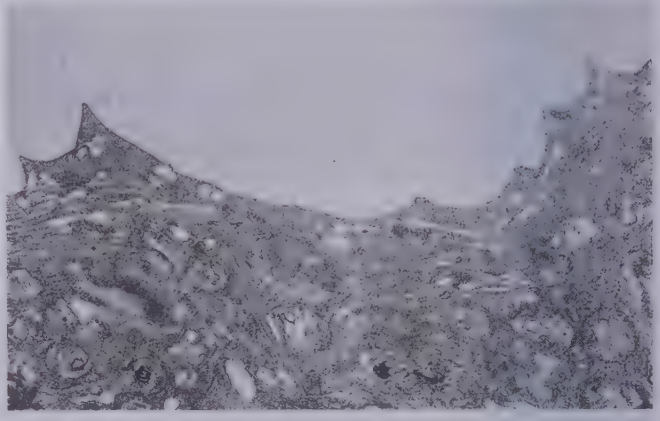
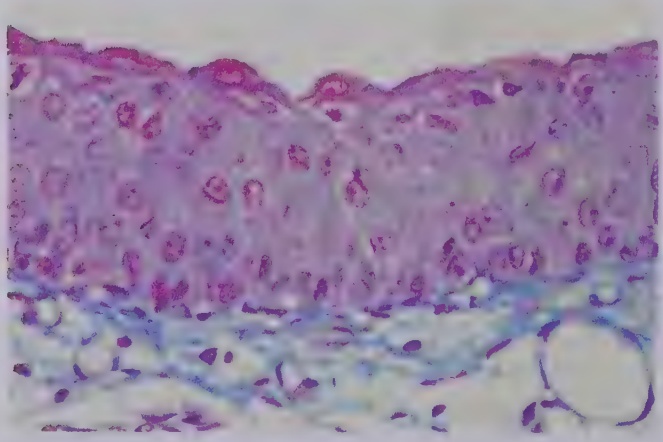
its cells go through the same transitions in general shape as seen in the keratinized type but do not fill completely with keratin or secrete glycolipid, and retain their nuclei until they desquamate at the surface. In sites where considerable abrasion occurs the epithelium is thicker and its more superficial cells may synthesize some keratin (*parakeratinised* epithelia in contrast to the fully, or *orthokeratinized*, state of keratinized epithelium), as e.g. on the hard palate, gingivae and dorsum of the tongue. Diets deficient in vitamin A may induce keratinization of such epithelia and excessive doses may lead to its transformation into mucus-secreting epithelium.



Cells gently removed by swabbing epithelial surfaces can be collected, stained and examined for signs of pathological (e.g. cancerous) transformations (exfoliative cytology).

STRATIFIED CUBOIDAL AND COLUMNAR EPITHELIA



Two or more layers of cuboidal or columnar cells are typical of the walls of the larger ducts of some exocrine glands, such as the pancreas and salivary glands and the ducts of sweat glands, presumably affording more strength than a single layer. These are not continually replaced by basal mitoses and there is no progression of form from base to surface.

Urothelium (Urinary or Transitional Epithelium)

This (1.49,60,61) lines much of the urinary tract, extending from the ends of the collecting ducts of the kidneys, through ureters and bladder to the proximal portion of the urethra. In males it covers the urethra as far as the ejaculatory ducts, then becomes intermittent, finally being replaced by pseudostratified epithelium in the membranous urethra (see also p. 1421). In females it also extends as far as the urogenital membrane. During development part of it is derived from mesoderm and part from ectoderm and endoderm. The epithelium appears to be 4–6 cells thick and lines organs which undergo considerable distension and contraction; it therefore can stretch greatly without losing its integrity. In stretching, the cells become flattened, without altering their positions relative to each other, since they are firmly connected by numerous desmosomes (see review by Hicks 1975). On close inspection, many cells are seen to be attached to the basal lamina of the epithelium by slender basal processes and it has been proposed that perhaps all cells, even the most superficial, are attached to the base; thus this tissue could be viewed as a type of specialized pseudostratified epithelium (see p. 54), in which case it should be reclassified as a unilaminar epithelium (see Scheidegger 1980, Walton et al 1982). When relaxed, the basally situated cells are cuboidal, uninucleate (diploid) and basophilic with many ribosomes. More apically the cells progressively fuse to form larger, binucleate or uninucleate but polyploid cells. The surface cells are largest and may even be octoploid; their luminal surfaces are covered by a plasma membrane bearing plates of glycoprotein particles embedded in its lipid bilayer. These arrays stiffen the membrane so that, when the epithelium is in the relaxed state and the surface area of the cells is reduced, the glycoprotein-lipid plates are partially taken into the cytoplasm within vacuoles or diverticula, re-emerging on to the surface when its area increases once more through stretching (see Minsky & Chlapowski 1978).

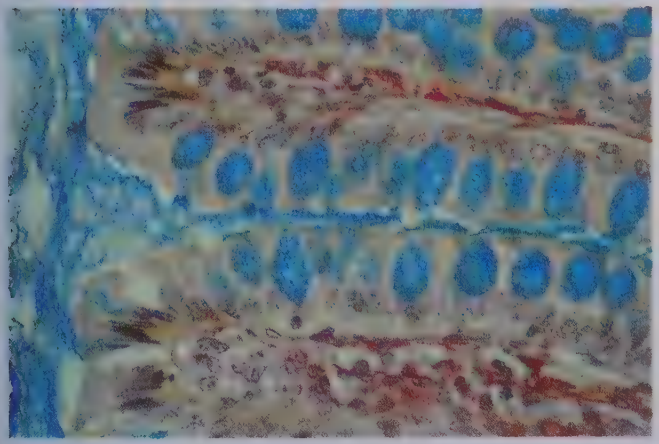
1.61B Scanning electron micrograph of the (relaxed) urothelial surface showing the plate-like arrangement of its plasma membrane. Magnification × 6000.

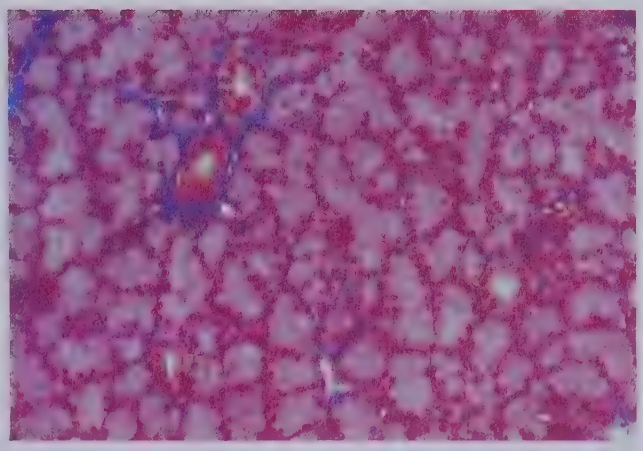
These unusual membranes, together with the occluding junctions of the surface cells, form an effective barrier preventing urine from passing into the epithelium or beyond into the adjacent tissues. The urothelium therefore creates a protective lining to the urinary system which prevents its rather toxic contents from damaging surrounding structures.

Normally, cell turnover is very slow, cell division being restricted to the basal layer and infrequent. When damaged, however, the epithelium regenerates quite rapidly (Annis 1962).



Pigmented epithelial cells are found in various parts of the body. As a single layer of cuboidal cells they form the external layer of the retina (p. 1195) and are present in the posterior epithelium of the iris (p. 1192). The pigment granules are densely crowded in the cytoplasm. *Melanocytes* within stratified squamous epithelium are not derived from ectoderm but are formed in the neural crest and migrate into epithelial sites during development (see p. 115).

Glands



Glands are epithelial derivatives in which cells elaborate a secretion (1.62,63, 8.1A). Some, *exocrine* glands, discharge on to an epithelial surface in continuity with the exterior, e.g. the alimentary, respiratory and urino-genital tracts. Others, *endocrine* glands, become detached from the epithelial surface; no ducts exist (hence the term *ductless glands*) and the secretion is discharged into the blood and lymph streams instead.

Exocrine glands may be *unicellular* or *multicellular*. In the former the secretory cell is part of the epithelial surface on to which it secretes, e.g. goblet cells (1.53). In *multicellular glands*, secretory cells are carried in diverticula of the surface, usually divided into a *secretory portion* and a *duct*. *Simple* glands have a single duct, e.g. the tubular glands of the stomach wall (p. 1352), while *compound* glands such as the parotid have branched ducts. The secretory portion may be tubular (straight or coiled), flask-like (*acinar*) or rounded (*alveolar*). Intermediate types, such as tubulo-acinar and tubulo-alveolar, also occur. Glands with highly distended secretory portions (e.g. the prostate, p. 1434) are sometimes called *saccular* glands. These different types of organization appear to be in part related to the amount and destination of secretions; thus tubular glands are typically found where a large epithelial surface receives a modest flow of secretion over a wide area, e.g. the gastric glands. Where copious secretion into a cavity is required, glands are usually highly branched, with relatively large secretory portions secreting into a complex series of branched ducts, e.g. the pancreas. In some glands the ducts may modify the secretion by ionic exchange (e.g. the major salivary glands).

The larger glands are supported by a delicate connective tissue skeleton, mainly of reticulin fibres, which often groups secretory portions into lobules and lobules into larger lobes, blood vessels, nerve fibres and branched ducts traversing the larger connective tissue septa. Ducts may therefore lie *within* or *between* lobes (intralobar and interlobar ducts, respectively). The final, large and often multilaminar conduit is often referred to as an *excretory duct*.

1.62 Section through part of a simple tubular gland (colon) stained with alcian blue to show mucous gland cells. Magnification × 500.

1.63 Section through a compound alveolar gland (nasopharynx), stained with periodic acid-Schiff to show mucus within secretory lobules. The connective tissue septa have been stained blue. Two small ducts are also visible. Magnification × 160.

The method whereby the epithelial cells of exocrine glands discharge their secretion varies. In *holocrine* glands, such as the sebaceous glands in the skin, the cells disintegrate to liberate the secretion. In *apocrine* glands, such as the mammary gland, a small amount of cytoplasm may be released with the secretory vesicles. In *merocrine* glands, which are the most widespread, the secretion is discharged by the fusion of the membranous walls of secretory vesicles with the plasma membrane, so that only the contents of the vesicle are released. This process involves a 'docking' mechanism by which proteins in the vesicle membrane recognize plasma membrane proteins, bind to them and bring the two membranes close enough for fusion to take place. Membrane added to the cell surface by repeated vesicle fusion can be taken back into the cell by endocytosis and re-cycled for further secretory vesicles (see Pearse & Bretscher 1981, Poisner & Trifaró 1982). The stimulus for secretion varies with the type of cell, but often appears to involve a classic 'second messenger' system such as the cyclic AMP pathway which causes internal calcium release in the cytoplasm (see Conn 1982, Novikoff & Novikoff 1979) e.g. mucous cells.

Glands are often classified by their secretory products. Exocrine glands of some regions, e.g. the buccal cavity, are divided into: *mucus-secreting* or *mucous* glands, whose cells possess frothy cytoplasm with basal flattened nuclei and stain with metachromatic stains and PAS methods, and *serous glands* where the cells have centrally placed nuclei, granular cytoplasm and secrete mainly proteins (e.g. lysozyme, a bactericide, or digestive enzymes).

Some glands are entirely mucous (e.g. the sublingual salivary glands), whilst others are mainly serous (e.g. the parotid salivary glands). The submandibular gland is mixed, some lobules being predominantly mucous and others serous. In some regions mucous acini are capped with crescents of serous cells (*serous demilunes*). The division into mucous and serous types is, however, a rather imprecise one, since their chemical nature is complex and a wide range of secretory products exists. Such terms are of limited use outside certain narrow contexts (e.g. salivary glands, p. 1290). Exocrine glands typically possess a rich blood supply, being metabolically active, and are also often under direct nervous or hormonal control.

Endocrine glands are composed of cell groups lying close to vascular channels; they mostly occur in *clumps* or *cords* of closely-knit cells supported by a network of fine reticular tissue; in the thyroid gland they form hollow balls of cells, or *follicles*, containing a secretory store. Endocrine glands have a particularly well

developed circulation and often the endothelium of capillaries is *fenestrated* (p. 689), facilitating the diffusion of large molecules of hormone into the blood. There are also numerous types of isolated endocrine cells, scattered in the epithelial lining of the alimentary tract and other sites, which have important activities in regulation of gut motility and many other processes (see also p. 1352).

The fine structure of gland cells is related to the type of secretion synthesized. In protein-synthesizing cells such as goblet and pancreatic acinar cells, the granular endoplasmic reticulum is extensive and Golgi complexes well developed, whereas in steroid-secreting cells (e.g. of the adrenal cortex) the elaborate endoplasmic reticulum is mainly smooth.

In salivary and mammary glands, *release* of secretion is accelerated by the neurally elicited contraction of *myoepithelial cells* which surround the alveoli and the initial segments of their ducts.

Patterns of synthesis and release of secretions by glandular cells vary considerably. In some, synthesis and release occur continuously (but with quantitative fluctuations), e.g. the adrenal cortex. In others, secretory vacuoles may be stored for long periods, to be released when suitably stimulated (e.g. pancreatic islet β-cells). A third pattern is seen in goblet cells of bronchi, which repeatedly undergo cycles of synthesis followed by release of secretion.

COMPLEX STRUCTURES DERIVED FROM EPITHELIUM

These include those organs which are largely derived from epithelia and retain their highly cellular nature; they often possess typical epithelial features such as secretory, absorptive and transport functions and include the liver, placenta, and the early tooth germ; indeed the nervous system as a whole can be viewed as a highly elaborate epithelial structure.

THE CONNECTIVE TISSUES

Introduction

The connective tissues may be defined as that group of elements, derived largely from embryonic mesoderm, where the tissue is predominantly composed of intercellular material, secreted mainly by its cells which are consequently widely spaced. Many of the special properties of connective tissues are determined by the composition of the intercellular substance and their classification is also largely based on its characteristics.

Connective tissues play several essential roles in the body, both *structural*, since many of the extracellular elements possess special mechanical properties, and *defensive*, a role which has a cellular basis (p. 59). Structural connective tissues are conveniently divided into 'ordinary' or 'general' types, distributed widely, and special types, namely cartilage and bone which are described elsewhere (pp. 283–29). A third variety, the *haemolymphoid tissues*, are comprised of the cells of the blood and lymphoid tissue and their precursors; these are often considered to be akin to other types of connective tissue because of their similar mesenchymal origins and also because the various defensive cells of the blood form part of a typical connective tissue cell population. However, for convenience, these tissues will be considered separately in another section (p. 662) with the circulatory system.

Connective tissue is thus formed of *cells* and *extracellular matrix*. The matrix in turn is composed of *fibres* and a relatively amorphous, viscous *ground substance*. (Some authors apply the term 'matrix' to ground substance alone but it will not be used in this manner here.) It is noteworthy that a number of cell types of connective tissue are also found in the circulating blood and lymph and there is a dynamic equilibrium between the two.

The Cells of General Connective Tissue

In general connective tissue, these can be conveniently separated into: (1) the resident cell population (fibroblasts, adipocytes, persistent mesenchymal stem cells, etc.) and (2) a fluctuating population of immigrant, wandering cells with various defensive functions (macrophages, lymphocytes, mast cells, neutrophils and eosinophils) which may change their activities, structures and numbers according to defensive demand. A graphic summary of these cell types is presented in 1.64.

Embryologically, fibroblasts and adipocytes arise from relatively undifferentiated *mesenchymal stem cells*, some of which may remain in the tissues, providing a postnatal source of new cellular elements. Most of the other cells migrate into the tissue from bone marrow, lymphoid tissue and other external sources.

FIBROBLASTS

These are usually the most numerous cells. They are flattened and irregular in outline, with branching processes; in profile they appear fusiform or spindle-shaped (1.64,65). Fibroblasts synthesize most of the extracellular matrix of connective tissue and accordingly have all the features typical of cells actively engaged in synthesis and secretion of proteins. Their nuclei are relatively large, active or euchromatic (open-faced) and possess prominent nucleoli. In young and active cells the cytoplasm is abundant and basophilic because of the high concentration of rough endoplasmic reticulum (Hall & Jackson 1968, Ross 1975, Hay 1981). In old and inactive fibroblasts (often termed *fibrocytes*) the cytoplasm is sparse, the endoplasmic reticulum scanty and the nucleus flattened and heterochromatic (close-faced). In active fibroblasts, mitochondria are abundant and several sets of Golgi complexes are present.

Fibroblasts are usually adherent to the fibres (collagen and elastin) which they lay down. In some highly cellular structures, e.g. glands and lymphoid tissue, fibroblasts and delicate collagenous fibres (reticulin fibres) form fibrocellular networks often called *reticular tissue*. The fibroblasts may then be termed reticular cells (see p. 62).

Fibroblasts are particularly active during wound repair, multiplying and laying down a fibrous matrix which becomes invaded by numerous blood vessels *(granulation tissue)* (see Ross 1968). Contraction of wounds (p. 87) is at least in part caused by the shortening of specialized contractile fibroblasts (myofibroblasts) which arise in such areas (Gabbiani et al 1973). Fibroblast activity is influenced by various factors such as steroid hormone levels, dietary content and prevalent mechanical stresses. In vitamin C deficiency there is an impairment of collagen formation.

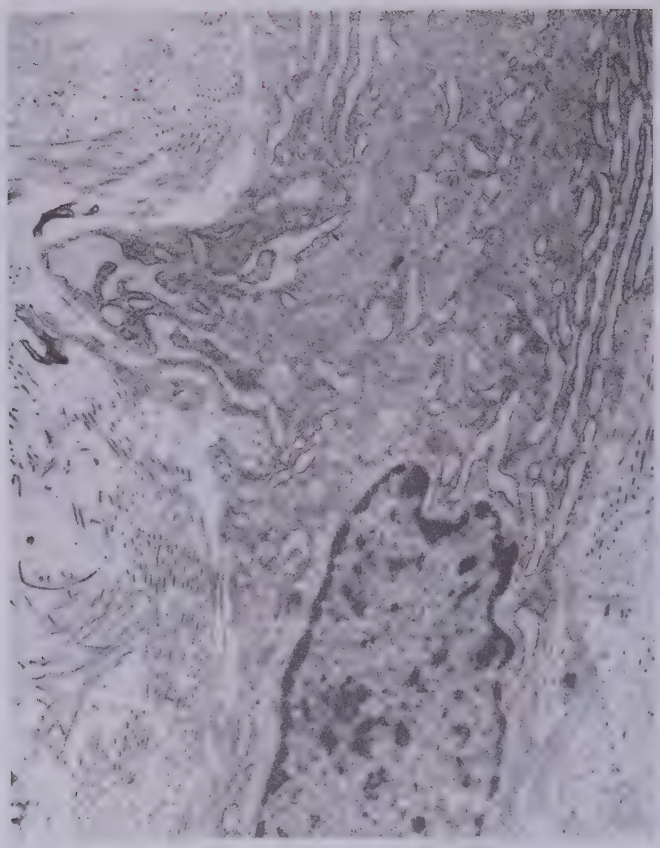
MACROPHAGES (HISTIOCYTES, CLASMATOCYTES)

These are also numerous in connective tissue where they may be either attached to matrix fibres (stationary, or fixed macrophages), when their shape is irregular with many filopodia (1.66); or they may be motile (nomadic macrophages) of a more rounded and regular form.

Macrophages are about 15–20 μm in diameter, their nuclei usually indented and somewhat heterochromatic, with a prominent nucleolus. Their cytoplasm is mildly basophilic and typically has a 'frothy' appearance under the light microscope. They are important phagocytes, forming part of the *mononuclear phagocyte system* (p. 669). They can engulf and digest particulate organic materials, such as bacteria and other foreign bodies, and are also able to dispose of dead or moribund cells prior to tissue regeneration.

1.64 Diagrammatic reconstruction of loose connective tissue showing the characteristic cell types, fibre and intercellular spaces.

Ultrastructurally, they contain numerous lysosomes which digest ingested materials (p. 27). Inert materials such as small particles of carbon or metals may also be taken up, a quality useful in demonstrating macrophages histologically, since their cytoplasm becomes filled with ingested particles if an experimental animal is previously injected with a suspension of India ink (1.67), trypan blue or lithium carmine (vital staining). Macrophages may also be separated magnetically from mixed cell samples by first treating them with iron carbamyl, which they ingest.



These cells are also of great importance in many immunological aspects of defence and their interactions with numerous defensive cells in the regulation of the immune system are widespread. Antigens adhering to macrophages can be (directly or after modification) passed to and thus stimulate lymphocytes (p. 671). They may selectively phagocytose particles previously coated by antibodies (*opsonins*, see p. 672) synthesized by lymphocytes and they are themselves sites for *homocytotropic antibody* attachment, which enables them to recognize and attack foreign substances (see also monocytes, p. 667).

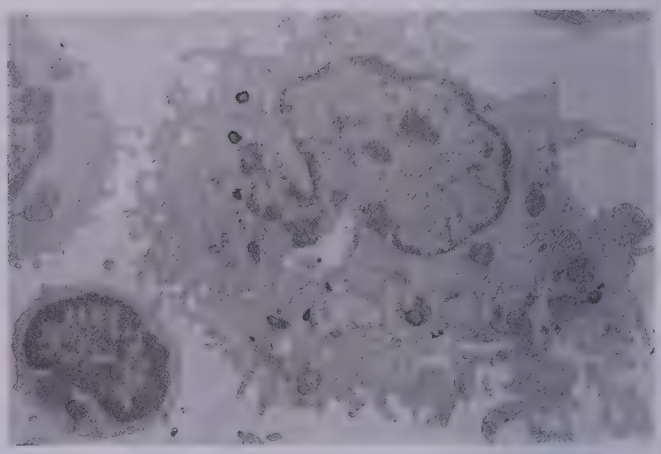
Many properties of connective tissue macrophages are similar to those of a number of specialized cell types in other sites, particularly: circulating monocytes, alveolar phagocytes in the lungs, littoral phagocytes in the lymph nodes, spleen and bone marrow, Kupffer cells of the liver sinusoids, microglial cells of the brain, Langerhans cells of the epidermis and dendritic cells of lymphoid tissue. Various cell-labelling experiments have shown that most precursors of these arise in the bone marrow as monocyte-like cells which then pass in the circulation to their final destinations, where, however, they may continue to divide. Recent evidence suggests strongly that these cells are specialized subclasses of a general macrophagic cell, having distinctive functions, preferred sites of action and possessing different antigenic markers as well as many common ones.

All macrophages are capable of motility, when suitably stimulated. When grouped around a large foreign body, macrophages may also fuse together to form *syncytial giant cells* and *epithelioid cells*. These and other aspects of macrophage biology will be considered further in Section 6 (p. 662).

LYMPHOCYTES

These cells are numerous in general connective tissue only in pathological states, migrating from adjacent lymphoid tissue or from the circulation. The majority are small cells (6–8 μm) with rounded, highly heterochromatic or often deeply indented nuclei (p. 671, and see 1.64,66). When appropriately stimulated they enlarge, developing numerous ribosomes. Two major functional classes exist, termed 'B' and 'T'-lymphocytes (see p. 672). B-lymphocytes originate in the bone marrow, then pass to various lymphoid tissue sites where they proliferate. When antigenically stimulated, they undergo further mitotic divisions, then enlarge

1.65 Transmission electron micrograph of a fibroblast. Note the abundant endoplasmic reticulum and extensive Golgi complex. Some extracellular collagen fibres are also visible. Magnification × 15 000.



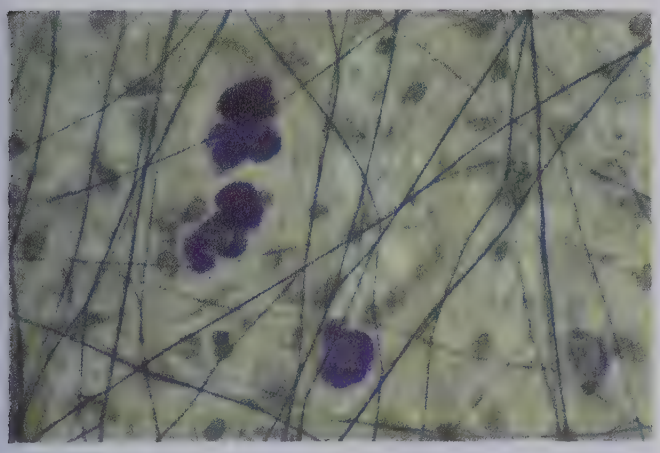
as they mature to form *plasmacytes* (plasma cells) which synthesize and secrete defensive proteins, the antibodies (immunoglobulins). Mature plasmacytes are rounded or ovoid, up to 15μm across, and have extensive arrays of granular endoplasmic reticulum. Their nuclei are spherical and have a characteristic 'cartwheel' configuration of heterochromatin which is regularly distributed in peripheral clumps. The prominent Golgi complex is also seen with a light microscope as a pale region to one side of the nucleus, whilst the remaining cytoplasm is deeply basophilic due to the abundant rough endoplasmic reticulum. Mature plasma cells are unable to divide.

T-lymphocytes stem from cell stocks initially formed by the bone marrow but later migrating to and multiplying within the thymus before passing into the peripheral lymphoid system where they continue to multiply. When antigenically stimulated, these cells enlarge and their cytoplasm becomes filled with 'free' polysome clusters. The functions of T cells are numerous and incompletely understood, but include the recognition and destruction of virus-infected cells, tumour cells, fungi, tissue and organ grafts, the modulation of B-lymphocytes and interactions with several other defensive cells. Different subsets of T-lymphocytes have distinctive roles in these activities.

Further details of the natural history of lymphocytes may be found on pp. 670–75.

MAST CELLS (MASTOCYTES, HISTAMINOCYTES)

Mast cells are important defensive cells which occur particularly in loose connective tissues and often in the fibrous capsules of certain organs such as the liver (see the review of this cell by Holgate 1983). They are characteristically numerous around blood vessels and nerves. Mast cells are round or oval, about 12 μm in diameter, with many filopodia extending from the cell surface (1.68). The nucleus is centrally placed and relatively small, being surrounded by large numbers of prominent vesicles, a well developed Golgi apparatus but scanty endoplasmic



1.66 Electron micrograph of a macrophage (right) and a small lymphocyte (lower left). Magnification × 6000.

reticulum. The vesicles show a strongly positive reaction with the periodic acid-Schiff (PAS) stain for carbohydrates and with toluidine blue, methylene blue, azure A and alcian blue; they show strong *metachromatic* staining reactions (staining red), also indicating an acid mucopolysaccharide content. Ultrastructurally the membrane-bounded vesicles (or 'granules') vary in size and shape (mean diameter about 0.5 μm) and have a rather heterogeneous content, differing with species. In man the vesicles usually contain dense osmiophilic material which may be finely granular, lamellar or in the form of membranous whorls; these variants may co-exist in the same vesicle, which may also present in places a crystalline substructure. For these reasons they have sometimes been termed *compound granules* (1.68c).

The available evidence points to the presence in mast cell granules of a wide variety of substances which can initiate and amplify a great range of defensive responses in the surrounding connective tissue, many of them associated with inflammation. The major granule components are the proteoglycan *heparin*, *histamine*, *tryptase*, *superoxide dismutase*, *aryl sulphatase*, β-*hexosaminidase* and various other enzymes; also present are *eosinophil chemotactic factors* (tetrapeptides) and *neutrophil chemotactic factors*. Mast cells may be disrupted to release some or all of their contents either by direct mechanical or chemical trauma, or following contact with particular antigens to which the body has previously been exposed (p. 672). The latter may result from interaction between the antigen and *homocytotropic antibodies* of the IgE and IgG_4 classes associated with the mast cell plasma membrane and may give rise to local responses (e.g.

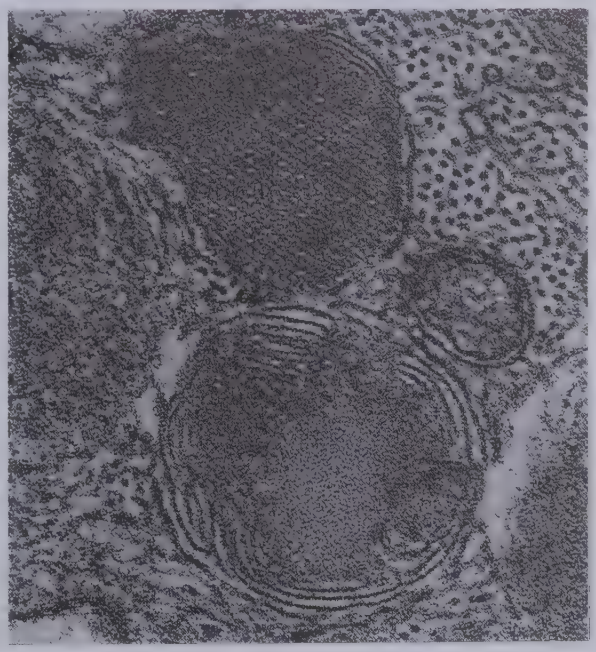
urticaria) or generalized ones (anaphylactic shock) following the release of large amounts of histamine into the general circulation. They have thus been implicated in many of the phenomena occurring in inflammatory reactions, allergies and hypersensitivity states. The modes of action of their released mediators are exceedingly complex and involve many chemical reactions which alter capillary permeability, can cause smooth muscle contraction, activate and attract various other defensive cells, activate platelets, inhibit clotting and lead to many other local or systemic reactions.

1.68B Electron micrograph of a mast cell showing the large densely staining membrane-bound cytoplasmic granules. Magnification × 6000.



Mast cells closely resemble basophil leucocytes of the general circulation and it is widely considered that they arise from the bone marrow and pass to the tissues perhaps as basophils, migrating through the capillary and venule walls to their final destination. However, there are minor differences between the basophil and the mast cell in terms of their cytochemistry, which suggest either a different lineage for the two, or perhaps that the basophil matures into a mast cell when it reaches its extravascular environment. In connective tissues at least two subclasses of mast cells have been recognized, one resident in the mucosae of the alimentary and respiratory tracts, and others situated elsewhere. They differ in their detailed chemistry and their reactions to drugs (Pearce 1983, Friedmann 1986).

ADIPOCYTES (LIPOCYTES, FAT CELLS)

These occur singly or in groups in the meshes of many but not all connective tissues, being specially numerous in *adipose tissue* (1.69,70, see also p. 69). When occurring singly the cells are oval or spherical in shape but when mutually compressed they are polygonal. They vary in diameter, averaging about 50 μm. Each cell consists of a peripheral rim of cytoplasm, in which the nucleus is embedded, surrounding a single large central globule of fat (see Slavin 1985). There is a slight accumulation of cytoplasm around the nucleus, which is oval in shape and appears compressed against the cell membrane by the lipid droplet, as does the Golgi complex. Ultrastructurally, lipid droplets are in direct contact with the surrounding cytoplasm without an enclosing membrane. Many microfilaments are also seen around the lipid vacuole as well as some endoplasmic reticulum and mitochondria.

In sections not specially prepared to preserve fat this is usually dissolved out by the solvents used, particularly xylol or benzene; only the nucleus and the peripheral rim of cytoplasm surrounding a central empty space are left, so that the cell has a signet-ring appearance. The fat is fixed and stained by osmium tetroxide and specially coloured by alcoholic solutions of certain dyes, notably Sudan III, Sudan black and Scharlach R, which are more soluble in fat than in the solvent; lipid is conveniently demonstrated in frozen or cryostat sections (1.69A). The fat consists of glycerol esters of oleic, palmitic and stearic acids.

Doubts exist as to whether fat cells are specifically and exclusively concerned with the storage, and perhaps the synthesis,

1.68C Higher magnification of part of a mast cell from human skin, showing the complex internal structure of its granules. Cross-sections of microtubules and intermediate filaments are also visible in this section. Magnification × 100 000.

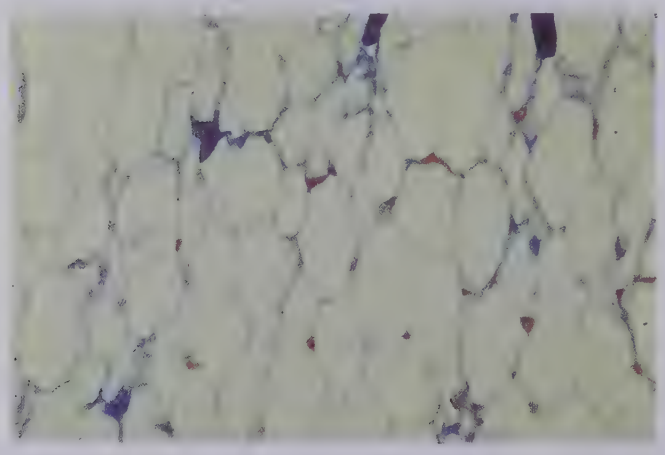
of fat. Prior to the storage of fat within them they are stellate in shape and difficult to distinguish from fibroblasts and, when depleted of fat, they revert to this appearance. As fat accumulates the cells enlarge and become rounded, the fat first appearing as isolated small globules which later coalesce to form a single large droplet. Conversely, during depletion the single large globule diminishes in size and then breaks up into droplets while the cells become stellate in shape. Fat cells, however, seem to have a well defined distribution within the body and there is evidence that they are indeed specific cells.

In most mammals which have been studied but especially in those which hibernate, certain deposits of fat are characterized by the presence of a large cell type in which the fat is present as several separate droplets and not as a single globule; their mitochondria also have unusually large and numerous cristae. These deposits of fat are often termed *brown* adipose tissue and are concerned with heat production, mediated by mitochondria. In many species they occur in the interscapular tissue, dorsally, in the subcutaneous tissue of the ventral thorax, axillae, renal capsule and posterior abdominal wall. In human neonates brown fat is present in the interscapular region and may be more widespread. Its importance in later years is uncertain. (See Cannon & Nedergaard 1985 for a review of this subject.)



The mobilization of fat is under nervous or hormonal control and noradrenalin released at sympathetic nerve endings in adipose tissue is particularly important in this respect.

PIGMENT CELLS

These occur in the corium (dermis) of skin, especially in dark races, and in the iris and choroid of the eye. Although some of these cells may be able to synthesize melanin (or related pigments), in which case they are described as *melanocytes* (derived from neural crest origins), the majority contain pigment which they have engulfed after its release from melanocytes, being unable to synthesize it themselves. Such cells are called *chromatophores* (or *melanophores*, when melanin is the pigment involved); they are typically stellate in form and may represent modified fibroblasts. They are generally stellate cells with long processes and numerous dark brown or black granules, believed to be melanin, in their cytoplasm. Their function is generally to prevent light from reaching adjacent cells.

RETICULAR TISSUE

In many situations, as in exocrine and endocrine glands, a fine meshwork of reticulin fibres supports the cellular elements (see p. 58 and Carr 1970). The cells responsible for forming this are indistinguishable from fibroblasts but are sometimes termed 'reticular cells'. This term is, however, also used for a variety of other cells in the reticulo-endothelial and haemopoietic tissues (p. 678), where reticulin is also laid down. The nomenclature and proposed relationships between these various elements is somewhat confused and will not be further explored here.

The Matrix of Connective Tissue

This includes all the extracellular materials of connective tissue, and may be divided into the *fibres* and the *ground substance*.

There are two major classes of fibre: collagen (including reticulin) and elastin. The *ground substance* is composed of hydrated networks of proteins, mainly associated with carbohydrates (glycoproteins and proteoglycans), the large spaces between which contain water, salts and other diffusible substances. These extracellular materials (fibres and ground substance) have complex mechanical properties, conferring varying degrees of strength as well as elasticity, depending on tissue type and site. They form the molecular environment of the contained cells and there are intimate biological interactions between them, governing many aspects of cell behaviour and chemistry. In the skeletal tissues (cartilage and bone), the matrix is stiff and can bear much greater stresses than other types of connective tissue. In cartilage, this is achieved mainly by a high concentration of collagen and proteoglycan complexes whereas, in bone, collagen and mineral crystals within and around the fibres are responsible for its strength.

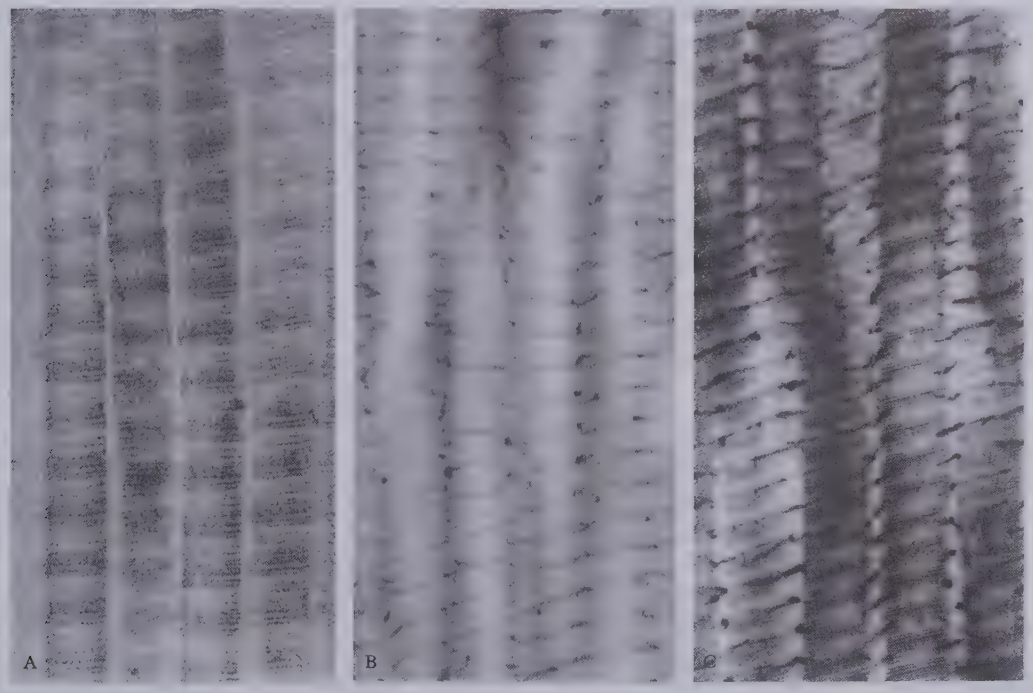
COLLAGEN FIBRES

These form the predominant fibrous component of ordinary connective tissue and are also major components of cartilage and bone as well as special structures such as the cornea, sclera and vitreous body of the eye and nucleus pulposus of intervertebral discs and notochordal tissue. Tendons, aponeuroses, ligaments, fasciae, sheaths of muscles and nerves, the meninges, dermis and many other structures have a particularly high collagen content. Collagen fibres are flexible but also have a high tensile strength with only a little elastic recoil, and are vital to the mechanical properties of the body in general.

Seen with the light microscope, fresh collagen fibres are white and glistening and show faint longitudinal striations. They form bundles of various size, whose component fibres may leave one fascicle and interweave with others (1.64,67) but, unlike elastin fibres, do not branch. Their precise disposition varies with site (p. 69); in unstretched loose connective tissue they are sinuous, but may straighten under tension to limit the degree of tissue expansion. They stain lightly with eosin but can be dyed strongly with aniline blue (e.g. in Mallory's triple stain) and with aldehyde fuchsin, as in van Gieson's method. Generally, they give only a weak reaction with silver impregnation, except in the case of a fine fibred variety, *reticulin*, which is strongly argyrophilic. Because of their highly orientated fibrillar substructure, collagen fibres show form birefringence when viewed with a polarizing microscope, an effect which can be greatly enhanced by first treating them with chemicals such as Sirius red, whose long molecules bind parallel to those of collagen.

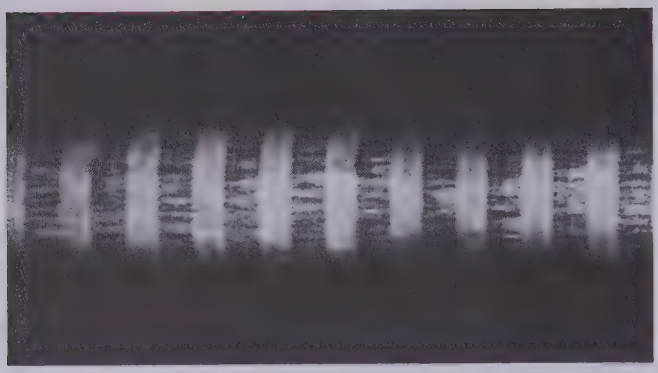
Under the electron microscope, collagen fibres are seen to be composites of narrower (20–200 nm) collagen *fibrils* and these in turn consist of fine (3.5 nm) *microfibrils*, which are aggregates of filamentous *tropocollagen molecules*.

Although there is some variation of detailed structure in different types of collagen (see p. 64), those which form fibres are mostly cross-banded with a characteristic regular repeating pattern of major and minor bands (1.71,72). X-ray diffraction measurements have shown the repeat distance of the major bands to be 67 nm, although in specimens prepared for electron microscopy, a process causing dehydration and slight shrinkage, a value of 64 nm is usually quoted. Longitudinal filaments are also visible in electron micrographs corresponding to linear arrangements of fibrillar tropocollagen subunits (1.71,72,73) whose ordered disposition is also responsible for the cross-striations, which are generated by alignments of chemical cross-links and other minutae of molecular composition (vide infra). The numerous minor cross-bands of collagen are asymmetrically arranged within each repeat pattern, since the tropocollagen molecules all point in the same direction within one fibre, which therefore has polarity.



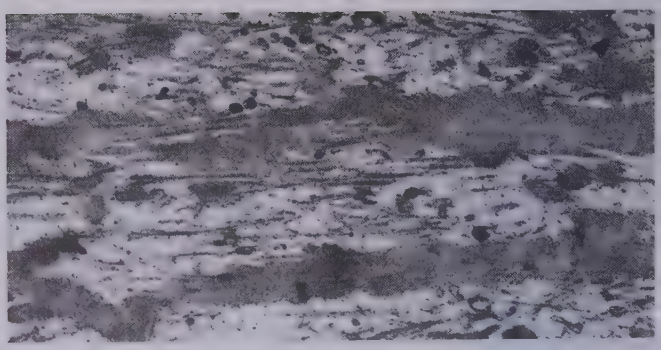
Some types of collagen exist which form only very narrow fibres, or no fibres at all, and in these cross bands are either not clear or are missing entirely (vide infra).

At every level of organization within collagen assemblies, there are cross-links between adjacent longitudinal elements and this is responsible for the great mechanical stability and tensile strength of collagen. Between microfibrils, fibrils and fibres, proteoglycans form regular connecting links (see 1.71), reflecting the periodic organization of the structures to which they are attached (Scott 1988). Individual tropocollagen molecules are also cross-linked by various chemical bonds between specific amino acid units along their length, as indeed are the polypeptide subunits of which they are composed (p. 65).



Tropocollagen

When appropriately treated with acids or alkalis, collagen fibres swell and disintegrate into the filamentous molecules of tropocollagen. In the fresh state these are 300 nm long (280 nm when dried) and 1.4 nm thick, with an M_r of 280 000–540 000 (see Table 1). *Gelatin*, obtained by boiling collagen, consists of disordered networks of such molecules.



Each tropocollagen molecule is composed of three polypeptide (*procollagen*) chains, arranged in a triple helix (1.73). Chemically, procollagen consists of about 100 repeating amino-acid triplets, each with glycine at the third position, the other two varying in

1.71 Transmission electron micrographs of skin collagen fibrils stained in different ways to demonstrate the banding pattern and the presence of associated proteoglycans. In A the fibres have been longitudinally sectioned and stained with uranyl acetate to show the characteristic major 64 nm repeat pattern with several sub-bands visible between. B has been stained with cupromeronic blue demonstrating the filamentous proteoglycans encircling and interconnecting collagen fibrils. In C both stains have been used to show that the proteoglycan connections correspond to the 64 nm cross bands. Micrographs provided by J Scott and Marion Haigh, Department of Chemical Morphology, University of Manchester. Magnifications: A × 100 000; B and C × 65 000.

type but often being the amino acids hydroxyproline and hydroxylysine (substances rarely found outside collagen). These, and other amino acids, form covalent bonds between the polypeptide chains, maintaining their triple helical configuration. The hydroxylysine residues also form attachment sites for certain (D-glycosidically linked) carbohydrates, which appear to be necessary for the assembly of tropocollagen into fibrils when released into the extracellular space.

Several variations in amino acid sequences of the procollagen chains have been found, so that many combinations are possible. This variability has been exploited to create collagens with a wide variety of different functions.

Classes of Collagen

Biochemical analysis, and more recently immunohistochemical detection, has shown that there is a large family of chemically related molecular species of collagen (see Table, also the review by Miller 1984). Different tissues and different stages of development or tissue repair show characteristic types or mixtures whose recognized number is still growing. The particular combination of polypeptide chains affects many of the structural features and properties of collagen, including their ability to form fibrils, the diameter of their fibrils, their binding to adjacent structures, degree of hydration and other aspects of collagen biology. Of these, types I–V are the best understood. The notation used to describe the composition of particular types of collagen is also shown in the Table.

Each tropocollagen molecule is a combination of three polypeptide chains with an α-helical chemical structure (α-chains), each major type having its own particular varieties (e.g. two possible chains, α1[I] or α2(I) for Type I collagen, etc.). There may be three identical chains in one tropocollagen (e.g. $[\alpha 1(I)]_3$ for one subclass of Type I), or a heterogeneous combination (e.g. $\alpha 1(I)_2$ $\alpha 2(I)$.

Type I collagen is the most widely distributed, being the major collagen of ordinary connective tissue including tendons, ligaments, the dermis and bone. Its fibres tend to be quite flexible and are strongly cross-banded. In calcified tissues, regular gaps between the ends of tropocollagen molecules can provide sites for calcium salt deposition and this appears to be an important initiating mechanism for tissue calcification (see p. 302).

Type II occurs in cartilage (p. 285) and a few other sites—the cornea, vitreous humour, notochord and nucleus pulposus—and has a mixture of larger (100 nm diameter) and very narrow (20 nm), short fibrils with indistinct cross bands. The larger fibres are found mainly in articular cartilage, where mechanical reinforcement is required. The collagen of white fibrocartilage is a mixture of Type I, which forms the larger fasciculi, and Type II, whose

Table of collagen types and their distribution adapted from Miller and Gay (1987)

Type	Older terminology	Main source	Number of unique chains	Chain *Mr*	Molecular species	Form of aggregates
I	Collagen	Virtually all C.T.	2	95K	$[\alpha 1(I)]_2\alpha 2(I)$ $[\alpha 1(I)]_3$	Fibres

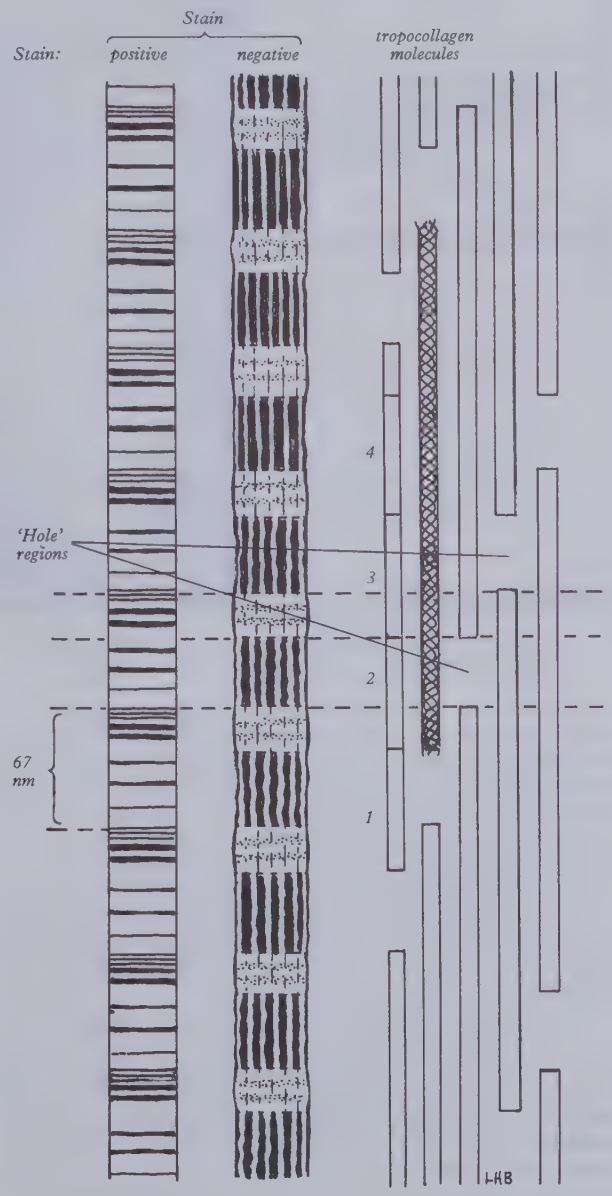
narrow fibres are not easily detectable by light microscopy. The finer fibres of the vitreous body (and incidentally of hyaline cartilage) are associated with unusual transparency; because of the larger amounts of attached carbohydrates, they bind much water and tend to form stiff, transparent gels of short, separated fibrils. The smaller fibrils also lack obvious cross-banding and do not join up to form fibres.

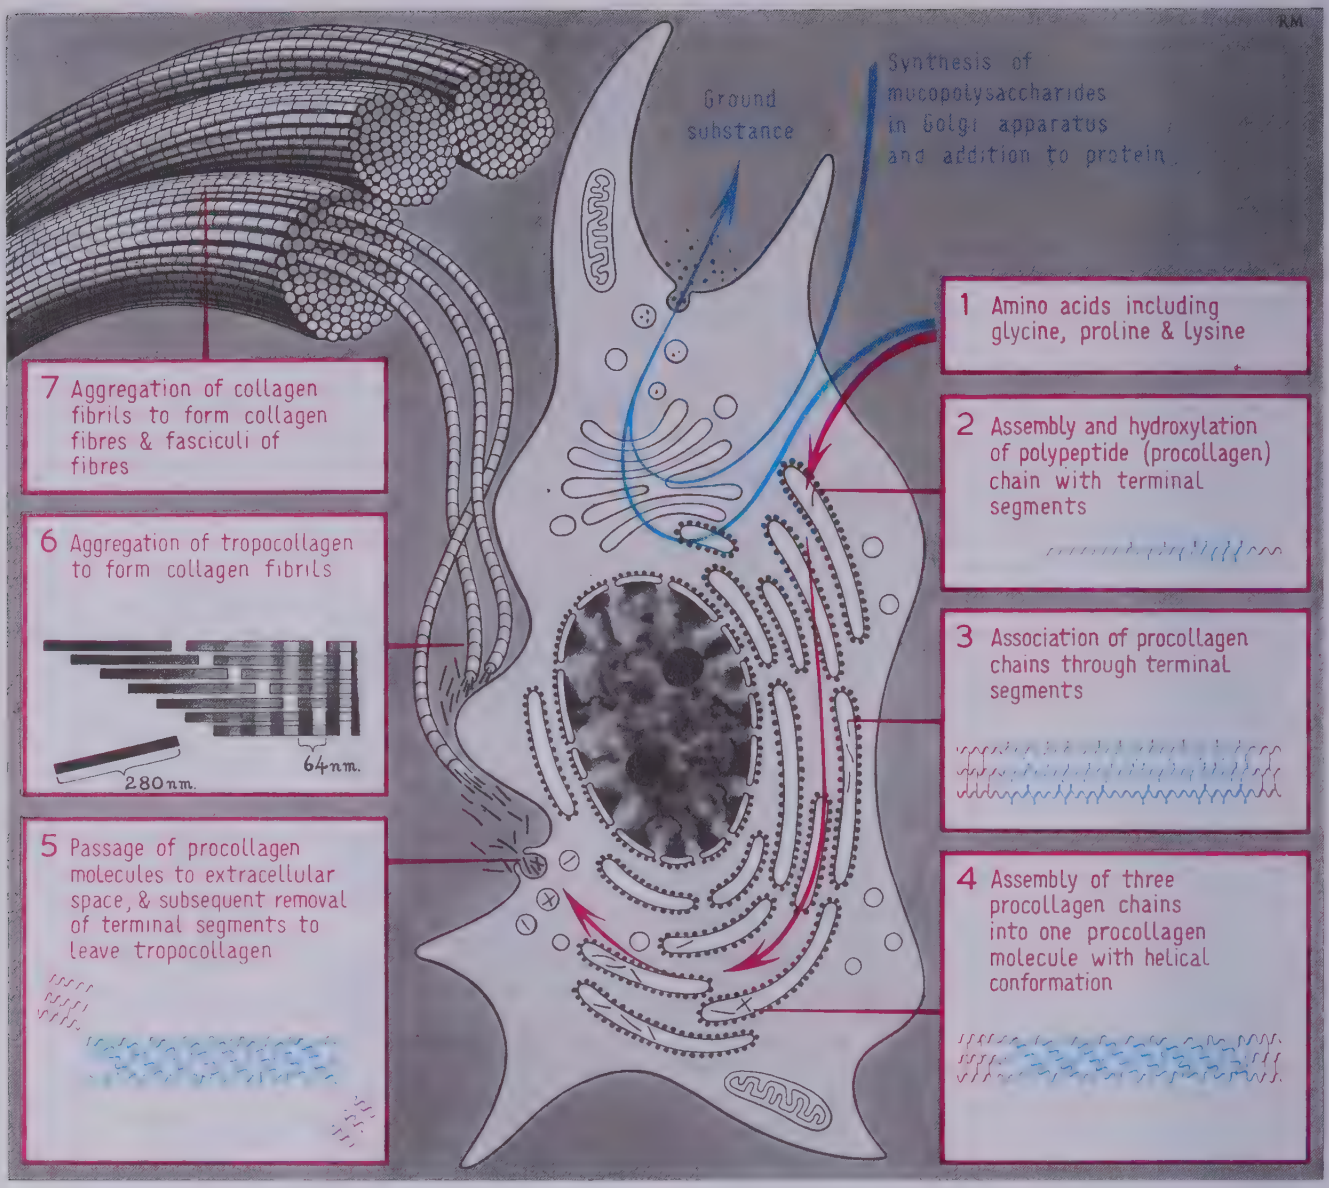
Type III forms the collagenous portion of reticulin (which is also rich in carbohydrate); these fibres are narrower than Type I and, seen with the light microscope, form extensive networks of delicate fibres providing support to many soft tissues, e.g. glands, lymphoid tissue, basement membranes, the papillary layer of the dermis, bone marrow etc. (see p. 66). Type III is chemically interesting because of the incomplete removal of terminal registration peptides (p. 66) which are normally cleaved away after secretion. This may in some way limit their growth in diameter. **Type IV** collagen is present in the lamina densa of basal laminae (p. 67); it consists of short filaments which do not form fibrils but aggregate by their ends into small groups of four, which then intermesh to form complex molecular feltworks. The individual filaments resemble procollagen molecules virtually unprocessed after secretion. Collagen of this type is important in forming the main skeleton of the basal lamina to which its other components are attached.

Type V collagen does not form fibrils either and is a relatively minor component of most connective tissues. It is highly glycosylated and tends to be present in pericellular zones, often associated with Type I fibres. Its functions are not certain.



Other minor collagen types. In addition to the foregoing classes, many other varieties of collagen have been described chemically. Some of these may merely be side-products of the synthesis or breakdown of other collagens, others more important but with as yet ill-understood functions. **Type VI**, like Type IV, forms tetramers but these assemble into microfibrils; it is often associated with elastin and may be related to the fine filaments which are a typical of elastic tissue (see p. 67). **Type VII** is a minor component of the total collagen of placental membranes, **Type VIII** is produced by endothelial cells and **Types IX**, **X** and **K** collagen are synthesized by chondrocytes, (X by hypertrophying cells) and are of unknown function.

Molecular Organization of Banded Collagen



The reason for the striated appearances of Type I and other fibrillar collagens lies in the ordered arrangement of tropocollagen molecules, a phenomenon which has been much studied. The essence of this organization is that, within each microfibril, the molecules, 300 nm long, are all aligned longitudinally in five longitudinal rows, with a gap of 40 nm between the end of each molecule and the next in longitudinal sequence. Thus each tropocollagen unit spans four 67 nm intervals, overlapping the fifth by a short distance of about 27 nm (see 1.72). Each row is staggered by 67 nm on its lateral neighbour and cross-linked covalently by various amino acid residues which, because of alignments when the assembly is viewed from the side, generate differences in density and staining patterns which appear as complex cross-bands of different sizes. Within a fibril the microfibrillar subunits are aligned by glycoproteins to give a specific cross-striated pattern to the whole structure. In negatively-stained electron microscope preparations, the hydrophilic gaps between molecules are penetrated by stain and these include the 'gap' regions between the ends of tropocollagen units so that a somewhat different pattern of banding is seen relative to sectioned, stained specimens (1.71). This regularity allows the addition of new tropocollagen molecules to the ends of fibrils and their assembly into structures of indefinite length.

The Biosynthesis of Collagen

The involvement of fibroblasts in the biosynthesis of collagen (1.73) has been studied extensively biochemically and also by autoradiographic electron microscopy (see Prockop et al 1979, Alberts et al 1983). In many respects it appears to be similar to the synthesis of collagen by chondrocytes (p. 285). Amino acids are taken up by the cell and synthesized on the ribosomes of the rough endoplasmic reticulum to form long polypeptides, the *pro-α-chains* (see review by Uitto & Lichtenstein 1976). These are longer than the final α-chains of tropocollagen because extra polypeptide segments (*extension peptides*), which are used to assemble the total molecule, are present at both ends, later to be removed. As chain synthesis proceeds and the polypeptide moves into the cisternae of the endoplasmic reticulum, various enzymes hydroxylate certain proline and lysine residues to hydroxyproline and hydroxylysine; ascorbic acid (vitamin C), molecular oxygen and other factors are needed for this step, so that vitamin C, iron deficiency and anoxia result in impaired collagen synthesis. Meanwhile, carbohydrate is attached to some hydroxylysine residues; then the three pro-α-chains associate at one end by means of their extension peptides, intertwining as cross-links are formed, to give the triple helix of the *procollagen molecule*. In this form, the molecules are transferred via the Golgi apparatus to the exterior in secretory vacuoles. Once outside, the extension peptides are removed by enzymes (procollagen peptidases) at the cell surface, so forming tropocollagen which aggregates spontaneously (given the correct ionic environment) to create collagen fibres, cross-linked at the lysine and hydroxylysine residues by the

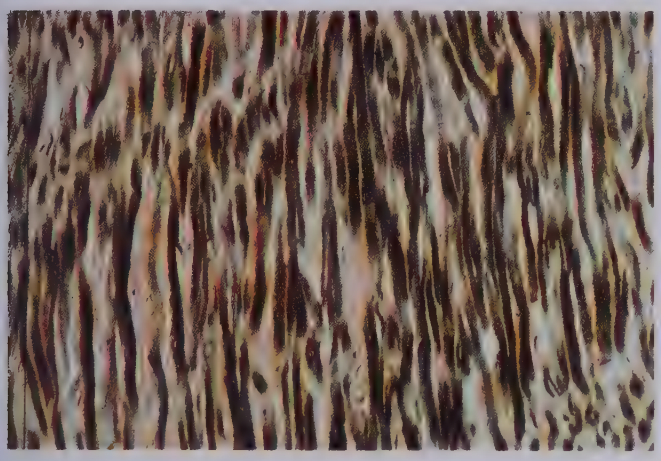
1.72 The organization of tropocollagen molecules in collagen (e.g. type I) and their spatial relationship to the appearance of banding patterns in a sectioned, positively stained fibril (left) and a negatively stained fibril (middle). The numbered segments of one tropocollagen unit indicate the degree of overlap.

1.73 A schematic diagram showing the major steps in collagen synthesis by fibroblasts in connective tissue.

action of an enzyme, lysyl oxidase, released by the cell. Tropocollagen molecules can be re-aggregated from acid solutions, in their characteristic pattern, by raising the *p*H to 7. The 67 nm banding pattern can, however, be altered by changing the glycosamino-glycan concentration.

The *direction* of fibre formation appears to be dependent on the stresses acting in the tissue. The relation between stress and the rate and direction of fibre formation is uncertain but may involve movement of fibroblasts along lines determined by piezo-electric currents consequent upon the deformation of pre-formed collagen fibres.

It is remarkable that in many situations collagen is laid down in a precise geometrical pattern, with successive layers regularly alternating in direction. This occurs in the cornea, where successive layers lie at 90° to each other, helping to provide the cornea with its mechanical and unique optical properties. Regularity of pattern exists also in ligaments, tendons, aponeuroses and connective tissue capsules, etc. (1.77.)



RETICULIN FIBRES

Fine branching and anastomosing reticulin fibres form the supporting framework of many glands, the kidney and the lymphoreticular tissues (lymph nodes, spleen, etc; e.g. see 6.175), also in association with basement membranes and often in the neighbourhood of collagen fibre bundles. Unlike other collagen fibres, reticulin takes up silver salts strongly but does not stain strongly with acid fuchsin.

Ultrastructurally reticulin shows a periodic banding which is identical with that of collagen, displays the same X-ray diffraction patterns and exhibits a similar chemical composition. It is now considered to be a type of collagen (Type III) with a particularly high degree of glycosylation (see p. 65). Fibroblasts are responsible for reticulin production in most or possibly all general connective tissues but are usually termed *'reticular cells'* when the amounts of reticulin are high.

ELASTIN FIBRES

These are less frequent than collagen fibres and are, in contrast, yellowish in colour and hence so are the tissues in which they abound. Elastin fibres (1.64,67,71E,74) branch and rejoin freely and are usually thinner (1.0–0.2 μm) than collagen fibres, although they can occur as thicker fibres, e.g. in the ligamenta flava, and sheets, as in the fenestrated elastic laminae of the aortic wall. Such fibres and laminae stretch easily, with an almost perfect recoil, Young's modulus of elasticity being 6×10^6 (Bergel 1961), although with advancing years they may calcify, losing elasticity.

1.74 Longitudinal section through an elastic ligament of an ox showing elastin fibres (black) interspersed with collagen fibres. Verhoeff's and van Gieson's stains. Magnification × 200.

Elastin fibres are highly resistant to hydrolysis in aqueous solutions of high or low *p*H, or boiling water, and to treatment with organic solvents. However, crude preparations of trypsin which contain the enzyme *elastase* and bacterial elastases are capable of dissociating the fibre structure.

Elastin fibres can be stained with orcein, with Weigert's resorcin-fuchsin and with Verhoeff's stain. The fibres display only weak or no birefringence when unstretched, indicating a lack of regular orientation but become strongly birefringent when stretched, indicating the rearrangement of its molecules (strain birefringence).

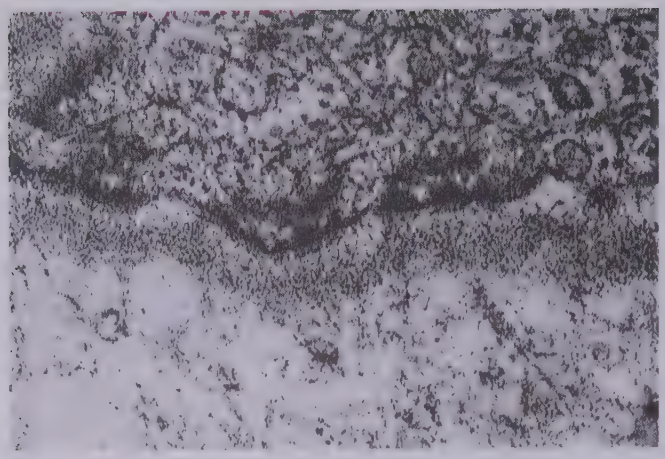
Seen by electron microscopy, the fibres are composed chiefly of the relatively amorphous protein *elastin* surrounded by fibrils, about 10 nm thick, the 'elastic tissue microfibrillar component' (Sandberg et al 1981). Also frequently present are thin (10–12 nm) filaments of two related proteins (which can be considered as types of elastin): *oxytalan* and *elaunin*; these appear to have similar elastic properties but give some different staining reactions (see Braverman & Fonferko 1982). Traces of collagen, proteoglycans and lipid may also be associated with elastin. Elastin itself is composed of subunits of *tropo-elastin* which have an *M*r of 7000. These subunits are believed to consist of unfolded irregularly coiled polypeptide chains ('random coils'), strongly cross-linked in a three-dimensional network, allowing deformation with storage of mechanical energy when stretched, and recoil. Chemically, elastin contains a high content of the amino acids, valine and alanine, and another named desmosine, which is apparently unique to elastin and has a complex mode of synthesis (see Siegel 1979) involving the enzyme lysyl oxidase. In connective tissue, fibroblasts are responsible for elastin formation, although fibres and sheets of elastin can also be formed by smooth muscle cells. During their formation, the microfibrillar component is laid down first, providing a scaffolding on which the more amorphous elastin is deposited (see Serafini-Fracassini & Smith 1974, Bradamante & Svajger 1977).

THE GROUND SUBSTANCE

This is the non-fibrous part of the matrix, in which cells and fibres are embedded (**1**.64,65). Except in mineralized connective tissue, the ground substance is a viscous gel containing a high proportion of water, bound largely to long-chain carbohydrate molecules and protein–carbohydrate complexes. Two major classes of such molecules exist, the *proteoglycans* and the *structural glycoproteins*, both being combinations of carbohydrate and protein.

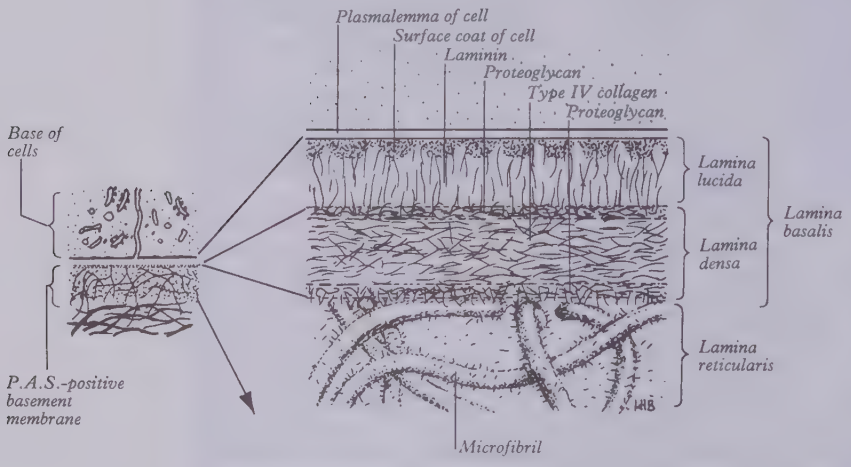
In **proteoglycans**, the carbohydrate is mainly in the form of glycosaminoglycan (GAG) molecules, long unbranched polymers of repeating disaccharides, each unit being a hexosamine residue bearing an acetyl group and a hexuronate or galactosyl residue (Hascall & Hascall 1981). The disaccharide may also bear either a carboxyl or a sulphuric ester group, conferring a strong negative charge on the whole polymer which acts as a poly-anion and therefore can be stained with cationic dyes such as Hale's colloidal iron, alcian blue and various metachromatic stains.

Such molecules range from 6000 to several million in relative molecular mass (*M*r). Because of their complex structure, wide variations in chemistry are possible and various combinations of these molecules can occur at any one site. In tissues, they are almost always found in combination with long filamentous proteins, these complexes being termed glycoproteins or proteoglycans depending on the ratio of the two compounds. A more detailed account of these and other ground substance components is given on p. 285.



The principal glycosaminoglycans are: chondroitin 4-sulphate and chondroitin 6-sulphate (chondroitin sulphates A and C), hyaluronate, dermatan sulphate (chondroitin sulphate B), keratan sulphate and heparan sulphate. All of these, except sometimes the hyaluronate, a huge randomly coiled molecule several million daltons in molecular weight, are normally attached to a core protein from which they extend like bristles on a brush, being repelled from each other by their negative charges. These GAG-protein units may be further grouped as even larger complexes by attachment to hyaluronate molecules; another *link* protein is necessary for this to occur. Such arrangements are usually highly viscous because of the formation of complex three-dimensional networks capable of binding water strongly. This water component is of great importance in facilitating diffusion of metabolites, electrolytes and gases between the capillaries and the cells embedded within the ground substance. The presence of negative charges determines their ion-binding power and they thus act as selective barriers to the passage of inorganic ions and charged molecules.

Structural glycoproteins (Yamada 1981) are filamentous proteins bearing small carbohydrate side-groups; they are important in the adhesion of cells to other matrix components and in general cell–matrix interactions of various kinds. They include *laminin* (*M*r: 220 000 – 800 000, depending on its aggregation of subunits), present in the lamina lucida of basal laminae of a wide variety of cells, and *fibronectin* (*M*r: 450 000) which is found both in the blood plasma (plasma fibronectin) and the connective tissue matrix and appears to act as a glue between different matrix components and between these and fibroblasts (see Hynes 1986); similarly *chondronectin* is a specific adhesive between chondroblasts and type II collagen (p. 286) and *osteonectin* has a similar role in bone (p. 296). Many other tissues may have similar specific adhesion molecules (see, e.g. p. 918).



Because of its high viscosity the ground substance also forms a mechanical barrier; some bacteria secrete the enzyme hyaluronidase which decreases its viscosity, so facilitating the spread of the organisms. The matrix is synthesized by fibroblasts (also by osteoblasts, chondroblasts and, in some sites, by smooth muscle cells) within the granular endoplasmic reticulum and Golgi complex. Its production may be affected by hormones, as shown e.g. in hypothyroidism, when much ground substance may be generated (myxoedema). The ground substance is difficult to demonstrate structurally since it is often highly soluble in water. At the ultrastructural level, fixation and dehydration usually cause the collapse of the large feathery proteoglycan complexes into dense granules, although isolated, negatively stained molecules show the highly extended condition well (see **3**.16).

BASEMENT MEMBRANES

These are laminae of dense amorphous material (**1**.75) which vary in thickness and are associated with many types of cell embedded in or adjacent to connective tissue (e.g. Schwann cells, muscle cells, capillary endothelium and epithelia in general). In some situations they may be particularly thick and so, incidentally, easier to investigate, as in the glomerular membrane of the kidney, the lens capsule, the anterior limiting (Descemet's) membrane in the cornea and Reichert's membrane in the placenta of certain mammals (see Kefalides 1973, Heathcote & Grant 1982).

1.75A Section through the base of the epidermis (human) showing the basal lamina. Visible are the lamina lucida just below the dense plasmalemma of the overlying cell and the thick fuzzy lamina densa, below which is the paler area of the connective tissue matrix containing a few microfibrils in section. Also shown are several hemidesmosomes with filamentous connections crossing the lamina lucida. Compare with 1.75B. Magnification × 60 000.

1.75B The arrangement of the components of a basal lamina, as currently envisaged. In this case the basal lamina of the epidermis is illustrated for comparison with 1.75A. Note that some of the structures depicted in this diagram are based on cytochemical data and are not visible in routine electron micrographs.

Such membranes may form supporting layers for cell attachment, to restrict the passage of large molecules and to anchor the adjacent cells to connective tissue fibres. There is much current research on the more complex roles of this structure in determining metabolic and behavioural patterns of the cells contacting them, a function of great importance in directing the development, maintenance and regeneration of tissues. Changes in their thickness are also often associated with pathological conditions, as in the thickening of the glomerular membrane in glomerulonephritis and diabetes, although it is difficult to allot causes and effects in such cases.

Ultrastructurally, the basement membrane usually consists of two zones: a *basal lamina* lying close to the plasma membranes of the neighbouring cell layer, and a more diffuse *reticular lamina* which merges into the adjacent connective tissue matrix. The basal lamina is usually about 80 nm thick and consists of a fibrillar layer, the *lamina densa* (20–50 nm wide), with an electron-lucent zone, the *lamina lucida*, intervening between the adjacent cell membrane and the lamina densa (see, e.g., Stanley et al 1982). The lamina lucida shows granular or fibrillar features, regularly spaced. The lamina densa is composed chiefly of a delicate network of type IV collagen fibrils and heparan sulphate proteoglycan, whereas the lamina lucida has been shown to contain laminin, fibronectin and various proteoglycans; amongst other activities these latter three groups of molecules may be important in the adhesion of cells to the basal lamina and adhesion of the basal lamina to the connective tissue matrix. These and perhaps other molecules may also carry information which can guide or otherwise affect the cells they adhere to during morphogenesis and subsequent life. Recently there has been much interest in their role in regeneration in the peripheral nervous system after injury (p. 903) when basal lamina components appear to be involved in guiding outgrowth of axons and the re-establishment of neuromuscular junctions.

Although all basal laminae have a similar form, their detailed organization varies with their site. At the epidermal-dermal junction, special glycoproteins are present in the lamina lucida (see p. 78) and special adhesive plaques (hemidesmosomes, p. 79) also anchor the neighbouring keratinocytes to the lamina densa. The kidney glomerular basal lamina is unusual in having a lucent zone on both sides of the lamina densa (laminae rarae interna and externa) and in various other features associated with the specialized filtering functions of this structure (p. 1401).

The *reticular lamina* is composed of condensed connective tissue matrix including a reticulum of fine collagen (not type IV) in the form of reticulin fibres; this layer may be quite thick and is the main component of the total basement membrane which can be demonstrated at the light microscope level with such staining techniques as the PAS method.

The basal lamina appears to be formed, in most cases, entirely by the adjacent cell layer (epithelium, endothelium, etc.), whereas the reticular lamina is, of course, of fibroblast origin.

Types of Connective Tissue

The connective tissues differ considerably in appearance, consistency and composition in different regions according to the local functional requirements. These differences are related to the predominance or otherwise of one or other of the cell types, the concentration, arrangement and types of fibre and the character of the ground substance. On these bases, *ordinary connective tissues* can be classified into *irregular* and *regular* types, distinguished by the absence or presence of a high degree of orientation in their fibrous elements.

IRREGULAR CONNECTIVE TISSUES

These can be further subdivided into *loose*, *dense* and *adipose*.

Loose (areolar) connective tissue (1.64,67) is the most generalized form. It is extensively distributed and its chief use is

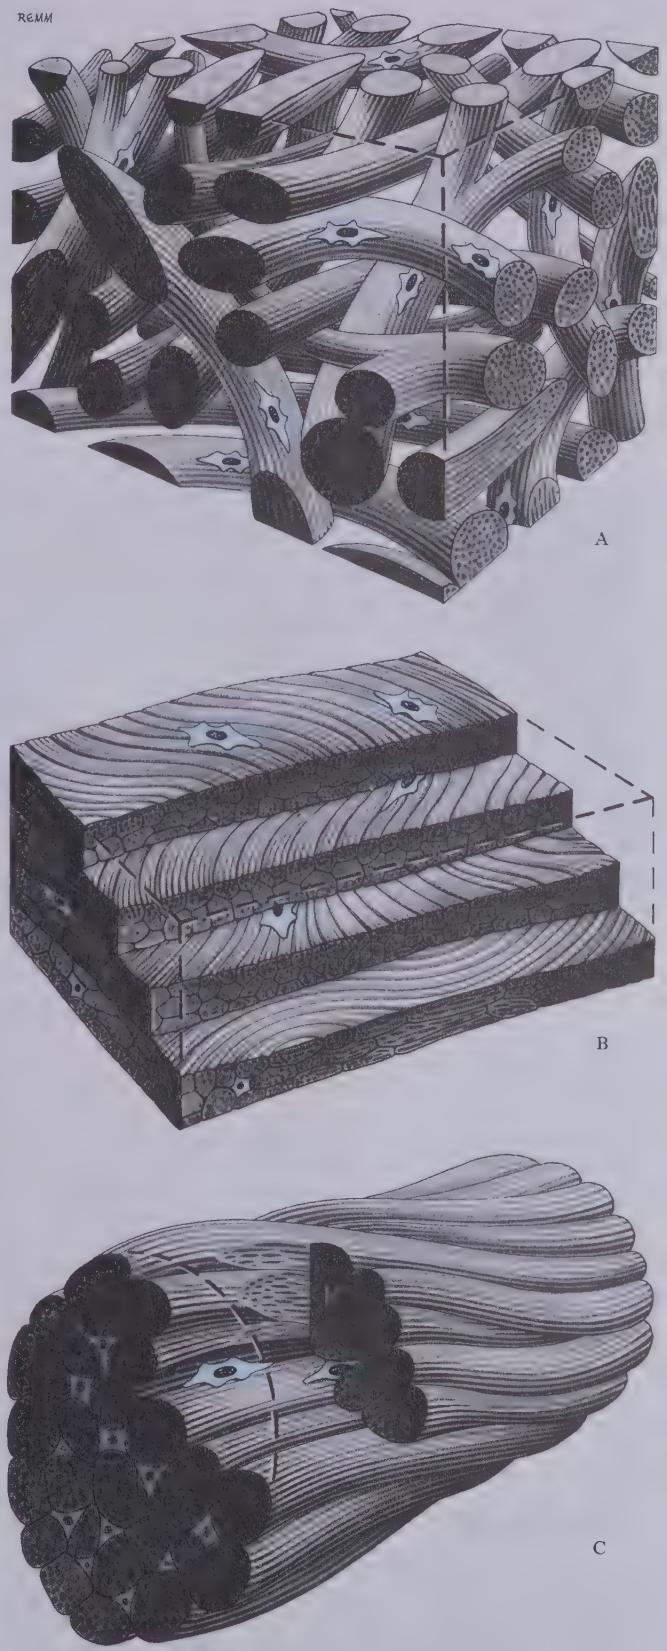
1.76 Scanning electron micrograph of dense irregular connective tissue (human dermis) showing the complex interwoven nature of its fibrous matrix. Magnification × 1000.

to bind parts together, though allowing a considerably amount of movement to take place because of its elasticity. It occurs as the submucous coat in the digestive tract and as subserous tissue. It forms the subcutaneous tissue in regions where this is devoid of fat as in the eyelids, penis, the scrotum and labia. It is also found between muscles, vessels and nerves, forming their investing sheaths and connecting them with surrounding structures. It is present in the interior of organs, binding together the lobes and lobules of the compound glands, the various coats of the hollow viscera and muscle and nerve fibres.

Loose connective tissue consists of a meshwork of thin collagen and elastin fibres interlacing in all directions to give a measure of both elasticity and tensile strength. The large meshes contain the soft, pliable semifluid ground substance and the different connective tissue cells, scattered along the fibres or in the meshes. Occasional adipocytes, usually in small groups, are seen, particularly around blood vessels.

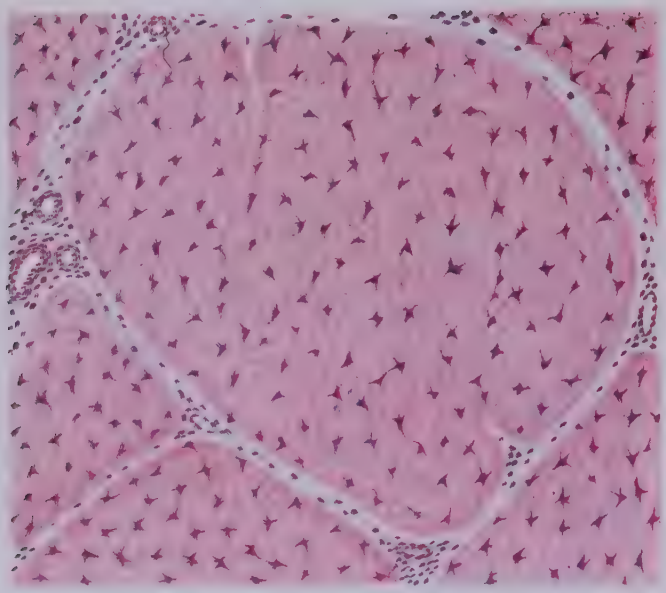
Dense irregular connective tissue is found in regions which experience considerable mechanical stress and where protection is given to ensheathed organs. The matrix contains a high proportion of collagen fibres which form thick bundles (1.76,77,81,85) interweaving in three dimensions and giving considerable strength. Active fibroblasts are few in number and most are flattened with heterochromatic nuclei. The vascular supply is limited, as might be expected.

Examples may be found in the reticular layer of the dermis, the connective tissue sheaths of muscle and nerves and the adventitia of large blood vessels. The capsules of various glands, the coverings of various organs such as the penis and testes, the sclera of the eye and periostea and perichondria are all composed of dense irregular connective tissue.



Adipose tissue. A few fat cells occur in loose connective tissue in most parts of the body. However, in adipose tissue (1.69) these occur in great abundance and constitute the principal component. Adipose tissue occurs only in certain regions and this selective distribution suggests that the fat is deposited in genetically determined sites. It occurs in abundance in subcutaneous tissue, which is sometimes referred to as the *panniculus adiposus*, around the kidneys, in the mesenteries and omenta, in the female breast, in the orbit behind the eyeball, in the marrow of bones and as localized pads in the synovial membrane of many joints. Its distribution in subcutaneous tissue shows characteristic age and sex differences.

Adipose tissue consists of adipocytes (p. 61) embedded in a vascular areolar tissue, which is usually divided into lobules by stronger fibrous septa carrying the larger blood vessels, whence each lobule receives an independent blood supply. Within the lobules the fat cells are round or, when mutually compressed, polygonal. Areolar tissue and septa both contain the other cellular components of fibrous tissue. These fat deposits serve as energy stores, sources of metabolic lipids, thermal insulation (subcutaneous fat), mechanical shock-absorbers (e.g. soles of the feet, palms of hands, gluteal fat, synovial membranes etc.), and may also serve more complex, cosmetic or behavioural functions. In some regions the connective tissue framework of the fatty tissue often contains large amounts of elastic tissue and in emaciation these deposits tend to be spared until a late stage, where mechanically important, e.g. plantar and palmar superficial fasciae, perirenal fat. In the newborn human, as in many adult lower mammals, there are areas of specialized *brown fat*, which is capable of generating heat by the breakdown of nutrients in unusual mitochondria (see also pp. 26, 62).

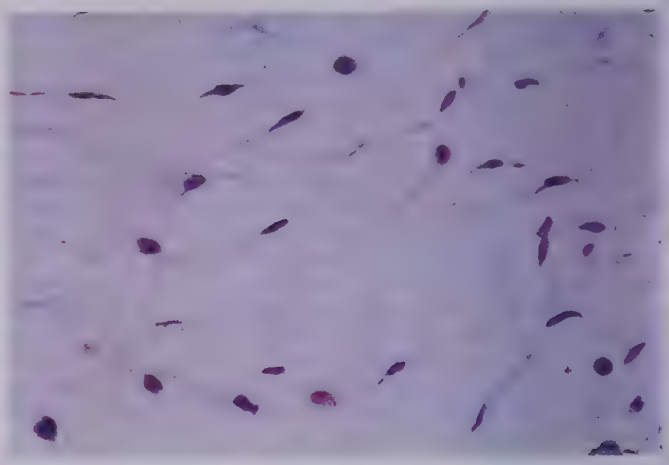


REGULAR CONNECTIVE TISSUE

This includes those highly fibrous tissues with fibres regularly orientated, either to form sheets such as fasciae and aponeuroses, or thicker bundles as ligaments or tendons (1.77,78). The direction of the fibres within such structures is related to the stresses which they undergo but there is considerable interweaving of fibrous bundles, even within tendons, which increases their structural stability and resilience.

The fibroblasts which secrete the fibres may eventually become trapped within the fibrous structure, where they are compressed, and present highly angular outlines. Cross-sections of tendons show inactive fibroblasts with stellate profiles and small heterochromatic nuclei. Fibroblasts on the external surface may be active in continued fibre formation and they afford a pool of cells able to repair damage (see McMinn 1969).

1.77 Three types of arrangement of collagen fibres in: (A) dense irregular connective tissue; (B) a ligament; (C) a tendon.



1.78A Transverse section of a tendon showing fibrocytes enclosed between bundles of collagen fibres.

1.78B Longitudinal section through a tendon, showing the parallel organization of its collagen fibres. A few long, flattened fibrocyte nuclei are also visible. Haematoxylin and eosin. Magnification × 200.

Regular connective tissue is predominantly collagenous but in some ligaments elastic components also occur, as in the ligamenta flava of the vertebral laminae and in the vocal folds. Some elastin is also present between the collagen lamellae of many other ligaments and fasciae. In other sites, the collagen fibres may form precise geometrical patterns, as in the cornea (see p. 1183).

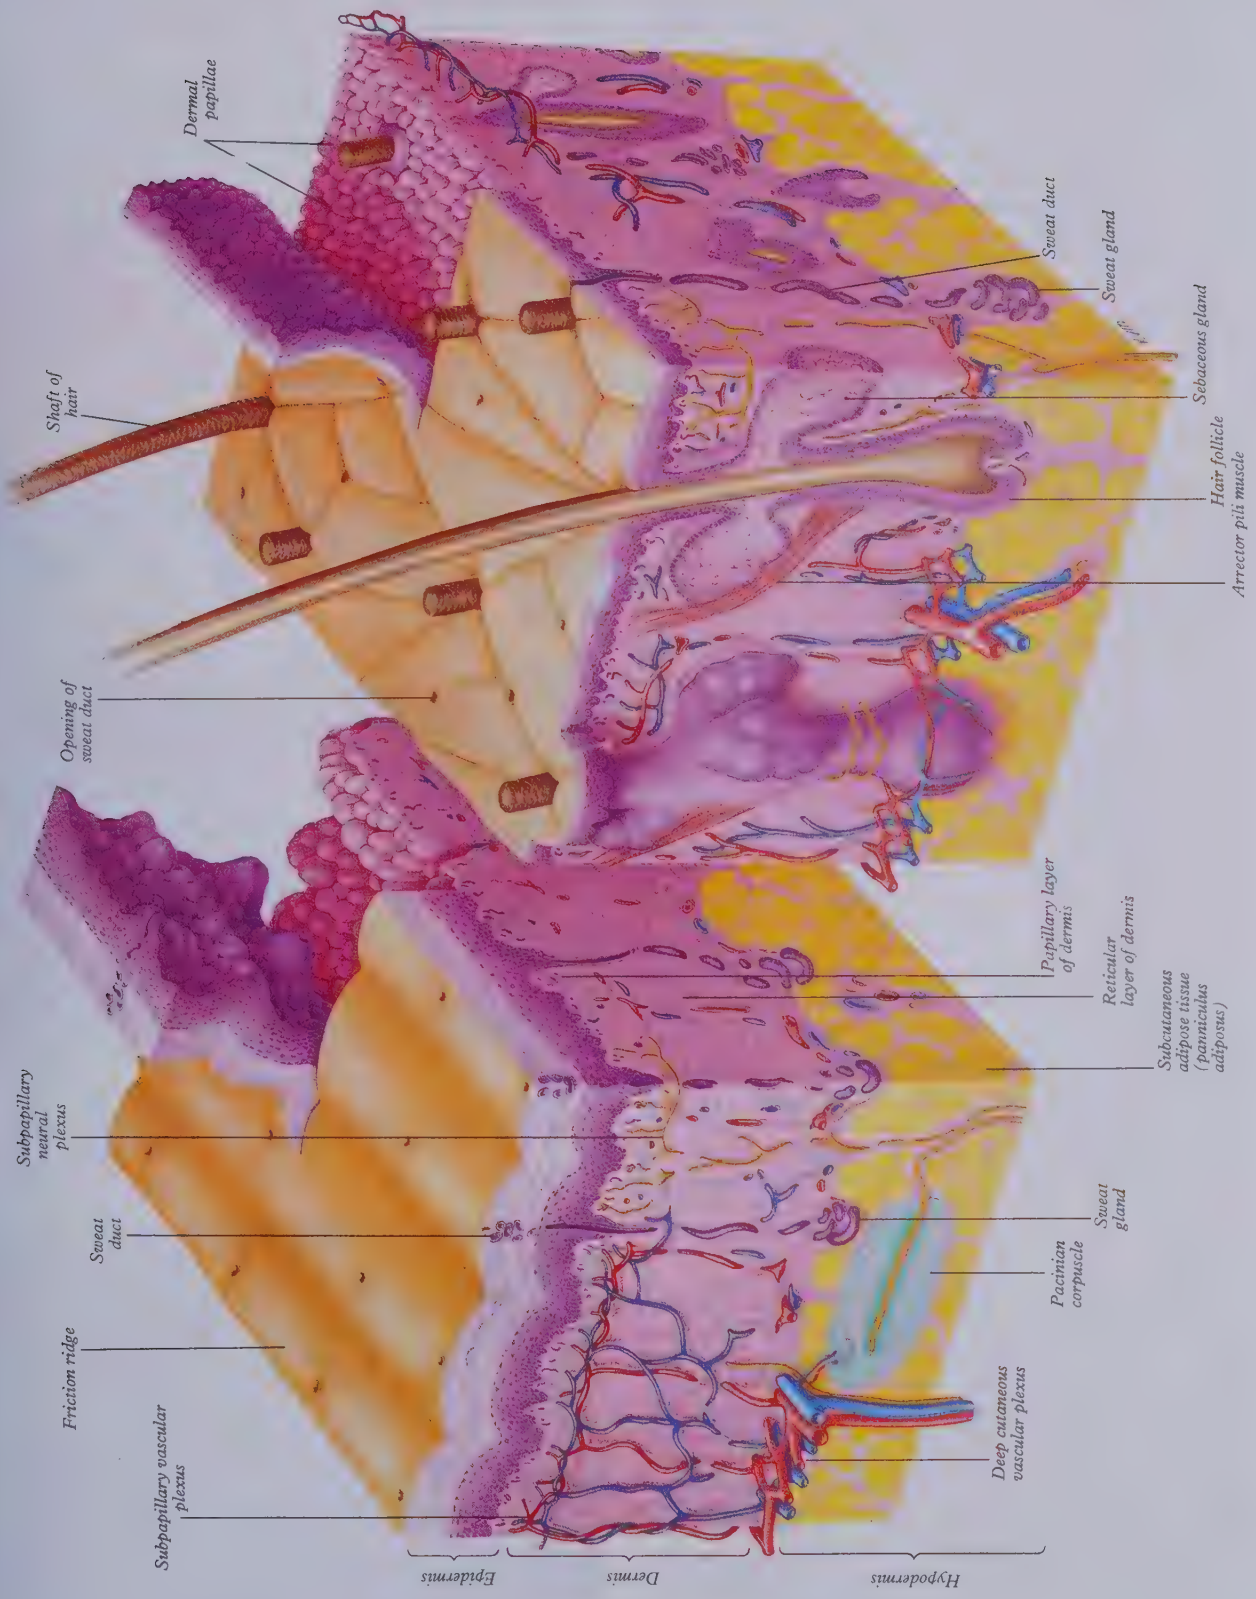
Mucoid tissue is a fetal or embryonic type of connective tissue (1.79), found chiefly as a stage in the development of connective tissue from mesenchyme. It exists in the 'jelly of Wharton', which forms the bulk of the umbilical cord, and consists of a copious matrix, largely made up of hydrated 'mucosubstances' and a

1.79 A section of fetal mesenchyme showing mucoid tissue sparsely populated with cells. Magnification × 500.

fine meshwork of collagen fibres, in which nucleated cells with branching process (probably fibroblasts) are found (Boyd & Hamilton 1970). However, the stellate appearance of the cells in Wharton's jelly probably results from fixation and staining of excised cords which have suffered a haemodynamic collapse (Parry 1970). When this is avoided the cells are aligned and strap-like. Such findings may well apply to other situations in which mucoid tissue is found. Usually few fibres occur in typical mucoid tissue, though at birth the umbilical cord shows a considerable development of perivascular collagen fibres; after birth it is still to be seen in the pulp of a developing tooth. In the adult the vitreous body of the eye is a persistent form of mucoid tissue in which the fibres and cells are very few in number, and the nucleus pulposus of the intervertebral disc is similar.

Pigmented connective tissue, such as occurs in the choroid and in the lamina fusca of the sclera of the eye, is composed of loose connective tissue, in which large numbers of pigment cells (melanocytes) are also present.

VESSELS AND NERVES OF CONNECTIVE TISSUE



Generally, few blood vessels supply the tissue itself, the numbers of cells and therefore the metabolic demand being relatively low, although many blood vessels may pass through *en route* for other tissues, as in loose connective tissue. In dense collagenous or elastic tissues the blood vessels usually run parallel to and between the longitudinal bundles, sending communicating branches across the bundles; in some of its forms, as in the periosteum and dura mater, they are fairly numerous. *Lymphatic vessels* are very numerous in most forms of connective tissue, especially in the loose tissue beneath the skin and the mucous and serous surfaces. They also occur abundantly in the sheaths of tendons, as well as in the tendons themselves. *Nerve* endings of various kinds also terminate in connective tissues and provide sensory innervation detecting mechanical stresses, painful stimuli and thermal changes (see p. 902).

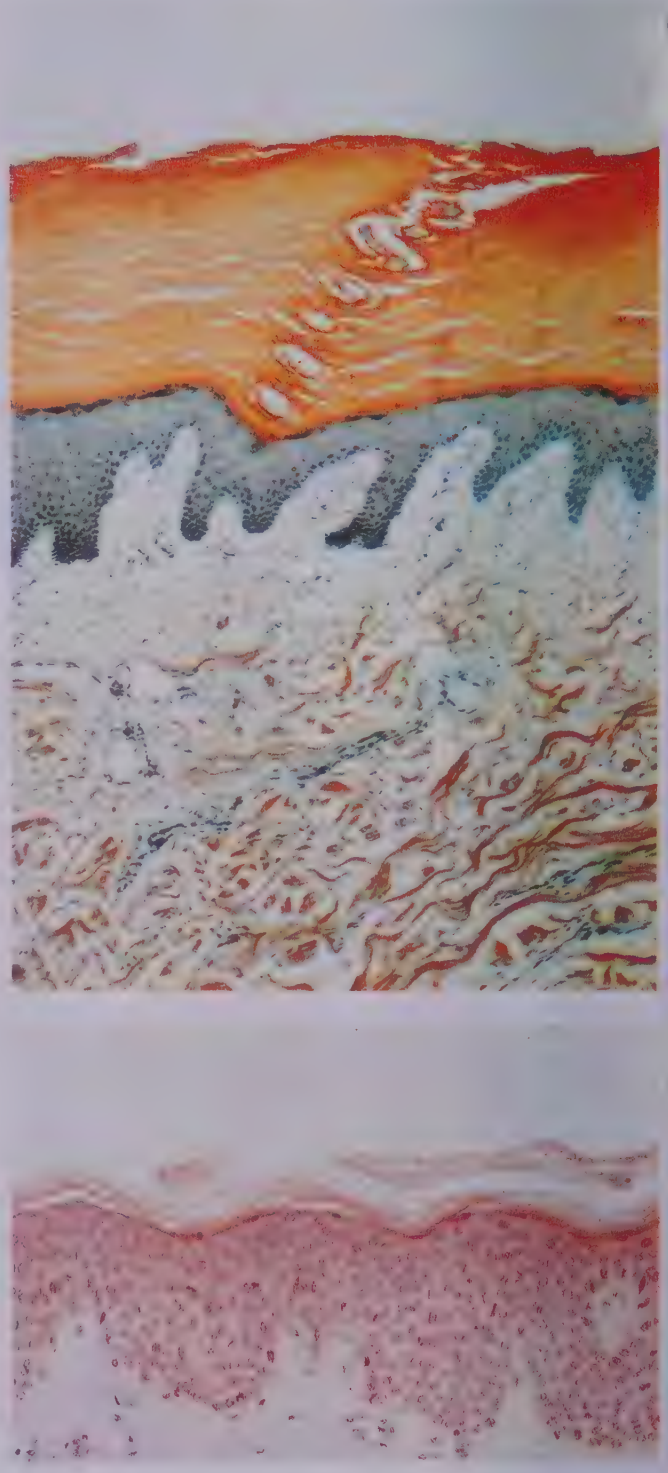
THE INTEGUMENT

Introduction

The integument, or skin (cutis) is an anatomically and physiologically specialized boundary lamina essential to life. It is a major organ of the body, forming about 8% of its total mass and having an area of between 1.2–2.2 m^2. In total thickness it ranges from about 1.5–4.0 mm. Skin covers the entire external surface of the body, including the external auditory meatus and the lateral aspect of the tympanic membrane. It is continuous with the mucosae of the alimentary, respiratory and urinogenital tracts at their respective orifices, where the specialized skin of mucocutaneous junctions occur; it also fuses with the conjunctiva at the margins of the eyelids and with the lining of the lacrimal canaliculi at the lacrimal puncta.

Structurally, skin is complex and highly specialized, as might be expected of the major interface between the body and its

1.80 Schema showing the organization of skin, comparing the structures present in thick, hairless (plantar and palmar) skin and thin, hirsute skin. The epidermis has been partly peeled back in this picture, to show interdigitating dermal and epidermal papillae. For details of the innervation (yellow), see p. 912.



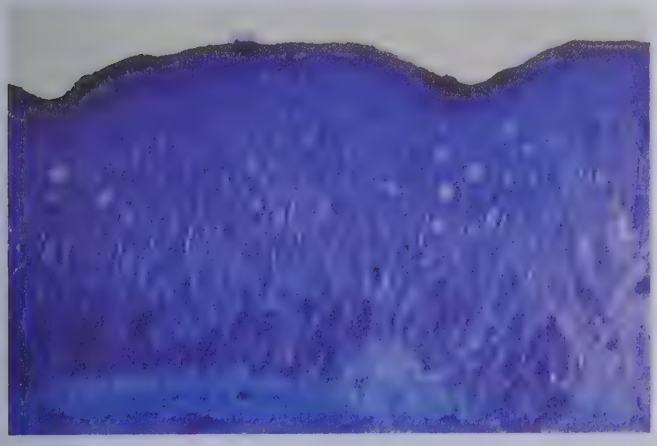
environment (see the reviews by Montagna 1968, Jakubovic & Ackerman 1985). Microscopically, it is formed as an intimate association between two distinct tissues: keratinized stratified squamous epithelium superficially, the *epidermis*, and a deeper layer of moderately dense connective tissue, the *dermis* (1.80,81). Because of this combination, it is within limits a most effective barrier against microbial invasion and dehydration and against mechanical, chemical, osmotic, thermal and photic damage. It limits and regulates heat loss, is a major sensory surface with elaborate systems of varied receptor types, is capable of limited excretion and absorption and carries out many specialized biochemical functions, including the formation of Vitamin D_3 from precursor steroids under the action of ultraviolet light. Skin also has good frictional properties, assisting locomotion and manipulation by its texture. Its sensory endings provide a means for subtle social communication and, in the case of facial skin, it can signal emotional states by means of muscular and vascular responses. Normal hormonal changes can affect the appearance and function of specific areas of the integument, e.g. the activity of its glands and growth of hair. The state of health, age and many other aspects of life are also reflected in the condition of the skin, and so clinically its appearance is important in the diagnosis of a wide variety of pathologies.

The outer surface of skin is covered by various markings, some of them large and conspicuous and others delicate to the point of being microscopic (see Montagna & Lobitz 1968, Millington & Wilkinson 1983) or only revealed after manipulation or incision of the skin. These are often referred to collectively as *skin lines* and include: externally visible grooves of the epidermis, i.e. *flexure lines*, positioned near or opposite synovial joints; *tension lines* which form a delicate pattern of geometric shapes over the surface of thin, hairy skin; and *papillary ridges*, forming fields of parallel lines on the thick, hairless skin of hands and feet. There are also lines which appear when tension is removed from skin (*relaxation lines*) and lines or bands which may appear after rapid local expansion of underlying structures, e.g. during pregnancy (*striae gravidarum*), etc. Pigmentation of the skin also varies in amount, type and distribution, with the occurrence in some races of abrupt boundary lines between darker and lighter areas on the upper limbs (Voigt lines) and, in young children, of blue-grey patches ('mongolian spots') on the trunk. Small, localized accumulations of pigment cells in the epidermis are *naevi* (moles). More hidden variations in structure are also revealed when skin is incised, a factor of importance in surgery (Langer's lines). These markings are considered in greater detail on pp. 80–82.

In addition to these variations, the appearance of skin is also affected by many other factors, e.g. size and shape and distribution of hairs and their follicles, of skin glands (sudorific, sebaceous and apocrine, see pp. 92–94), changes associated with maturation, ageing, metabolic changes, pregnancy and many other considerations.

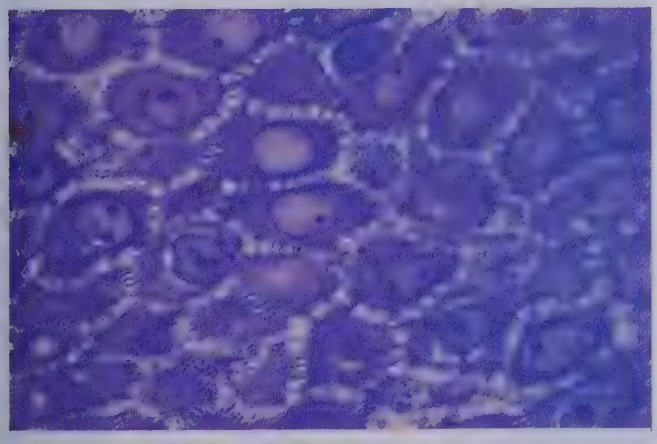
Types of Skin

Although skin over the entire body is fundamentally of similar structure, there are many local variations in thickness, mechanical strength, degree of keratinization, sizes and numbers of hairs, frequency and types of glands, pigmentation, vascularity, innervation and other features. However, it is useful to distinguish between two major classes of skin which cover large areas of the body, but show important differences of detailed structure and functional properties; these are *thin, hairy (hirsute) skin*, which constitutes the great majority of the body's covering, and *thick, hairless (glabrous) skin* forming the surfaces of the palms of the hands, soles of the feet and flexor surfaces of the digits (1.80, 81,86–89). As mentioned above, these two classes differ in their surface markings, thick skin having complex patterns of friction ridges absent elsewhere on the body. As implied by their names, they also differ in thickness of both epidermal and dermal components, and in the presence or absence of hairs with attendant sebaceous glands and arrector pili muscles ('pilo-sebaceous units'). These dissimilarities reflect their distinctive functions. Thick hairless skin forms frictional surfaces for manipulation and locomotion and requires extra strength and numerous sweat glands for cooling during sustained activity (a design feature perhaps more appreciated in warmer climates) and dense clusters of sensitive sensory endings with spatial discrimination unimpeded by the presence of hairs. Thin hairy skin is responsible for the general cutaneous functions over the remainder of the body.



1.81 A. Low-power light micrograph of a vertical section through skin from the sole of the human foot: Mallory's triple stain. The finer collagen fibres of the papillary and reticular layers are stained blue and the coarser collagen of the reticular layer stains red. The epidermis is differentiated into the stratum corneum and stratum lucidum above (red-brown) and the strata basale, spinosum and granulosum, which stain blue-grey. A spiral duct from a sweat gland is also seen in vertical section. The base of the epidermis is irregularly ridged. B. Vertical section through the epidermis of the scalp between hair follicles. Note the reduced keratinized layer (compare with A). Haematoxylin and eosin. Magnifications: A × 150; B × 200

Minor areas of skin also have special features which do not fall into either of the major categories. The *mucocutaneous junctions* of the lips, outer rim of the anal canal and urethral openings each have a characteristic histology; e.g. the lips have a delicate epidermis lacking glands or hairs, as also does the covering of the glans penis and glans clitoridis.



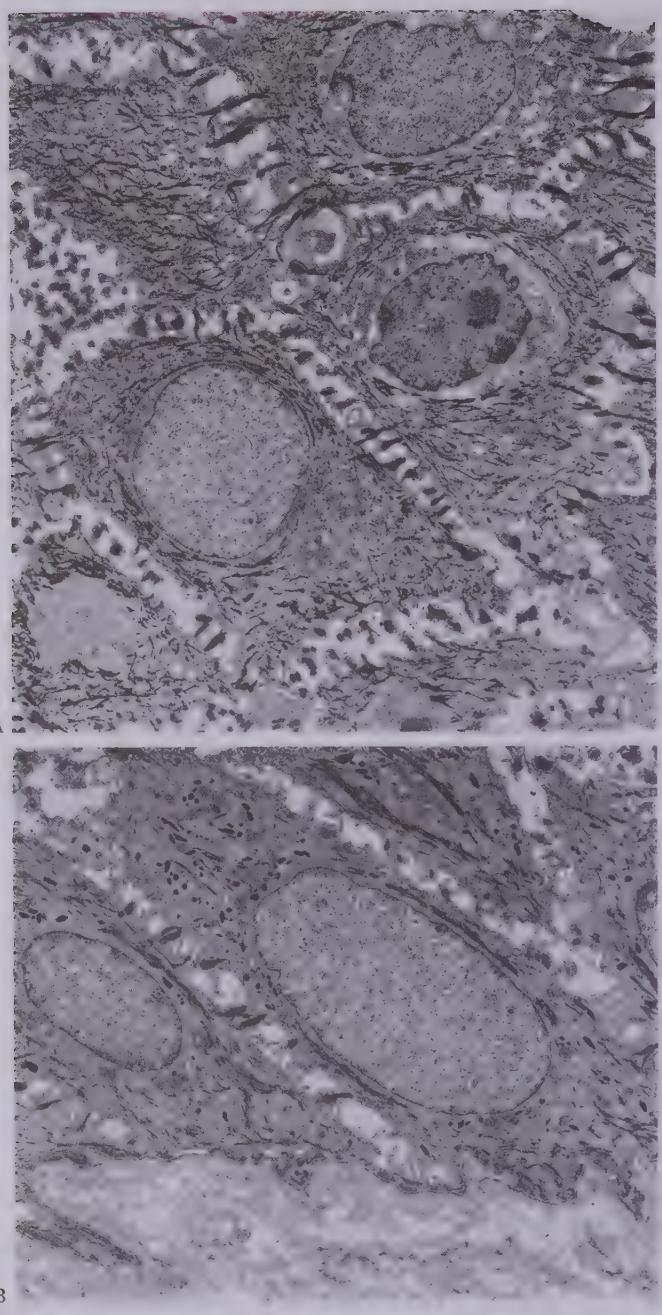
Microscopic Structure of Skin

THE EPIDERMIS

The epidermis (1.80–85) is composed of keratinized stratified squamous epithelium (p. 55). In this tissue there is a continuous replacement of cells, a mitotic layer at the base replacing cells shed at the surface. As they move away from the base of the epidermis, they undergo progressive changes in shape and content, eventually transforming from polygonal living cells to dead, flattened squames full of the protein keratin. The cells which differentiate in this way are called *keratinocytes*, but there are also other less numerous cell types in the epidermis not engaging in constant replacement. These include pigment-forming *melanocytes*, phagocytic *Langerhans cells* and neurally-associated *Merkel cells*. It is usual to divide the epidermis into a number of strata, representing different stages in keratinocyte maturation from deep to superficial as follows: stratum basale, stratum spinosum, stratum granulosum, stratum lucidum (where present) and stratum corneum. The first three of these layers are metabolically active and are often grouped together as the *germinative zone* or *stratum Malpighii*. The more superficial strata of cells achieving terminal keratinization constitute the *cornified zone*. The term stratum germinativum is, however, quite commonly used as a synonym for the stratum basale, and stratum Mapighii for the stratum spinosum alone. We have not used these two collective names therefore in the present description and have treated each stratum separately. In addition to the different layers, various structures formed by ingrowth or other modifications of the epidermis (*epidermal appendages* or *adnexa*) include *glands* (sebaceous, sudorific, apocrine, ceruminous, tarsal, Meobomian glands, glands of Moll), *hair follicles*, *hairs* and *nails*. (For reviews of skin structure, see Montagna 1962, Breathnach 1971, Jakubovic & Ackerman 1985, Thody & Friedmann 1986.)

1.82A Section through human epidermis from the dorsum of the thorax. Note the cellular organization of its layers including the densely stained stratum corneum at the surface. Compare with 1.93. Epoxy resin section stained with toluidine blue. Magnification × 410.

1.82B High magnification of the same specimen shown in 1.82A showing part of the stratum spinosum. The keratinocytes are held together by numerous desmosomal contacts giving the characteristic spiny appearance of cells in this layer (compare with 1.82A and 1.83). Magnification × 1650.

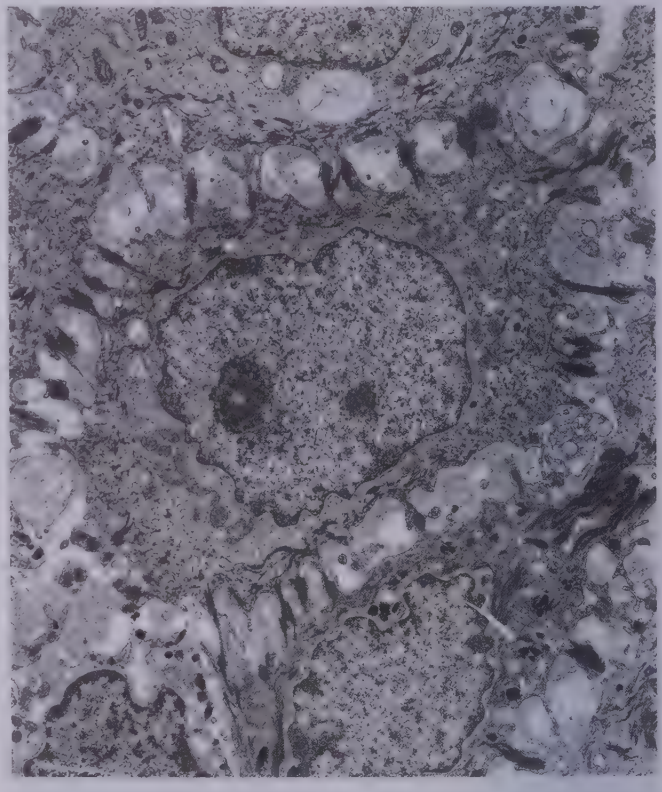


Epidermal Strata and Structural Maturation of Keratinocytes

The stratum basale includes the single layer of cells which lies in contact with the basal lamina. Keratinocytes are formed in this layer by division of a population of *stem cells*, then move apically, dividing again two or three times in the deeper regions of the stratum spinosum before ceasing mitotic activity (1.82–84). Structurally, the cells of the stratum basale are heterogeneous, since they comprise stem cells and keratinocytes in various stages of early maturation, as well as non-keratinocytes (vide infra). The majority of basal cells are columnar to cuboidal and are attached by hemidesmosomes to the basal lamina (p. 68). In most cases their basal surfaces are highly folded, interdigitating with projections of the basal lamina; some cells, however, have smoother bases and may constitute a separate group of keratinocytes with different turnover rates, present in epidermal papillae (Lavker & Sun 1982).

Ultrastructurally, basal cells have many free polyribosomes, many mitochondria and nuclei varying from euchromatic (in stem or young cells) to heterochromatic (older keratinocytes). They have many cytoskeletal filaments, including actin microfilaments and keratin filament bundles, some of them anchored to desmosomes or hemidesmosomes. Melanin granules are also present in many of these cells (vide infra).

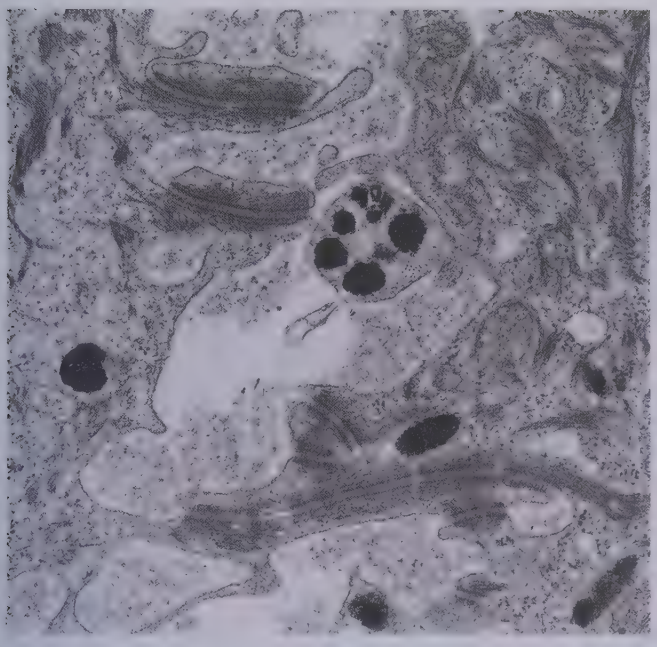
The stratum spinosum (prickle cell layer) contains more mature keratinocytes several layers deep, the cells packed closely and interdigitating by means of numerous projections and indentations at their surfaces which are linked by many desmosomes. Internally, these cells possess large numbers of keratin filament bundles (formerly termed tonofibrils or tonofilaments), many of them attached to desmosomes at the cell surface. Because the cells are anchored together in this way, this stratum provides much tensile strength and coherence to the surface of the integument. When skin is prepared for routine histology, these cells tend to shrink away from each other except where joined by their desmosomes, so giving them a spiny appearance (hence 'prickle cells' and the name of this stratum). The nuclei of these cells are moderately euchromatic, with prominent nucleoli. In the cytoplasm there are numerous polyribosomes and typically vacuoles containing melanin granules (melanosomes). In heavily pigmented skin, these may be numerous and each vacuole may have several granules within it. The melanin is derived from epidermal melanocytes (vide infra); the granules are most numerous in the deeper parts of this stratum and are gradually degraded by the keratinocytes so that in the surface layers they are usually absent.



The stratum granulosum. In this layer various changes already begun in the upper stratum spinosum accelerate dramatically and a drastic change in keratinocyte structure occurs. The cells become flattened and accumulate many large (up to 5 μm), dense, basophilic granules (*keratohyalin*). Their nuclei become pycnotic and begin to disintegrate and other cellular organelles degenerate. Ultrastructurally, such cells contain feltworks of keratin filament bundles enclosed or enmeshed by the irregular masses of densely staining *keratohyalin granules*. These appear to contain some carbohydrate and lipid, but the predominant material is a highly phosphorylated protein rich in the amino acid, histidine (*histidine-rich protein*, also called *stratum corneum basic*

1.83 Electron micrographs of human epidermis showing (A) a section through the stratum spinosum with several keratinocytes interconnected by desmosomal contacts attached intracellularly to interweaving bundles of keratin filaments; (B) a section through the stratum basale where it abuts the basal lamina and papillary layer of the dermis (below). Note the presence of numerous melanin granules in the epidermal cells. Magnification: A × 50 000, B × 7000.

1.83C Electron micrograph of human skin in vertical section. This shows the transition between the stratum spinosum (below), stratum granulosum (middle) and stratum corneum (the dark laminae above). The microfilamentous bundles of the keratinocytes, below, become denser and more compact in the stratum granulosum; finally the cells flatten, becoming scale-like and electron dense. Magnification × 8000.



1.83D Electron micrograph of a keratinocyte from the stratum spinosum showing details of its cytoplasmic and nuclear structure and the desmosomal attachments between cells. Magnification × 14 000.

protein or *profilaggrin* which eventually matures into the protein filaggrin: (vide infra). Also visible are smaller, finely granular *dense homogenous bodies* and elliptical membrane-bounded vacuoles, 0.1 by 0.3 μm in diameter, known as *membrane-coating granules, lamellar bodies* or *Odland bodies* (see the review by Hayward 1979), containing carbohydrate, lipid and hydrolytic enzymes, in the form of transverse or obliquely orientated lamellae. These eventually discharge their contents into the intercellular spaces of the upper layers of this stratum, creating a thick, waterproof layer of lamellar cement, rich in neutral lipids, between the cells of the stratum corneum.

The stratum lucidum. This layer is only found in thick, glabrous skin and represents a rather poorly understood stage in keratinization; characteristically, it stains more strongly than the stratum corneum with acidic dyes, is more refractile optically and often contains nuclear debris. Ultrastructurally, its cells closely resemble those of the stratum corneum.

The stratum corneum consists of closely packed layers of flattened, dead keratinocytes (*squames*). In thin skin, e.g. of the scalp, this stratum is only a few cells deep, but in thick skin it may be more than 50. The cells are compact and contain high concentrations of keratin filaments each about 8–10 nm thick, often lying parallel and 8 nm apart, and embedded in another protein, *filaggrin*, which is derived from histidine-rich protein. Disulphide bond formation appears to stabilize this protein complex.

1.83E Higher magnification of desmosomal contacts between adjacent keratinocytes. Note the oblique arrangement of desmosomes and the intracellular keratin filaments. Also visible between keratinocytes is a circular profile of a melanocyte dendrite containing dense melanosomes, some of which have also been endocytosed by neighbouring keratinocytes. Magnification × 25 000.

1.83F Scanning electron micrograph of a portion of the epidermal surface surrounding the aperture of a sweat duct. Several scale-like corneocytes, polygonal in form, are visible. Magnification × 2000.

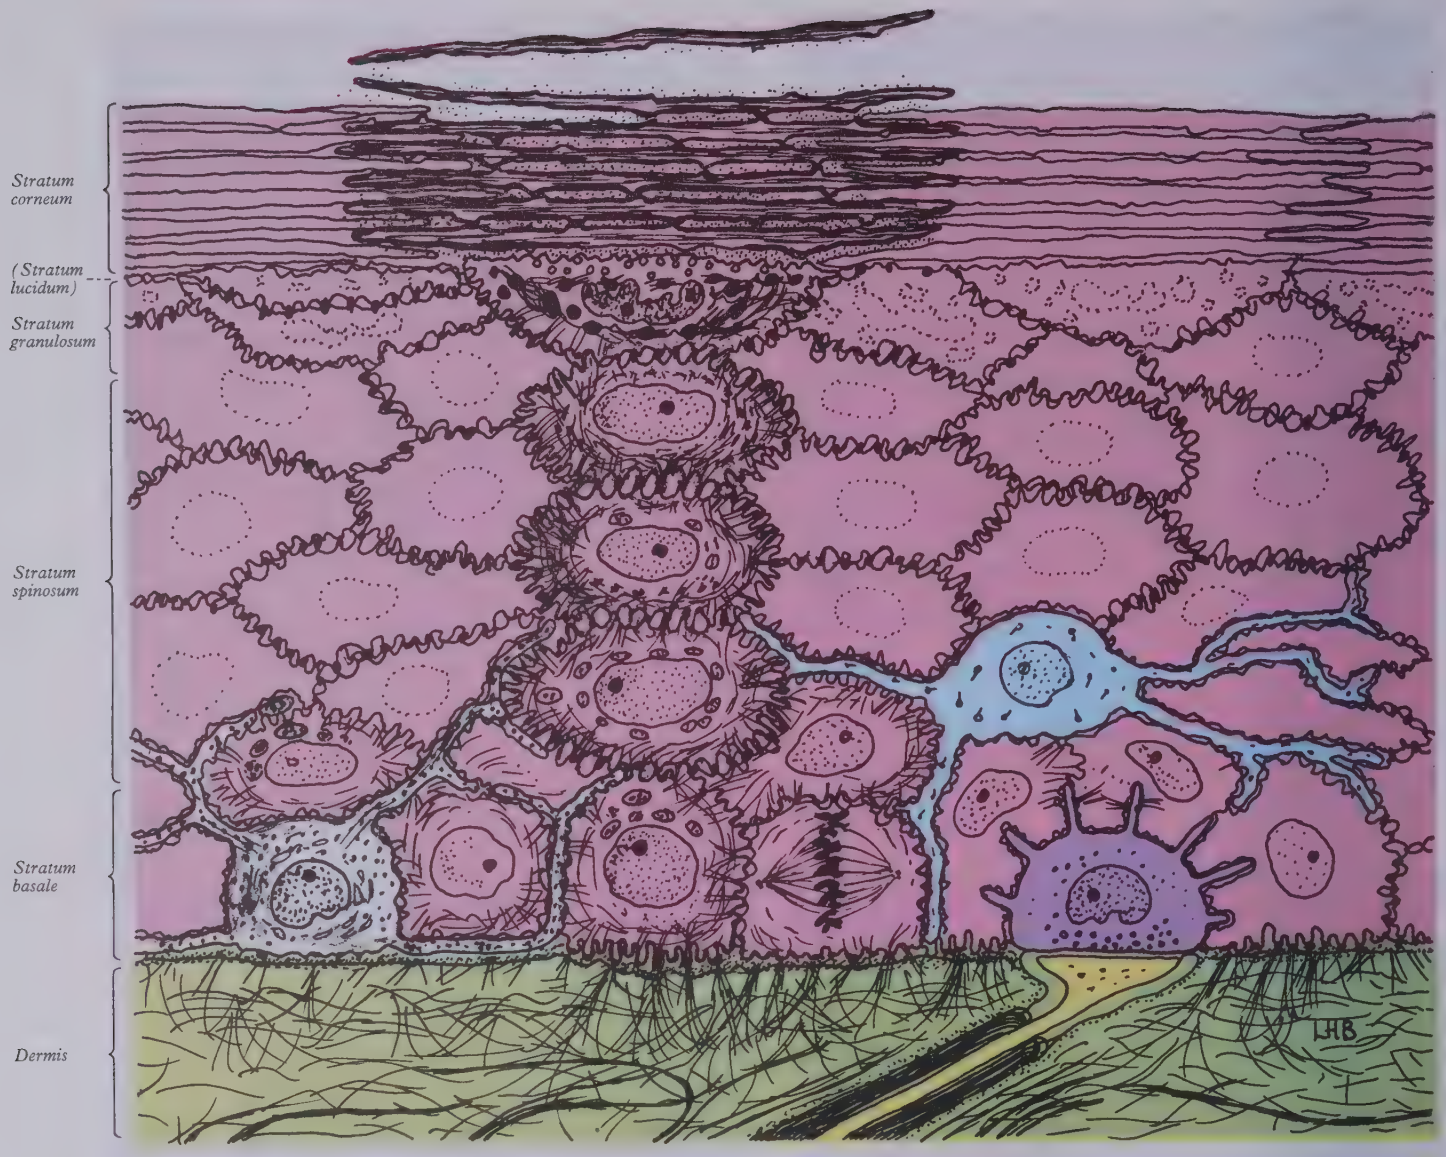
This regularity can be detected in whole skin preparations by X-ray diffraction studies and was known before the advent of electron microscopy.

The internal surface of the cell membrane is also coated with a dense 12 nm layer, the *protein envelope*, composed of a number of highly cross-linked, chemically inert proteins including *keratolinin* and *involucrin* (*M*r 36 000 and 140 000 respectively) which are probably derived from the dense homogeneous bodies of the stratum granulosum. The intercellular space is filled with a thick layer of lipidic cement (vide supra), crossed by occasional remaining desmosomes which persist from the deeper layers. Eventually the cells disengage from each other and become detached from the epidermal surface (desquamation). The causes of this event are not certain but may involve the activation of lipases released earlier from the membrane-coating granules.

The cells of this layer, *corneocytes*, are quite large, with a surface area ranging from about 800–1100 μm². They can be stripped away with adhesive tape for histological or chemical analysis.

Cell Turnover in the Epidermis

Disturbances in division and maturation rates are common in various skin diseases and have received close scrutiny in both normal and pathological states. In animal models, epidermal cell population dynamics can be analysed by pulse-labelling with [³H]-thymidine, with subsequent microautoradiography of sections to determine the position and degree of nuclear labelling. Human skin samples can also be cultured for short periods and examined in the same way. These and other studies have shown that replacement rates (i.e. the time taken for a newly-formed keratinocyte to pass to the surface and be shed) vary with body position, epidermal thickness, degree of skin abrasion, ambient temperature, time of day, hormonal changes, age and many other factors. Typical replacement times have been variously estimated to range in human skin from 45 to 75 days (Halprin 1972, Bergstresser & Taylor 1977), although they may be much lower than this in thinner epidermal regions. In some pathologies of the skin, turnover rates can be exceedingly rapid; e.g. in psoriasis it may be as little as eight days and in such cases the surface cells do not have time to keratinize properly so that the normal barrier functions of the skin break down.



The reasons for the shedding of keratinocytes are not known but it still occurs even if replacement from below ceases, e.g. when mitotic activity is inhibited.

Epidermal proliferative units (1.84B). If the epidermis of some mammalian species (e.g. rats) is treated with dilute alkali before histological sectioning, the cells of the stratum corneum swell and can then be seen to be stacked in regular columns. From this observation, coupled with autoradiographic analysis of cell division and migration within the epidermis, the concept of the Epidermal Proliferative Unit (EPU) arose (Potten 1975, 1983). According to this view, the whole epidermis is a mosaic of prismatically-shaped territories, each resting on the basal lamina and extending to the epidermal surface. In the stratum basale at the base of each prism is a group of about eight cells capable of mitosis, surrounding a single *primary stem cell* from which they and all the keratinocytes in the overlying column are derived; a single Langerhans cell lies close to the primary stem cell, perhaps directing local mitotic activity. This cluster of basal cells and Langerhans cell together constitutes the Epidermal Proliferative Unit (EPU).

According to this theory, repeated divisions of the primary stem cell give rise to an encircling ring of basal cells which then migrate in sequence into the stratum spinosum, dividing two or three times as they do so ('amplification divisions'); they are thus viewed as *intermediate stem cells*. They then differentiate into non-mitotic keratinocytes and, after a variable period of transit within the stratum spinosum, eventually pass into the stratum granulosum. There, having become flattened and terminally keratinized, they move superficially as a single column of corneocytes until finally shed at the surface.

The distributions of melanocytes and Merkel cells do not correspond to the proliferative units and obey some other territorial rule.

Subsequent studies have in general provided support for this model where it applies to species and sites where epidermal cell turnover is regular and not too fast. However, regular columns of keratinized cells have not been found in normal human epidermis, perhaps due to abrasion from clothes, movement, washing, etc. which may have a stimulatory activity on cell renewal, disrupting any highly ordered migration of keratinocytes within it (Bergstresser & Chapman 1980). It has also been reported that in addition to the mitotic basal cells there is another type of basal cell, post-mitotic and with deep interdigitations at its base, which may have special anchoring functions (Lavker & Sun 1982).

1.84A Diagram of the main features of the epidermis, including its cell layers and different types of cell, including: keratinocytes (pink); two dendritic varieties, the melanocyte (grey) and Langerhans cell (blue); and a Merkel cell (purple). Also depicted are the dermis (green) and the sensory axon (yellow) associated with the Merkel cell. In this picture the epidermis of thin skin is shown so that the position of the stratum lucidum as it would appear in thick (hairless) skin is only indicated. For clarity only a single column of keratinocytes arising from the mitosis of a basal cell is shown in any structural detail, although desmosomal contacts are not illustrated because of the level of magnification.

Epidermal Keratinization

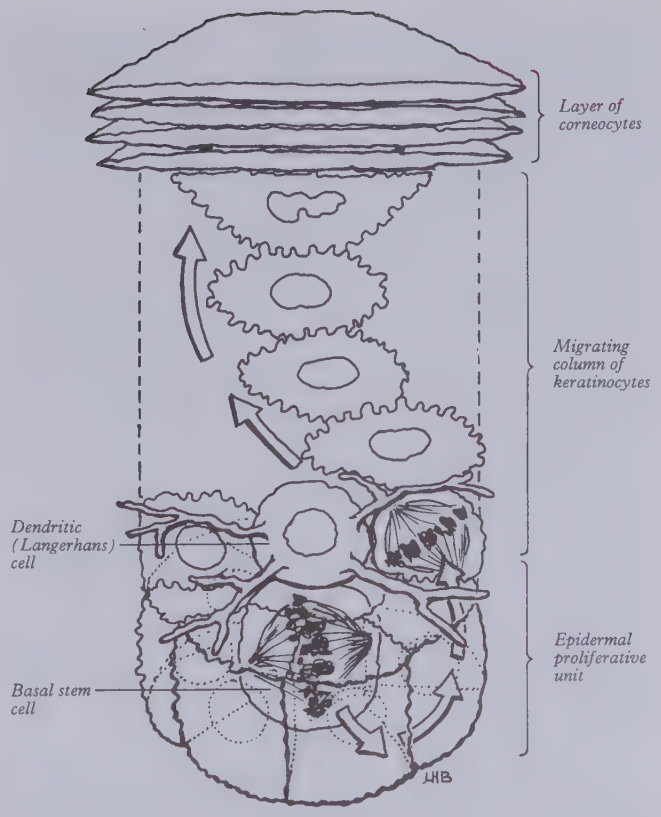
Traditionally, this term applies to the final stages of keratinocyte maturation during which cells are converted into tough, cornified squames (*orthokeratinization*, in contrast with the incomplete *parakeratinization* of areas of the buccal mucosa, see p. 56). However, the keratin filaments of corneocytes are only one subtype of the general family of keratin filaments of similar size and broadly comparable chemistry which are characteristic of all varieties of epithelia (see p. 51). Indeed, recent immunocytochemical studies show that the cells of the epidermis have a varied and changeable pattern of keratin filament chemistry which changes as keratinocytes mature. Thus, keratins of basal stem cells are different from those of young keratinocytes and it is only in the upper layers of the stratum spinosum that the final type of keratin filament begins to emerge. During a keratinocyte's life span there must be sequential synthesis and probably some dissolution of different keratins as cells move from the base towards the surface. The classic process of epidermal keratinization therefore describes only the final stages of maturation in which dead squames filled with keratin and other proteins are formed.

The crucial steps in this process are, first, the formation of the appropriate keratin filament proteins by the free ribosomes of the keratinocytes, their assembly into 8–10 nm thick filaments, then their progessive aggregation on contact with keratohyalin in the stratum granulosum. Finally, chemical changes which involve the formation of disulphide bonds stabilize this filament–filaggrin complex as a mass of chemically inert, mechanically resistant parallel fibres embedded in a dense matrix.

Other types of terminal keratinization occur elsewhere, particularly in hairs and nails, where the keratin is chemically distinct and becomes much tougher than in the general epidermis ('hard keratin' as opposed to 'soft' keratin). These processes will be considered further below (p. 89). The *thickness* of the keratin layer can also be influenced by local environmental factors, particularly abrasion, which can lead to a considerable thickening of the whole epidermis including the stratum corneum, so that the soles of the feet become exceedingly resistant if shoes are dispensed with, and keratinized pads develop in areas of habitual pressure, e.g. corns from tight shoes, palmar callouses in manual workers, digital callouses in guitar players, etc. Exposure to high levels of sunshine or other stressful agents may also cause general epidermal thickening.

Epidermal Dendritic Cells, Langerhans Cells

These cells (1.84) are regularly scattered throughout the epidermis (vide supra) and the stratified squamous epithelia of the buccal mucosa. They are derived from bone marrow cells and are continually renewed (Katz et al 1979). The cell bodies of Langerhans cells are situated in the base of the stratum spinosum and their extensively branched dendrites are insinuated between the surrounding cells, although no desmosomal junctions occur with them. The nucleus is euchromatic and indented; the cytoplasm contains many mitochondria, granular endoplasmic reticulum and a well developed Golgi complex; lysosomes are also present. Characteristic of Langerhans cells are the membrane-lined *Langerhans bodies* (Birbeck bodies), a diagnostic feature of this cell type. They are elongated vacuoles approximately 0.5 μm long and 30 nm wide, usually with expanded spheroidal ends, and contain a central lamina marked with regular cross-striations at 9 nm intervals. These bodies are derived from the Golgi complex and discharge their striated contents at the cell surface into the intercellular space; their function is unknown.



Langerhans cells have many features in common with connective tissue macrophages, including immunochemical reactivity with macrophage-specific monoclonal antibodies, plasmalemmal receptors for the Fc fragment of Immunoglobulin G (IgG), the third component of Complement (C_3) and the same class of histocompatibility antigens (HLA-D/DR in humans, I-A in mice, see Rowden 1981); they are also strongly positive for the enzyme ATPase and, like macrophages, they are derived from cells of the bone marrow. However, the unique Langerhans bodies show that they are not identical with macrophages and recent immunohistochemical findings suggest that the Langerhans cells may belong to a class of dendritic immune cell also present in other sites, including lymph nodes and the thymic medulla (Kashihara et al 1986).

Functionally there is much evidence that, like macrophages, they are important in cellular defence, particularly in detecting, binding and presenting antigens to local T-lymphocytes, as part of the immune mechanism of the skin. Such a system appears to be important in cell-mediated immunity to epidermal viral infections, in the elimination of epidermal cancers and in a diversity of other defensive responses, e.g. to ectoparasites such as ticks (Nithiuthi & Allen 1984). In addition, Langerhans cells may participate in the regulation of cell division, a role which has been postulated for other dendritic, macrophage-like cells elsewhere (see p. 669). The close relation of Langerhans cells and mitotic epidermal basal cells is certainly suggestive of such an activity, which could be either stimulatory or inhibitory, although this has not yet been demonstrated unequivocally.

Clinically, misdirected reactions of Langerhans cells are implicated in various skin pathologies, such as allergic contact dermatitis and in graft rejection. Their absence from the cornea may be an important factor in the ease with which grafts of this tissue can be accomplished. In the epidermis, they are adversely affected by ultraviolet light and various chemicals, which can inactivate them and deplete their numbers. This suppressive effect may contribute to the higher incidence of epidermal carcinomas in Caucasians exposed habitually to strong sunlight or artificial ultraviolet light and may play a part too in the chemical induction of neoplasms.

During development, Langerhans cells appear in the epidermis at six to seven weeks of gestation (Foster et al 1986) and are renewed continuously from a proliferative pool of myeloid precursors, as well as multiplying to some extent within the epidermis (Czernielewski & Demarchez 1987). In adult life they number 400–1000/mm². For further information regarding this cell type, see the reviews by Stingl et al (1980), Rowden (1981) and Friedmann (1986).

Recently another category of non-pigmented epidermal dendritic cell derived from myeloid tissue has been demonstrated in mice; instead of the typical macrophage-like surface markers (vide supra), they have an antigen, Thy-1, also found in various lymphocytic cell lines. They may represent a type of Natural Killer (NK) cell working cooperatively with Langerhans cells in the defence of the epidermis (see e.g. Romani et al 1986).

1.84B The concept of the epidermal proliferative unit and its relationship to the overlying column of differentiating keratinocytes, finally maturing through the stratum granulosum into the flattened corneocytes of the stratum corneum. In this model, keratinocytes arise by the repeated mitosis of a single basal stem cell, move laterally, then pass into the base of the stratum spinosum, where they may divide again one or more times before passing towards the surface. A single basal stem cell and its progeny within the stratum basale constitutes the epidermal proliferative unit as initially conceived. The dendritic Langerhans cell, situated above the basal stem cell, has also been suggested as a controlling influence on cell division. For further explanation see text.

Epidermal Melanocytes

The rounded cell bodies of melanocytes (1.84A) lie in the stratum basale in contact with the basal lamina; from their apices a number of cytoplasmic dendrites emerge and ramify extensively among the surrounding cells, reaching deep into the stratum spinosum. Developmentally, they originate from the neural crest and migrate as melanoblasts into the epidermis at 12 to 14 weeks' gestational age.

Melanocytes are attached to the basal lamina by hemidesmosomes but do not form desmosomal attachments to other cells. Their nuclei are rounded or elliptical and euchromatic; the perikaryal cytoplasm contains granular endoplasmic reticulum, a Golgi complex and numerous mitochondria. Microtubules, intermediate filaments and microfilaments extend peripherally within the dendrites. For a detailed account of their structure see Breathnach (1969, 1971), Fitzpatrick et al (1983).

The characteristic organelles of these cells are the *melanosomes*, membrane-bound bodies containing pigment, budded off from the Golgi complex then transported from the cell body to the ends of the dendrites. Terminal portions of dendrite cytoplasm containing melanosomes are periodically shed (*cytocrine secretion*) and are immediately engulfed by neighbouring keratinocytes and basal stem cells, and the melanosomes incorporated into their cytoplasm. In this way, the germinative cells of the epidermis are provided with a pigment shield against the damaging effects of ultraviolet light on their DNA. Of course, pigment is constantly being lost from the epithelium as the basal cells divide, migrate and are shed from the surface, so a continuous production of

melanosomes is needed. Where protection is inadequate, intense ultraviolet light may cause acute damage and cell death in epidermal cells, as in sunburn, or after chronic exposure, epidermal neoplasms may occur because of damage to basal cell DNA; this is seen in the higher incidence of squamous cell carcinoma amongst pale-skinned people in areas of strong sunshine in comparison with the indigenous, melanized populations.

The darkness of the skin depends on a number of factors, including melanocyte frequencies and the number and composition of their melanosomes. These may vary depending on genetic, environmental and hormonal factors. Melanocytes are often most numerous on the face, mucosal orifices, external genitalia, nipple and areola and limbs, varying between 800 and 2000/mm^3. Their numbers are similar in pale and dark races but their activity and the structure of their melanosomes differ (vide infra). Melanocytes are also present at the bases of hair follicles (see p. 91) and are responsible for hair colour. They are, however, absent from the matrix of the nail bed.

Melanosomes are oblong, membrane-bound, rounded bodies containing the dark brown pigment *eumelanin*. Similar, though more spheroidal, bodies enclosing a reddish-yellow pigment *phaeomelanin*, are called *phaeomelanosomes*; they occur mainly in reddish hair. In the more heavily melanized races, mature melanosomes are rod-shaped, (up to 3 μm long by 0.5 μm wide) and are intensely pigmented. In Caucasian skin they are smaller, elliptical (0.3–0.7 μm long) and have areas of differing density within each granule; in both cases their form changes with melanosome maturation.

Melanosomes are generated (see Fitzpatrick et al 1983) by budding from the granular endoplasmic reticulum as spherical vesicles containing granular material and a few peripheral cross-striated filaments (Type I melanosomes, promelanosomes). The filaments increase in number to fill the vacuole which changes to an elliptical shape (Type II melanosomes); then gradually more and more finely granular eumelanin is deposited amongst the filaments (Type III) until finally only the melanin is visible (Type IV), giving a homogeneous dense appearance punctuated by local spheroidal areas of lower density (vesiculo-globular bodies). Phaeomelanosomes remain spheroidal throughout their development and, instead of a homogeneous, dense interior, mature specimens have several rather granular masses with a distinctive structure (Breathnach 1965).

The filaments found in immature melanosomes appear to be molecular assemblies of the enzyme *tyrosinase* which take the form of helices 10μm in diameter, with a 10 nm periodicity and up to 500 nm long.

Eumelanin is a highly insoluble, proteinoid polymer of DOPA-quinone, formed by a series of reactions involving tyrosinase and other oxidative enzymes. The amino acid tyrosine is first converted by melanocytes into dihydroxyphenylalanine (DOPA). then into DOPA-quinone, which, after various chemical steps, polymerizes into eumelanin. These changes occur in the developing melanosomes, tyrosinase and other enzymes being added to promelanosomes by fusion of vesicles derived from the Golgi complex. Melanocytes can be demonstrated histochemically by incubating pieces of fresh epidermis with DOPA, which is then converted to pigment by their enzyme systems.

Phaeomelanin, reddish brown in colour, has a similar chemistry — but the synthetic pathway diverges from that of eumelanin, since it is a cysteine-rich polymer of DOPA and therefore contains disulphide bonds.

Control of Melanization

The extent and position of melanocyte activity is determined by various factors as already mentioned. Genetic differences are generally reflected in the numbers and types of melanosomes produced rather than the numbers of melanocytes. Various hormones can also alter these parameters, including melanocyte stimulating hormone (MSH) from the adenohypophysis. Oestrogens and progesterone can also increase melanization, particularly on the face, abdominal and genital skin and on the nipple and areola, which may remain permanently darker after the first pregnancy. Age and many pathological conditions can also affect the degree of local, or general, pigmentation.

Changes in colour caused by exposure to ultraviolet light (or other short-wavelength electromagnetic radiation including X-rays and gamma-rays) involves a number of different mechanisms. With brief exposure, individual melanosomes darken within minutes because of photo-oxidation of melanin, returning later to their original colour. With increased exposure duration there is evidence from animal experiments that melanocytes multiply mitotically (see e.g. Nordlund et al 1981) and increase their rates of both melanin synthesis and transferral to keratinocytes (which are also produced more rapidly) within two to three days.

The extent of these changes depends on genetic constitution as well as dosage and varies considerably within racial groups as well as between races. In some individuals, melanocytes with eumelanin are grouped together to give freckles or larger pigmented patches. In albinism, an autosomal recessive genetic condition, certain melanogenic enzymes (e.g. tyrosinase) are absent, so that melanin pigments are totally missing from all regions of the body, including skin and eyes. At least six biochemically distinct classes of oculocutaneous albinism are known.

Epidermal *melanocytic naevi* (moles) are regions where melanocytes are clustered in high densities and are considered to be small benign, quiescent neoplasms, melanomas, usually formed early in development. Although most such naevi remain inactive and innocent, some have the potential to become malignant, particularly if exposed to stresses such as excessive abrasion (e.g. on palms and soles and, because of chafing during walking, on the scrotum) or excessive sunlight. Malignant melanomas, which typically disrupt the surrounding skin and often give rise to smaller melanomas around them, are able to spread and grow rapidly, and become quickly fatal unless immediately checked.

In addition to melanin, there are other factors which determine epidermal colour, including the presence of carotenes in the epidermal keratinocytes, pigmented hairs inserted within it and various other normal and pathological factors. The causes of general skin colour will be considered later (p. 83).

Merkel Cells

These are present only in thick hairless skin (**1**.84). They lie at the base of the epidermis, usually protruding somewhat from it into the dermis, and form the terminal attachment of certain mechanoreceptive cutaneous nerve endings. The cells are elliptical in shape and from their apical surface several cytoplasmic spikes arise, inserted among the epidermal cells and connected to them by desmosomes. Within the cytoplasm are numerous dense-cored vesicles and intermediate filaments. They are thought to play some as yet uncertain role in sensory transduction and are considered in more detail on p. 910.

The Basement Membrane of the Epidermis

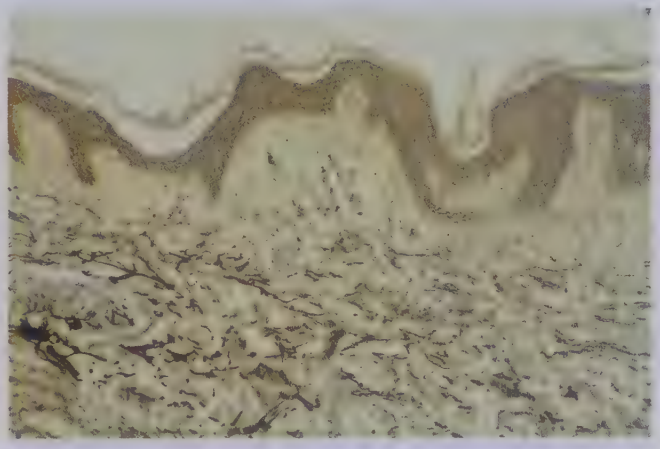
This, and basement membranes of other epithelia, consists of a basal lamina, about 80 nm thick (**1**.75), to which cells of the stratum basale are attached, and, on the dermal aspect, a reticular lamina which grades into the connective tissue of the dermis (see the reviews by Stanley et al 1982, Briggaman 1983). This structure and its role in the normal and pathological behaviour of skin are of great interest at present and it is known that it has a chemical composition peculiar to the integument.

Similar to other basal laminae (p. 68), that of the skin consists of a lamina lucida lying close to the epidermal cell bases and a deeper lamina densa. The lamina lucida is occupied by various macromolecules giving this layer a finely granular or filamentous appearance; here are laminin, heparan sulphate proteoglycan and pemphigoid antigen (a protein unique to skin and with an *M*r of 220 000). The lamina densa includes a network of Type IV collagen molecules (p. 65), a glycoprotein named epidermolysis bullosa acquisita antigen (Woodley et al 1986), fibronectin and various proteoglycans. The lamina lucida is strongly adhesive to the epidermal cell membrane, while the meshwork of the lamina densa may limit the passage of macromolecules from the dermis to the epidermis. The basal lamina may also suppress keratinocyte differentiation in the stratum basale (Regnier et al 1986) and regulate various other cellular activities in the epidermis. However, a major function of the whole basement membrane is to

stabilize the epidermis mechanically by its hemidesmosomal attachments, the fine filaments attached at one end to epidermal cell desmosomal plaques traversing the lamina lucida and inserting into the lamina densa, from which delicate microfibrils of elastin-like proteins (e.g. oxytalan, elaunin, see p. 67) are anchored into the dermis.

THE DERMIS

The dermis consists of irregular, moderately dense, soft connective tissue (1.80,85A, B). Its matrix consists of an interwoven collagenous meshwork, with a varying content of elastin fibres, proteoglycans (the glycosaminoglycans being predominantly hyaluronic acid and dermatan sulphate, with some chondroitin-6-sulphate, heparin sulphate), fibronectin and other matrix components, blood vessels, lymphatic vessels and nerves. Non-striated myocytes occur in the dermis as *arrector pili* (p. 92) muscles. The density of its fibre meshwork also varies, both within an area and in different sites, and its degree of elasticity also varies much, being particularly great in areas subject to much stretching (e.g. axillary skin). Mechanically, the dermis provides considerable strength to skin by virtue of the numbers and arrangement of its collagen fibres and it also has elastic recoil because of its elastin content. It also provides a compartment for blood vessels, lymphatics, nerves and defensive cells and so is vital to the survival of the epidermis and to much of the skin's physiology.

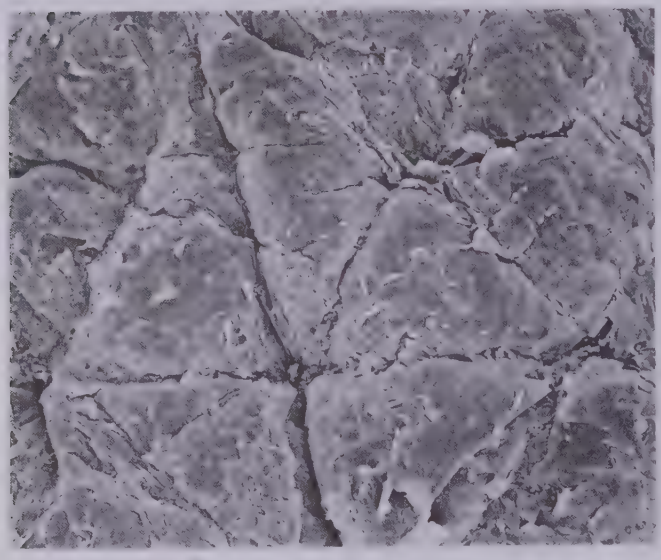


The dermis can be divided into two distinct zones, a narrow superficial *papillary layer* and a deeper *reticular layer*.

The papillary layer is immediately deep to the epidermis and is specialized to provide mechanical anchorage, metabolic support and trophic maintenance to the overlying tissue, as well as housing rich networks of sensory nerve endings and blood vessels. Its superficial surface is marked by numerous *papillae* which interdigitate with recesses in the base of the epidermis and form the dermo-epidermal junction at their interface. The papillae have round or blunt apices which may be divided into several cusps. In thin skin, especially in regions with little mechanical stress and minimal sensitivity, papillae are few and very small, while in the thick skin of the flexor aspects of the hands and feet they are much larger, closely aggregated and arranged in curved parallel lines following the pattern of ridges and grooves typical of these surfaces (1.86). Lying under each epidermal ridge are two longitudinal rows of papillae, one on either side of the midline through which sweat ducts pass within the epidermal rete pegs (see 1.80). Each papilla contains narrow, densely interwoven bundles of fine type I and III collagen fibres and some elastic fibres and microfibrils, many of them attached to the basal lamina of the epidermis. Also present is a capillary loop and in some sites, especially in thick hairless skin, Meissner's corpuscular nerve endings (see pp. 910–911).

The reticular layer merges with the deep aspect of the papillary layer. Its bundles of collagen fibres (mainly type I except early in development when type III predominate) are thicker than those in the papillary layer and interlace with them and with each other to form a strong yet deformable three-dimensional lattice, in which many of the fibres are parallel to each other and within which lies a variable number of elastic fibres. The predominant orientation of the collagen fibres may be related to the main direction of action of the mechanical forces to which the dermis is subjected locally and thus may be involved in the development of some of the surface lines which occur on the skin (p. 80). The deeper collagenous fasciculi are coarse and separated by loose connective and adipose tissue containing sweat ducts, some of which may extend into the underlying hypodermis.

1.85A Scanning electron micrograph of the surface of a section through the skin showing the epidermis (above) and the layers of the dermis. The papillary layer close to the epidermis contains fine collagen fibres, while in the deeper reticular layer the fibres become increasingly more coarse. Magnification × 300.



1.85B Section through thin skin, stained by the Verhoeff method to demonstrate elastin fibres. The fibres of the superficial layers of the dermis are thin while the deeper layers have more conspicuous coarser elastic fibres. Magnification × 120.

1.86 Low-power light micrograph of hairless skin, in surface view, from the palm of the hand showing epidermal friction (papillary) ridges and larger flexure lines (left). Magnification × 6.

1.87 A light micrograph similar to that shown in 1.86 but taken from hairy skin on the extensor aspect of the forearm; note the pattern of surface grooves (tension lines) and hairs. The oblique direction of the emerging hair shafts points away from the pre-axial border of the limb. Magnification × 6.

1.88 Scanning electron micrograph of the surface of thin skin (human: dorsum of thorax), showing the interlacing network of fine creases and predominantly triangular areas between them. Magnification × 400.

SKIN LINES

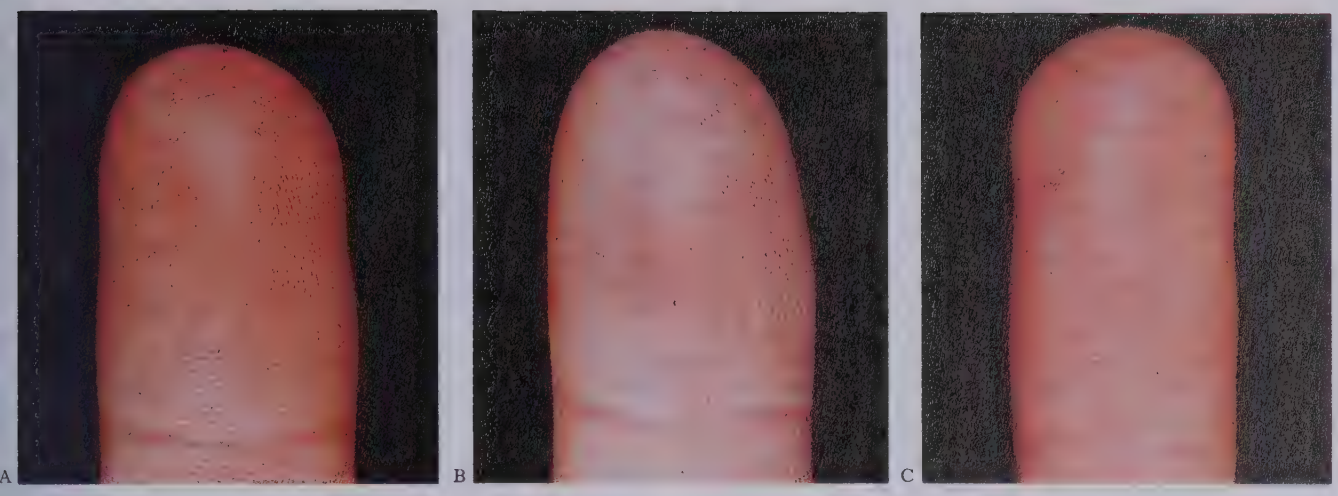
As already mentioned (p. 72), the surface of the skin and its deeper structures show various 'skin lines'. Over 35 different names, many of them synonymous, have been applied to such lines, relating to various systems of grooves, raised areas, preferred directions of stretching, lines of naevus occurrence and spread of infection. Some of these are clearly visible in intact skin, others are recognizable only after some sort of intervention, while yet others are at present only debatable postulates. Here, we will briefly describe some of the major varieties of lines, dividing them into externally visible markings (tension lines, flexure lines, friction ridges, striae gravidarum, pigmented markings or transitions) and deeper 'directional' lines of the dermis.

Externally Visible Skin Lines

These are related to various patterns of epidermal creasing, ridge formation, scarring and pigmentation.

Tension lines, skin creases (1.80,87,88). A simple lattice of skin creases or folds occurs on all major areas of the body other than the thick skin of volar and plantar surfaces. The lattice pattern typically consists of polygons (generally parallelograms) formed by relatively deep primary creases visible to the naked eye, irregularly divided by finer secondary creases into triangular areas (Hashimoto 1974, Millington & Wilkinson 1983), which are further subdivided by tertiary creases limited to the stratum corneum of the epidermis and finally, at a microscopic level, by quaternary 'creases' which are simply the outlines of individual corneocytes. Apart from the quaternary creases, all the others increase the surface area of the skin, permitting considerable stretching and recoil and distributing stresses more evenly. Details of the pattern vary according to the region of the body; e.g. on the cheek the primary creases radiate from the hair follicles, on the scalp they form hexagons, while on the calf and thigh they form parallelograms, whose longer sides are inclined at about 30–40° to the vertical. Superimposed on this basic pattern are deeper creases associated with flexion (vide infra) (Bruner 1951).

Flexure lines (skin joints) are major markings found in the vicinity of synovial joints, where the skin is attached strongly to the underlying deep fascia (1.86). They are conspicuous on the flexor surfaces of the palms, soles and digits and, in combination with associated skin folds, facilitate joint movement. Their patterns on the palms and soles may vary and are to some extent genetically determined; in Down's syndrome, affected individuals tend to possess a prominent transverse palmar crease at the bases of the metacarpals, which is of some diagnostic importance.

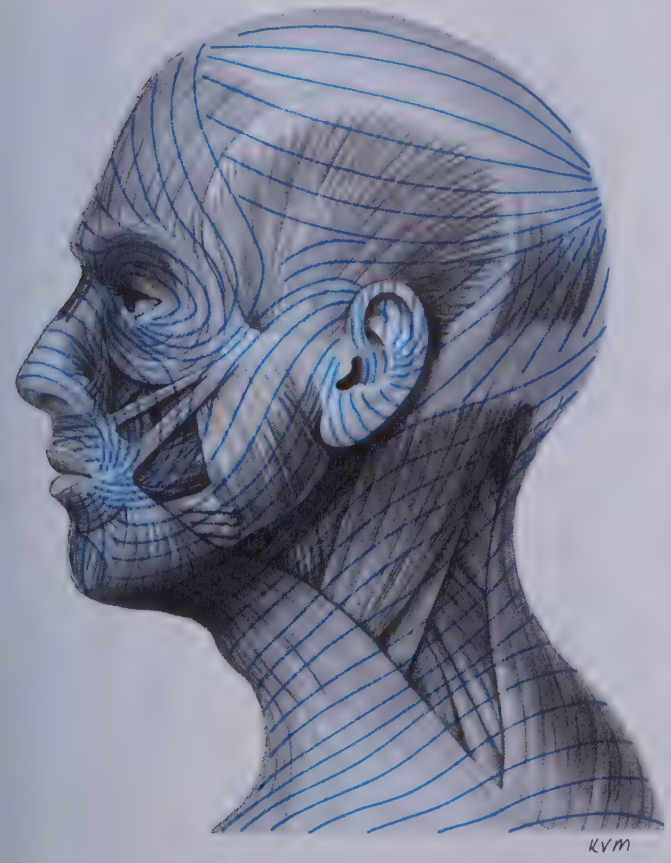


Papillary ridges (friction ridges) are confined to the palms and soles and the flexor surfaces of digits, where they form narrow parallel and often curved arrays separated by narrow furrows (1.80,86,89). Along the midline of each ridge the apertures of sweat ducts open at regular intervals; each ridge corresponds to an underlying pattern of dermal papillae which help to anchor the epidermis and dermis together. The dermal papillae also have more subtle morphogenetic properties, as their pattern determines the early development and maintenance of the epidermal ridges throughout life. Functionally this arrangement increases the gripping ability of hands and feet and, because of the great density of tactile nerve endings beneath their epidermal lining, they are also important sensory structures (p. 914).

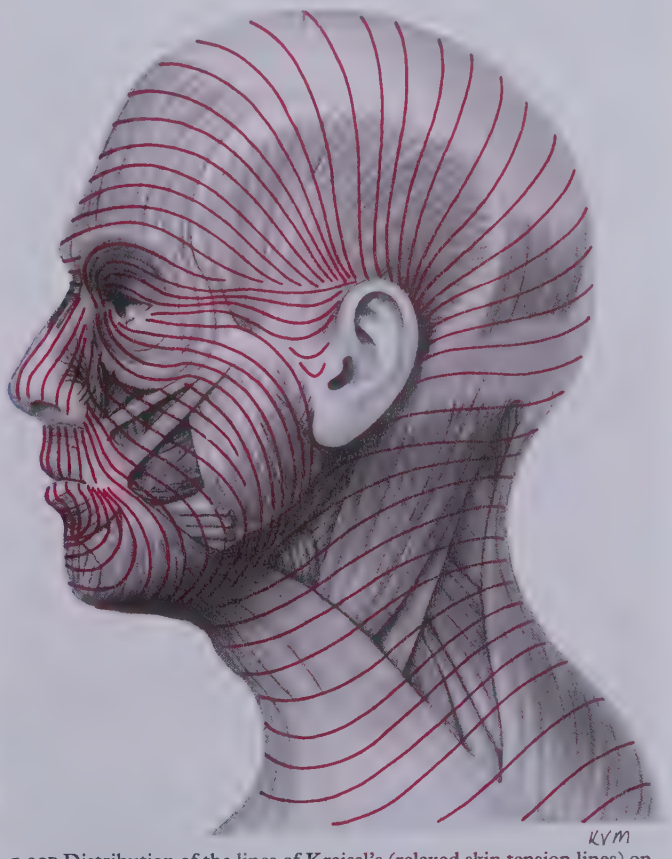
Since the patterns of ridges and furrows are formed early in the fetus and are thereafter stable throughout life and vary between individuals, they are of considerable interest as a means of identification and also clinically, because they are affected by certain abnormalities of early development, including genetic disorders.

The analysis of these patterns or *Dermatoglyphics* (skin carving, see Cummins 1926) has attracted much attention and has complex mathematical ramifications which are beyond the scope of this account.

Measurable parameters include the disposition of *tri-radii*, junctional areas where three sets of parallel ridges meet, and the frequency of ridges in particular patterns. Ridge configurations on the terminal segments of fingers can be separated into three major types: arches, loops and whorls (1.89), arches having no tri-radii, loops one, and whorls two or more. Arches may be simple or tented, loops may have a tri-radius towards the ulnar or radial side of the hand (ulnar and radial loops); whorls may be symmetrical, spiral, or double loop. Ridges within these patterns may branch or join, or may be discontinuous. Similar considerations apply to the toes. In any such configuration the number of ridges may also vary, the *ridge-count* being given by counting the total intersected when a line is drawn from the central point of a pattern to its nearest tri-radius. Such patterns can vary from digit to digit in any individual but, in the hand, loops are the most common and arches the least; with toes the converse is true. These variable features provide an astronomical number of possible combinations, so that each individual is almost certain to have a unique set of patterns.



Tri-radii also occur on the palms and soles, including the bases of each digit except the thumb; a characteristic tri-radius is also present on the proximal edge of the hand in the midline above the flexor retinaculum (the axial tri-radius). The precise positions, numbers and ridge-counts associated with tri-radii have an inherited basis but in general the genetics are multifactorial and too complex at present to be clinically useful. However, the total



1.89 Photographs of the palmar aspect of a terminal phalanx in three different individuals to show the major types of pattern of the fingerprint ridges. The pattern in A is commonly termed a whorl: B is composed of loops; C is composed of arches. Note interphalangeal flexure lines.

ridge-count of all ten digits of the hand appear to have a simpler inheritance; in Down's syndrome, all ten finger-prints have ulnar loops in about 35% of affected persons, in contrast to about 8% of the normal population (Thompson & Bandler 1973). Other conditions affecting skeletal development, e.g. polydactyly, and teratogens such as thalidomide, also cause disturbances to the pattern of papillary ridges. For further details of this subject, see Cummins & Midlo (1961), Penrose & Loesch (1969) and Schaumann & Alter (1976).

Intrinsic scarring. If the mechanical demands placed on the skin are greater than the skin creases and the elasticity of the dermis can accommodate, the reticular layer of the dermis may rupture and be replaced first by highly vascular granulation tissue (p. 85) and finally by highly collagenous, poorly vascularized scar tissue. Such changes can be termed intrinsic, to distinguish them from scars formed by external wounding (see p. 84). Sites of dermal rupture are visible externally as lines, *striae* or 'stretch marks', which are initially usually pink in colour, later widen and become a vivid purple or red and eventually fade, becoming paler than the surrounding intact skin. They develop on the anterior abdominal wall of some women after pregnancy (Poidevin 1959), when they are termed *striae (lineae) gravidarum*. Although the development of striae may be due to excessive stretching of normal skin by the rapid growth of structures deep to it (e.g. a fetus,

1.90A Distribution of Langer's cleavage lines on the face. For further details see text.

1.90B Distribution of the lines of Kraissl's (relaxed skin tension lines) on the face. It has been reported that incisions made along these lines heal with minimum scarring (see text).

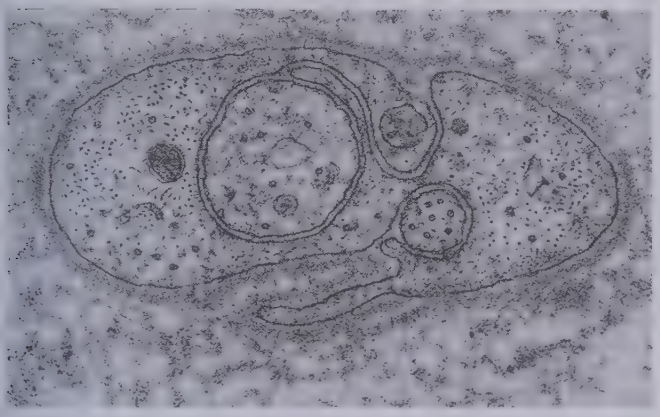
adipose tissue, hypertrophying muscle, a tumour), more often they indicate pathological or hormonally-induced weakening of the dermis. Striae have been associated with many debilitating diseases, some chronic infections and changes in steroid hormone levels, and are possible side effects of the therapeutic administration of adrenocortical hormones (Geschwandtner 1973). Striae result from extensive dermal changes involving stressing of collagen fibre bundles (Arem & Kischer 1980), inducing a form of remodelling or dermal scarring, perhaps under the influence of steroid hormones.

Pigmentation. Variation in pigmentation can also produce externally visible lines, such as 'Voigt lines', on the surface of the skin. Found in some infants, Voigt lines mark differences in pigmentation between the darker extensor and paler flexor surfaces of the arms (Matsumoto 1913). They occur along the anterior axial lines (p. 1151), extending from the sternum to the wrist.

Lines Detectable after Manipulation or Incision

Lines of Langer and Kraissl (1.90A,B,C). Skin is normally under tension, the direction in which this is greatest varying regionally. The first consideration of skin tension was published in 1834 by Dupuytren, who observed in a post-mortem examination that a wound inflicted with an awl was elliptical although the weapon was round in cross-section. Malgaigne (1838) demonstrated that, in a particular area of the body, the long axes of such elliptical wounds were parallel to each other and formed a pattern of *cleavage lines*. Langer (1861) studied these patterns exhaustively in cadaveric material and proposed the hypothesis that the skin is always in a state of tension, due to the rhomboidal arrangement of its dermal fibres. When these fibres were disturbed, the tension exerted in the long axis of the rhomboid predominated and the wound became distorted. The surgical significance of Langer's cleavage lines was first recognized by Kocher (1892), who advised that surgical incisions should be made parallel with them to minimize postoperative scarring. The observation behind this advice was that wounds made at right angles to cleavage lines gaped widely and that linear scars widened and even hypertrophied, if the wounds extended into the dermis. Conversely, wounds made parallel to the lines remained narrow, as did any scar tissue. Unfortunately, the lines mapped out by Langer, using supine cadavers, do not always coincide with the lines of greatest tension (Conway 1938) and therefore are not the most appropriate lines for elective incision in the living (Kraissl 1951). In some locations Langer's lines and 'Kraissl's lines' (the latter being usually orthogonal to the line of action of any immediately subcutaneous muscle fibres and often coincident with wrinkle lines) are at right angles to each other. Examples of differences are shown diagrammatically in 1.90A and 1.90B. Lines of greatest tension similar to those described by Kraissl have been termed 'relaxed skin tension lines' by Borges & Alexander (1962). The position of the relaxed skin tension lines can be found, as their name suggests, by 'relaxing' the skin of a region by, e.g. joint mobilization or passive manipulation. The resulting skin creases follow the direction of relaxed skin tension lines. Incisions made in the direction of these lines result in minimal scarring.

Blaschko lines. These refer to the way in which patterns of naevi and related dermatological pathologies are distributed or develop (Blaschko 1901) along certain preferred cutaneous pathways. These do not appear to correspond to vascular or neural elements of the skin and may be related to early developmental boundaries of a 'mosaic' nature. (See Jackson 1976 for a review of this subject.)



AGE-RELATED CHANGES IN SKIN

The major features of skin are essentially formed well before birth and during the first two to three decades of life the main changes are an expansion of its surface area and thickening of the epidermis and dermis, as well as various changes in hair and gland patterns which occur at puberty. The arrangement and numbers of creases and friction ridges is essentially the same from their early fetal formation onwards, although their sizes increase until cessation of growth. However, from about the third decade onwards there is a gradual change in the appearance and mechanical properties of the skin which reflect natural ageing processes. In old age, or under adverse environmental conditions, these alterations may become very marked.

Normal human ageing is accompanied by epidermal and dermal atrophy, which result in some changes in the appearance microstructure and function of the skin; alterations include wrinkling, loss of elasticity and the development of purpura. Epidermal atrophy is accompanied by flattening of the dermal papillary ridges (Montagna & Carlisle 1979), the resulting reduction in interdigitation between epidermis and dermis decreasing resistance to shear. Dermal changes include thickening of elastic fibres and the localized appearance of material resembling degraded collagen. The latter is particularly marked in chronically sun-damaged skin (Mitchell 1967). Skin extensibility decreases with age (Leveque et al 1980) and so does elastic recoil. Although the amount of collagen in skin normally exposed to the sun decreases with age (Shuster et al 1975), no quantitative changes in total collagen have been observed in skin normally shielded from solar irradiation; there is, however, a change in the ratio of type I: type III collagen, the relative amount of type III collagen increasing after the age of about 65 years (Lovell et al 1987). Whether the increased proportion of type III collagen in older subjects is due to preferential synthesis of type III (possibly resulting from impaired synthesis of type I), preferential degradation of type I, or a combination of both, remains undetermined. Unlike the situation in fetal skin, where there is a temporary preferential synthesis of type III collagen, active increase in the synthesis of type III collagen is unlikely, since fibroblasts obtained from older skin synthesize less total collagen than those from younger skin, as well as having a shorter lifespan (Martin et al 1970). Changes which occur with age in the number, thickness and arrangement of the bundles of collagen fibres in the dermis

1.90C Lines of Kraissl associated with the anterior (left) and posterior (right) aspects of the lower limb.

1.91 Electron micrograph of an example of an unmyelinated cutaneous afferent nerve bundle close to the surface of the dermis (human thin skin). Two axons are visible within the Schwann cell sheath. Note also the thick basal lamina and the pale profiles of sectioned collagen fibrils surrounding the nerve fibres. Magnification × 20 000.

(Lovell et al 1987) may be correlated with the decrease in tensile strength reported in ageing human skin by Vogel (1983).

THE COLOUR OF SKIN

Cutaneous colour is determined by several factors, the most important being its intrinsic pigmentation, its vascular supply and thickness. Pigments of mature skin are usually present only in the epidermis and hair, the chief being the brown-black *melanin* and (mainly in hair) the closely related red-brown *phaeomelanin* (see p. 78). These vary greatly according to body site, genetic constitution, incident ultraviolet light and other factors. During fetal and early postnatal life pigment cells (*melanoblasts*) derived from the neural crest migrate into the epidermis from deeper sites and when still in the dermis may show as patches of grey-blue colour ('Mongolian spots') in young children of negroid and mongolian (and occasionally Caucasian) races. The boundaries between the darker dorsal and paler ventral aspects of the upper limbs may also be clearly defined (Voigt lines, see also p. 82).

Epidermal cells and underlying dermal and subcutaneous tissues may also contain yellowish carotenes giving poorly melanized skin a sallow hue, particularly when the superficial blood vessels are few or constricted, or when the epidermis is particularly thick. However, in the absence of large amounts of melanin, the main determinant of skin colour is the oxygenated haemoglobin of the dermal vascular beds, particularly the superficial (papillary) plexus (see p. 84). These are of course viewed through the overlying epidermis, whose surface layers scatter and reflect some of the light, and is somewhat opalescent, giving well-oxygenated skin a pink colour. Where less oxygenated blood is present, e.g. in congestive heart failure, a bluish hue results. Skin colour dependent on blood flow also varies with ambient temperature, exercise, emotional state, haemoglobin content of blood and various other features, often affected by general health.

INNERVATION OF SKIN

The integument has a rich nerve supply which is concerned mainly with two major functional roles of skin: as a major sensory organ and as a thermoregulator. These are mediated, respectively, by the regional sensory and efferent sympathetic fibres of segmental cranio-spinal nerves.

Cutaneous sense provides us with a wealth of information about the external environment and its interactions with the skin, through receptors tuned to mechanoreceptive stimuli of various kinds (rapid or sustained touch, pressure, vibration, stretching, bending of hairs, etc.), thermal stimuli (hot and cold), and damaging effects (moderate, perceived as discomfort, itching, etc. and more severe pain, associated with extremes of temperature, sharp penetration of the dermis and other overtly destructive stimuli). These are sensed by a wide variety of specialized neurons whose cell bodies lie in the spinal and cranial ganglia and whose fibres terminate in the dermis and superficial fascia.

Efferent autonomic fibres are non-myelinated noradrenergic and cholinergic in type, innervating the arterioles, arrector pili muscles and myoepitheliocytes of sudorific and apocrine glands and, in the scrotum, labia majora, perineal skin and nipples, non-striated muscle fasciculi of the dermis and adjacent connective tissue. Except in the nipples and genital areas, activity of these nerves is concerned with regulation of heat loss by vasodilation and vasoconstriction, sweat production and (only incipiently in humans) pilo-erection.

Nerve fasciculi pass into the skin through the superficial fascia in which they often form a deep, subcutaneous plexus which serves sweat glands and the bases of hair follicles where these protrude into this layer. In thick, glabrous skin, fibres are given off here to Pacinian corpuscles (large encapsulated sensory endings) present in the subcutaneous tissue. On reaching the dermis, the fasciculi branch extensively to form a deep, *reticular plexus* which serves much of the dermis including most sweat glands, hair follicles and the larger arterioles. Many small fasciculi pass from this plexus to ramify in another superficial *papillary plexus* at the junction between the reticular and papillary layers of the dermis; twigs from this supply the dermal papillae or in some cases contact the base of the epidermis.

The detailed structure and behaviour of the sensory endings are described in detail in another section (p. 906) and will be considered here only briefly (see 1.80). They include the branched 'free' endings of fine non-myelinated (C) and narrow (Aδ) myelinated fibres which belong (in humans) to thermo- and noci-ceptors. Myelinated fibres of different sizes have mechanoreceptive functions: in thick skin many of these are encapsulated terminals including *Meissner's corpuscles*, rapidly adapting touch endings in dermal papillae, and Pacinian corpuscles (vide supra), already mentioned, which are vibration and flutter sensors. Genital skin also has numerous small encapsulated mechanoreceptive endings ('genital corpuscles'). The *Merkel endings* of thick skin are branched slowly adapting mechanoreceptors which are attached to the bases of a specialized type of epidermal cell (Merkel cell, see p. 78) which abound on the bases of friction ridges. They appear to be important in detecting pressure exerted on the skin surface. Also within the dermis are various types of terminal associated with hair follicles which signal deflections of hairs, and the thinly encapsulated *Ruffini endings*, slowly adapting stretch receptors in the dermis.

The density of cutaneous endings varies greatly over the body surface, as do the sizes of the receptive fields formed by the terminal

1.92 A thick vertical section through palmar skin, the arteries, arterioles and capillaries of which have been injected with red gelatin to demonstrate the pattern of dermal vascularization. At the base of the dermis a broad flat arterial plexus supplies a more superficial papillary plexus, which in turn gives off capillary loops which enter the dermal papillae. Sweat glands and their ducts are numerous in this specimen; they extend basally into the subcutaneous tissues. Magnification × 200.

1.93 Vertical section through a dermal papilla and adjacent epidermis, showing a capillary loop. Notice the closeness of the vessel to the basal layer of the epidermis. Also visible are the layers of the epidermis, including a prominent stratum granulosum and above it the stratum lucidum stained dark orange and the paler orange stratum corneum. The section was taken from the thick skin of the foot. (Compare also 1.80 and 1.84A.) Mallory's triple stain. Magnification × 800.

branches of individual nerve fibres—and therefore their ability to locate stimuli and their point-to-point discrimination and also their thresholds to mechanical and thermal stimuli. In general, these properties vary in parallel with one another, being most marked in the extremities of the limbs, and progressively less so towards the abdomen, thorax and head, although some areas such as the skin around the mouth and ano-genital regions reverse this pattern. Discrimination is also to some extent asymmetrical, the right side of the body being generally better in this regard, at least in dextral individuals. Sex differences have also been reported, females generally having lower thresholds to pressure stimuli than males, although this is probably due to a thinner epidermis.

Sympathetic efferent fibres are typical non-myelinated axon groups which branch a number of times, and may have several synaptic zones where neurotransmission can occur. They end in close proximity to the structures they innervate.

For further reviews of these topics see, e.g. Sinclair (1973), Burgess & Perl (1973), Mountcastle (1980) and Brown (1986).

THE VASCULARIZATION OF SKIN

The metabolic demands of skin are not generally great, since the majority of it is dermal matrix containing few cells, and relatively few capillaries are present in the deeper, very fibrous layers of the dermis. However, the epidermis, glands, hair follicles and nerve supply have many active cells and are closely related to rich dermal capillary beds (Montagna & Parakkal 1974, Keatinge & Harman 1980).

Blood enters the skin through small arteries penetrating the reticular layer from its deep aspect, ramifying and anastomosing in a sheet-like plexus, the *rete cutaneum (reticular plexus)*, at the interface between the dermis and the superficial fascia (1.80,92). From this plexus, some arterioles pass deeply to supply the adipose tissue and, where present at this depth, cutaneous sweat glands and hair follicles. Other arterioles pass superficially, some turning laterally to anastomose with other arterioles at this level, giving off capillaries to glands and hair follicles here while the majority form a second major plexus at the junction of the reticular and papillary layers of the dermis (*rete subpapillare, superficial plexus, papillary plexus*). Capillaries from this plexus loop into the dermal papillae (1.93) and so approach closely the base of the epidermis before passing back into a venous plexus present just beneath the arteriolar papillary plexus. This in turn drains into a flat intermediate plexus in the reticular layer and again into another venous plexus close to the deep arteriolar reticular plexus. Venous capillary beds surrounding glands and hair follicles drain into these plexuses at appropriate levels.

In the deeper layers of the dermis, arteriovenous anastomoses are common, particularly in the extremities subject to cooling (hands, feet, ears) where, as *glomera* (see p. 693), they are surrounded by thick muscle coats. Under autonomic vasomotor control, these vessels when relaxed divert blood away from the superficial plexus and so reduce heat loss, while at the same time ensuring some cutaneous circulation and preventing anoxia of structures such as nerves which might otherwise be at risk. Generally, muscle tone of the vascular bed is constantly adjusted by autonomic efferents according to the need for heat loss or retention or, in some areas of the body, also to emotional states. Various humoral agents (noradrenalin, angiotensin, histamine, etc.) also affect vascular muscle and therefore cutaneous blood flow. In very cold conditions, the peripheral circulation is greatly reduced but some blood flow is maintained even in the superficial layers by intermittent opening and closing of arterioles (the hunting reaction).

Many of the small arteries and large arterioles run closely parallel with veins, so that at low temperatures heat can be conserved by a countercurrent mechanism.

THE LYMPHATIC DRAINAGE OF SKIN

Blind-ending lymphatic capillaries are numerous in the reticular layer of the dermis and drain into plexuses within this stratum and into wider vessels of the superficial fascia. The lymphatics tend to be distended and the larger ones have prominent valves; lymph flows through these to the deeper lymphatics draining the region. Lymphatics of skin are quite profuse and there appears to be free anastomosis between vessels of all levels, so that there is ready interchange of lymph between adjacent areas of skin (Forbes 1938).

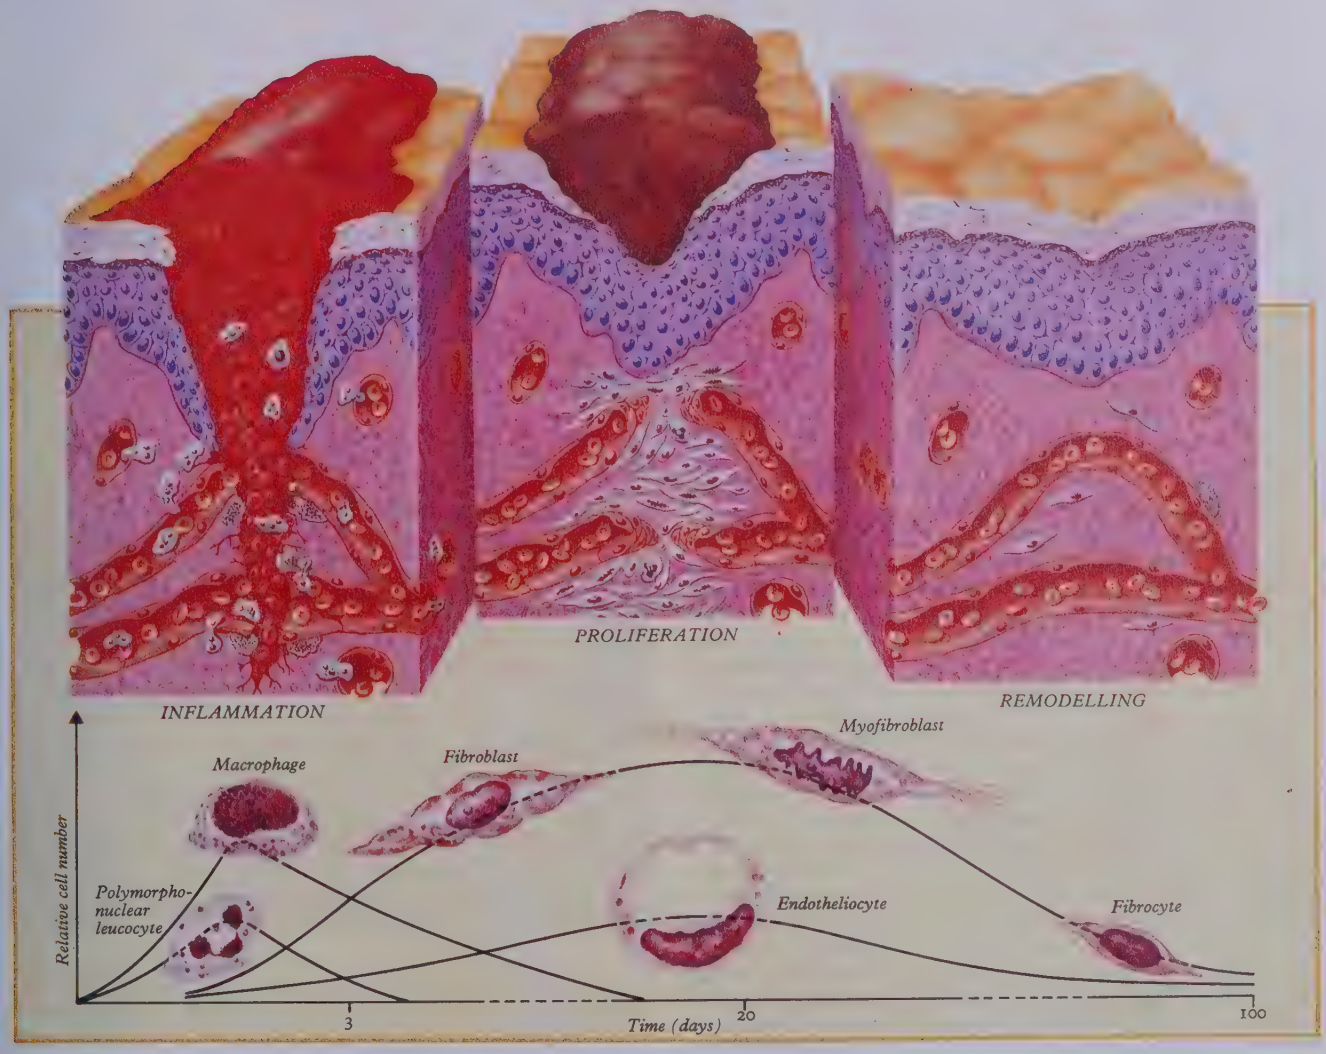
Wound Healing in Skin

The normal response of an organism to injury is either regeneration, the complete restoration of the damaged part, or repair, the reconstruction of the injured region in such a manner that scar tissue covered, where appropriate, by an epithelium is produced at the site of the injury. Evolutionary progress has been accompanied by an apparent loss of regenerative capacity; while regeneration of entire limbs is possible in some of the less advanced vertebrates (e.g. urodeles), it is restricted in man and other mammals to limited regeneration of some tissues (e.g. epithelia and endothelia, bone, peripheral nerves) and to partial regeneration of some organs, e.g. the liver. Whether or not this loss of regenerative capacity is irreversible remains to be discovered. When skin is injured the dermis responds by repair, while the epidermis responds by regeneration. The collective response of the skin to injury is termed *wound healing*.

DERMAL REPAIR

For descriptive convenience, dermal repair can be divided into three overlapping phases: *inflammation, proliferation* and *remodelling* (1.94–98).

Inflammation

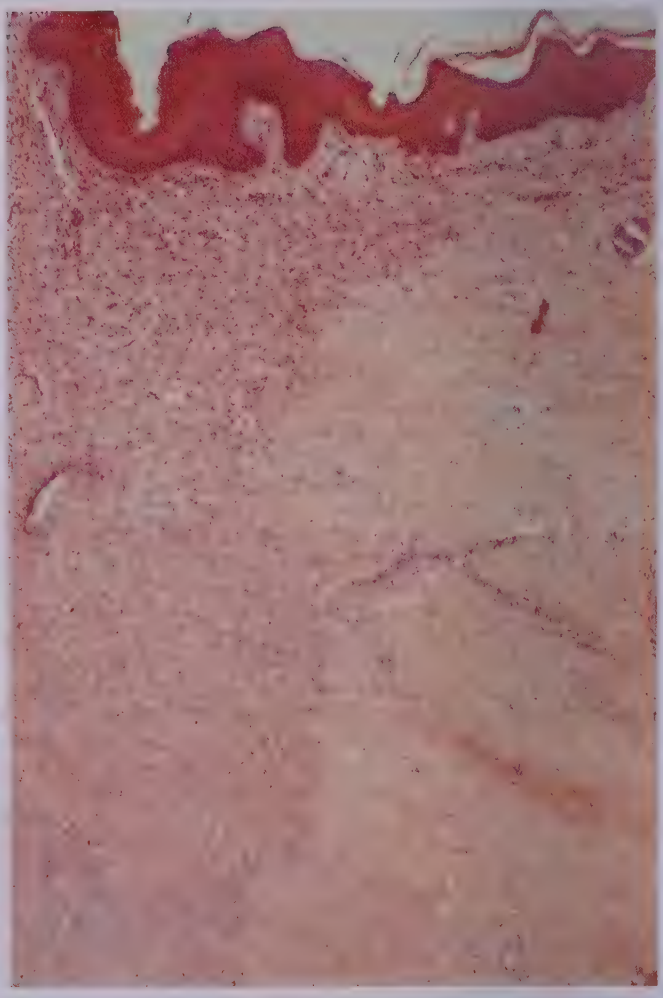


Acute inflammation begins with the activation of platelets and mast cells as an immediate response to injury. During inflammation, haemostasis is achieved, removal of damaged tissue occurs and factors which start the formation of granulation tissue are released or deposited in the wound. Multiple interacting pathways of inflammation (1.98) are triggered when dermal blood vessels are injured and end automatically when the inflammatory stimuli dissipate; should these stimuli persist, then inflammation persists and wound healing is delayed.

Tissue injury and bleeding are followed by blood clotting. This involves many complex chemical interactions between components of the extravascular tissue and of blood, including activation of the Hageman factor (for intrinsic coagulation), factor VII (for extrinsic coagulation) and the activation of platelets. These are all responses to the surface adsorption and activation of specific coagulation pro-enzymes normally inhibited in intact tissues, but free to act in the protease inhibitor-free microenvironment temporarily provided by the wound. Blood clotting is a crucial part of inflammation, because activation of Hageman factor leads to bradykinin generation (Habal et al 1976), initiation of the classic complement cascade (Ghebrehiwet et al 1981) and possibly also to production of anaphylatoxins C3a and C5a (Clark 1985), among many other complex and as yet poorly understood reactions. These anaphylatoxins, together with bradykinin, increase local blood vessel permeability (Williams & Jose 1981), causing leakage of plasma proteins and formation of an extravascular clot. They also stimulate release of the vaso-active mediators, histamine and leukotrienes C4 and D4, from mast cells (Hugli & Muller-Eberhard 1978, Stimler et al 1982) and attract neutrophils and monocytes to the wound (Fernandez et al 1978).

The main function of the neutrophils while at the wound site is the phagocytosis of pathogenic bacteria. Once bacterial contamination has been controlled, neutrophil infiltration ceases and the early inflammatory phase of repair is at an end. In contrast, monocytes, which develop into macrophages on entering the wound bed, remain throughout the entire inflammatory phase. Macrophages are not only phagocytic but also release a host of biologically active materials, including substances essential for the initiation and propagation of granulation tissue during the next, proliferative, phase of repair.

Proliferation



During this stage, cells and intercellular substances increase greatly to form *granulation tissue*. This is a highly vascular material consisting largely of macrophages, pluripotent pericytes, fibroblasts and endothelial cells lining capillaries, all embedded in a matrix of fibronectin, proteoglycans rich in hyaluronic acid and collagen, which at first is mainly type III, changing later to type I. The profuse assemblies of capillaries, which are the main type

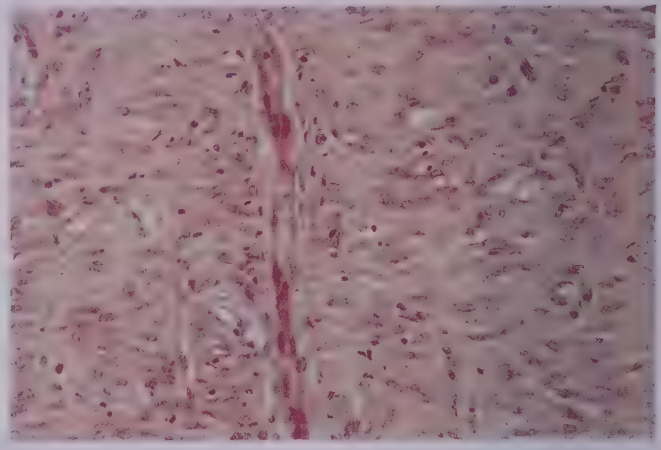
1.95 Low magnification light micrograph of part of the site of a full-thickness excised lesion produced in porcine skin, three days after injury, during the inflammatory phase of repair. Intact skin can be seen on the right. Polymorphonuclear leucocytes and macrophages are present beneath the exudate covering the wound bed, and epidermal migration from the intact skin has already commenced. Stained with haematoxylin and eosin. Material supplied by Steve Young and photographed by Kevin Fitzpatrick, Department of Anatomy, UMDS, Guy's Campus, London. Magnification × 135.



1.96 Low magnification light micrograph of part of the site of a full-thickness excised lesion produced in porcine skin, 10 days after injury, during the proliferative phase of repair. Granulation tissue, over which epidermal cells have migrated, fills the wound bed. Stained with haematoxylin and eosin. Material supplied by Steve Young and photographed by Kevin Fitzpatrick, Department of Anatomy, UMDS, Guy's Campus, London. Magnification × 135.

of blood vessel, give this tissue its 'granular' appearance when incised, hence its name (see 1.94, 96, 97).

Granulation tissue forms in response to various signals, which may include chemotactic and growth factors, structural molecules and proteases which digest connective tissue matrix (Clark 1985). It forms a nutritive substrate over which the regenerating epidermis can migrate and is gradually replaced by scar tissue. Apart from the absence of osteogenic cells and chondroblasts, granulation tissue resembles the blastema which develops at the site of fracture repair (p. 314).

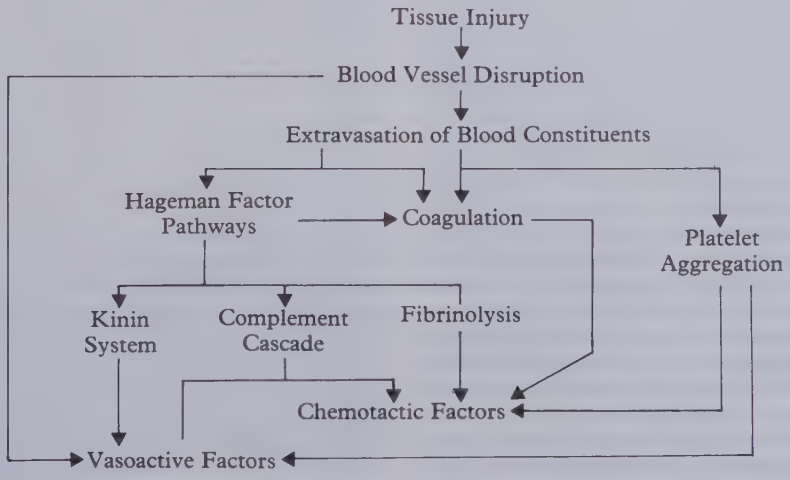
Macrophages, fibroblasts and blood capillaries migrate into the wound bed as a mutually dependent unit termed a *wound module* (Hunt & Van Winkle 1979). In the lead are activated macrophages, followed in sequence by newly differentiated fibroblasts, dividing fibroblasts and capillaries. The macrophages release chemotactic agents which attract pericytes, fibroblasts and endothelial cells into the wound. As the fibroblasts mature they produce a matrix through which other cells can readily migrate and from which delicate new capillaries can obtain mechanical support. As each capillary loop becomes functional it brings nutrients and oxygen to nearby cells, enabling the fibroblasts to secrete materials for the matrix, through which macrophages and other cells can migrate further. The above proliferative and migratory processes are repeated sequentially until the wound bed is filled with granulation tissue.

1.97 High magnification light micrograph of granulation tissue, 10 days after the production of a full-thickness excised lesion in porcine skin. The tissue is well vascularized and contains many myofibroblasts, orientated approximately parallel to the base of the wound and at right angles to the majority of the blood vessels. Material supplied by Steve Young and photographed by Kevin Fitzpatrick, Department of Anatomy, UMDS, Guy's Campus, London. Magnification × 300.

There is considerable experimental evidence to support the proposition that macrophages are key cells in dermal repair. They assist in tissue debridement, release chemotactic agents which attract fibroblasts and endothelial cells to the wound site and secrete lactate which stimulates collagen synthesis by fibroblasts (Comstock 1970), thus strengthening the tissue which develops within and adjacent to the wound (Silver 1974). Intercellular contacts between macrophages and fibroblasts (1.99) suggest that the cells may exert a direct effect on each other. If the migration of macrophages into the wound bed is prevented by anti-inflammatory steroids, or if they are eliminated from it by the application of antimacrophagic serum, the formation of granulation tissue is inhibited (Leibovich & Ross 1975). Inhibition due to anti-inflammatory steroids can be reversed by vitamin A administration, which permits migration of macrophages to the wound site (Hunt et al 1969).

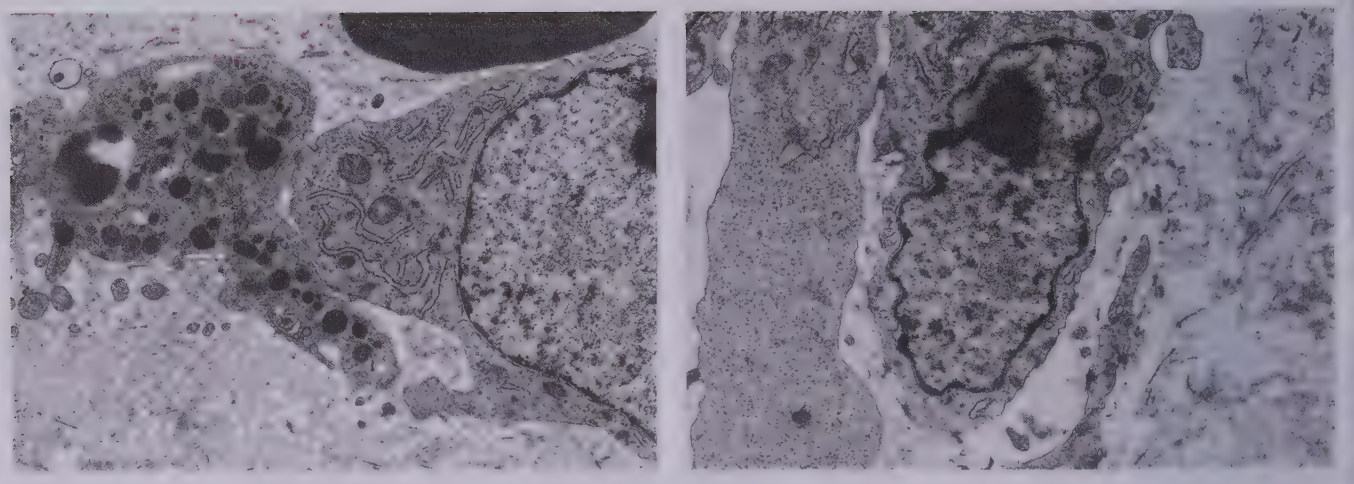
During the proliferative phase of repair fibroblasts of the granulation tissue develop into cells termed *myofibroblasts* (Majno 1979). These cells, which are responsible for wound contraction, the centripetal movement of the wound margin and the consequent reduction of the size of the wound, are immunologically similar to non-striated myocytes, contain peripherally located myofilaments and become linked together by desmosomes and other intercellular contacts (1.99B). Links between the cells and their substrates have also been found (Ryan et al 1974). Intracytoplasmic filaments of actin and vinculin form co-linear assemblies, each termed a *fibronexus* (1.100), with extracellular matrix fibrils of fibronectin (Singer 1979) and types I and III procollagen (Furcht et al 1980). It has been suggested (Singer et al 1984) that a fibronexus is a cohesive complex which transmits the collective forces generated by contraction of all the myofibroblasts of the granulation tissue to the wound margins, thereby effecting wound contraction.

Angiogenesis is a vital part of the proliferative phase of dermal repair. Without it invasion of the wound bed by macrophages and fibroblasts would cease through lack of oxygen and nutrients. In vitro studies have shown that capillary endothelial cells release collagenase in response to angiogenic factors. This degrades the collagen of the basement membrane which later fragments, permitting migration of endothelial cells into the perivascular spaces, where they form buds which are added to by the proliferation of cells within and near the parent vessel (Kalebic et al 1983). During dermal repair these buds grow rapidly towards the free surface, where they branch at their tips and unite to form functional capillary loops. New buds then develop on these loops so that a superficial capillary plexus rapidly forms in the granulation tissue (1.101).



Although the factors responsible for angiogenesis during dermal repair remain unidentified, several candidates have been proposed. These include a macrophage-derived growth factor known to stimulate proliferation of endothelial cells in vitro (Martin et al 1981), low oxygen tension (Remensnyder & Majno 1968), lactic acid (Imre 1964) and biogenic amines (Zauberman et al 1969). Endothelial migration may be more significant than proliferation during angiogenesis after injury. If so, then chemotactic factors will play a key role in vivo. Such factors include platelet-derived substances (Wall et al 1978), heparin (Azizkhan et al 1980) and fibronectin (Bowersox & Sorgente 1982). Successful angiogenesis depends not only on chemotactic and mitogenic factors, but also on the presence of a suitable substrate over which migration of endothelial cells can occur. This may be produced, at least partly, by the endothelial cells themselves, since they have been shown to synthesize fibronectin (Birdwell et al 1978) and collagen (Madri & Stenn 1982).

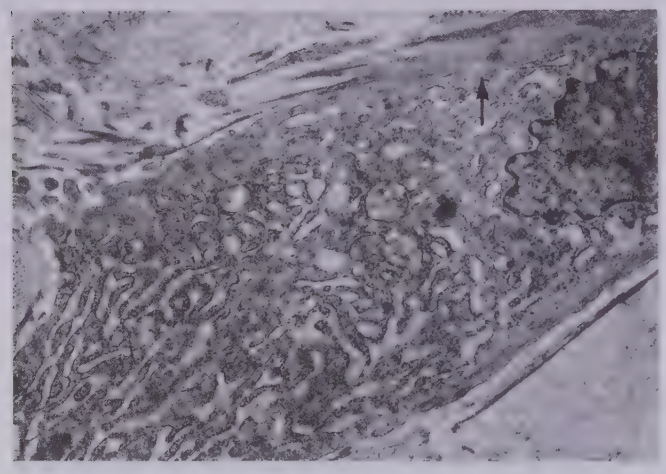
Remodelling



Just as the proliferative overlaps the inflammatory phase, so remodelling overlaps proliferation. During remodelling the highly cellular and highly vascular granulation tissue is gradually replaced by scar tissue with few cells and blood vessels. During the process of remodelling, which may occupy months or even years, most of the fibronectin is removed from the matrix and there is a slow accumulation of large bundles of type I collagen fibres which, as they form cross-links, increase the tensile strength of the scar tissue. Changes in the arrangement of the collagen with time after injury have been studied by scanning electron microscopy (Forrester 1973). When it first appears in the granulation tissue of the wound bed it forms randomly arranged fibrils, which gradually develop into large irregular masses without evidence of any fibrillar substructure. The absence of the characteristic pattern found in uninjured dermis may be associated with the decrease in extensibility and tensile strength which are typical of scar tissue. During subsequent remodelling, the orientation of fibres becomes less random and its strength increases. This change may be caused by the action of mechanical forces exerted on the scar during normal usage to produce orientation of the collagen fibrils in the scar tissue and improve its mechanical function, so that it resembles uninjured dermis more closely.

Such forces may also produce a piezo-electric effect which affects the arrangement of collagen fibrils and fibres. There is now convincing evidence that the pattern of collagen within granulation and scar tissue can be altered by local forces, i.e. that remodelling occurs (Forrester 1973). As long ago as 1892 Wolff noted that bone responded structurally to functional demands. It is likely that scar tissue responds in a similar manner.

The cellular changes involved in dermal repair can be accelerated by treatments which improve the microenvironment of the wound (Dyson et al 1988) and by application of electrotherapy modalities which increase the rate of ingress of macrophages (Dyson 1987, Dyson & Young 1986), possibly by temporarily modifying their membrane structure. The use of such techniques has considerable clinical and surgical significance.



1.98 Mediator pathways of inflammation initiated by tissue injury. After Clark (1985).

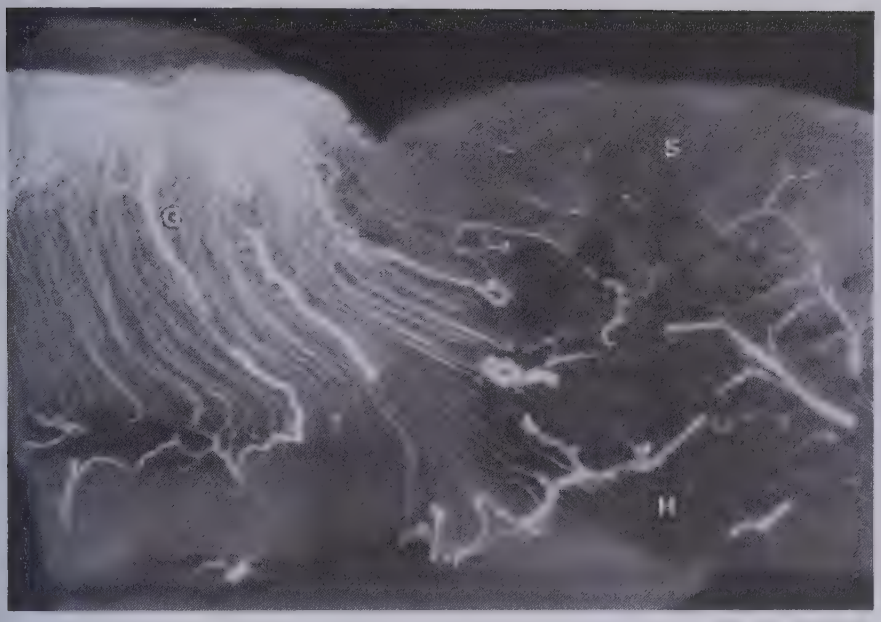
EPIDERMAL REGENERATION

Changes in the epidermis leading to re-epithelialization begin within a few hours of the formation of a cutaneous wound. Intact keratinocytes at the free edge of the cut epidermis begin to migrate across the defect (Winter 1962). Migration is made possible by a change in gene expression of the cells, involving temporary dissolution of hemidesmosomes and desmosomes (p. 24), freeing the cells to move, and the formation of peripherally located actin filaments enabling them to do so (Gabbiani et al 1978). According to the 'leap-frog' hypothesis of epidermal regeneration, (Winter 1962, 1964) cells superficial to the stratum basale at the edges of the wound elongate laterally and crawl over each other until they make contact with the wound bed; they then cease to move and begin to divide, producing a new supply of cells, some of which add to the thickness of the regenerating epidermis. Meanwhile other cells migrate over the first cells, reach the wound bed, divide and repeat the process in 'leap-frog' fashion until prevented from doing so by contact inhibition. According to this hypothesis no single keratinocyte moves more than about four or five cell diameters (approximately 40μm) from its original position during epidermal regeneration. Within 48 hours of injury the basal keratinocytes of the new epidermis begin to divide, generating more cells capable of migration (Hell & Cruickshank 1963). The stimulus for epidermal proliferation after injury is still unknown. It may be the removal of an inhibitory chalone (Bullough & Lawrence 1961) and/or the release of epidermal growth factors (Cohen 1965).



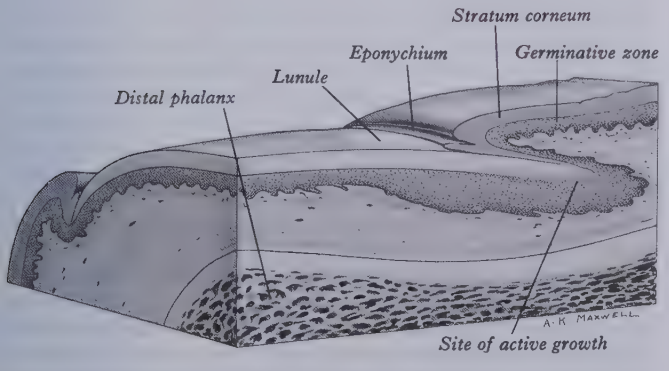
In shallow, partial thickness wounds of thin skin, each cut hair follicle acts as a source of reparative epidermal stem cells. These cells can be recognized by their ability to form a characteristic stem cell keratin (type 19). After migration and division, they produce cells which manufacture other keratins (types 9 and 16) which allow the cells to remain sufficiently flexible to migrate over the wound bed. Later products of keratinocyte division produce more rigid keratins (types 1 and 10), typical of mature epidermis.

If the injury is sufficient to disrupt the basement membrane, the keratinocytes migrate over a temporary matrix of fibronectin, fibrin and type V collagen (Clark et al 1982, Repesh et al 1982, Donaldson & Mahan 1983). Keratinocytes have been shown to secrete fibronectin in vitro (Kariniemi et al 1982, O'Keefe et al 1984, Kubo et al 1984) so it is possible that they may produce at least part of the matrix over which they migrate. Once migration ceases, the temporary matrix is replaced by basement membrane.

Regeneration of the basement membrane occurs in sequential stages. Bullous pemphigoid antigen (p. 78) is always present between the basal plasma membrane of the migrating cells and the temporary matrix and can thus be considered to be the first part of the basement membrane to regenerate (Stanley et al 1981, Clark et al 1982). Once the epidermal cells cease to migrate, first type IV collagen and then laminin become incorporated in the regenerating basement membrane (Clark et al 1982).

If the migrating keratinocytes make contact with small foreign particles of approximately 1μm in size, the cells may remove them by phagocytosis (Odland & Ross 1968), possibly after opsonization by fibronectin (Takashima & Grinnell 1984). The keratinocytes migrate deep to any larger particles and dead tissues which lie in their path. Secretion of plasminogen activators (Isseroff et al 1984), collagenases and neutral proteases (Donoff et al 1971) by the keratinocytes may help to clear the way for their migration.

Once re-epithelialization is complete, the keratinocytes revert to their original phenotype (Clark 1985).



1.101 Microangiograph of a transverse section of granulation tissue (G) showing its invasion by new blood vessels; adjacent intact skin (S), and hypodermis (H) are also visible. The specimen was perfused with barium sulphate and gelatin 10 days after the production of a full-thickness excised lesion in porcine skin. The majority of the regenerating vessels lie at right angles to the surface and are linked by a superficially located capillary plexus. Supplied by Steve Young, Department of Anatomy, UMDS, Guy's Campus, London. Magnification × 130.

APPENDAGES OF THE SKIN

Nails (Ungues)

The nails are horny translucent plates of approximately rectangular shape lying on the extensor surface of the distal segment of each digit (1.102). They are mostly convex in both longitudinal and transverse axes, although there is much variation both between individuals and the different digits of one person. The thickness of mature nails varies from about 0.5 to 0.75 mm. During early development, nails are formed by invaginations of the embryonic epidermis at about nine weeks' gestation and are completely formed by 12 weeks (Zaias 1963).

The nail includes three major regions, the proximal *root (radix)*, the exposed *body* of the nail, and the free distal *border*. The root is inserted in a deep, curved cleft, about 5 mm long, with an overlying *proximal nail fold* whose stratum corneum is prolonged distally on to the body of the nail as the thin *cuticle* or *eponychium*. The sides of the body are bordered by the convex cutaneous *lateral nail folds* (nail walls), the *lateral nail grooves* marking this conjunction. The root of the nail rests on a thick plate of living epidermal cells, the *germinal matrix*, which is closely bound by fibrous dermal tissue to the dorsum of the underlying phalangeal bone (Forslind 1970, Hashimoto 1971). In most digits the matrix extends for some distance distally beneath the nail's body, where it contributes to the appearance of the pale, proximal crescentic area, the *lunule* (lunula); in the hand, the lunule is always visible on the pollex but on the other digits it is progressively covered by the proximal nail fold and on minimus it is usually hidden.

1.102 Longitudinal section through the root of a nail.

The majority of the body is firmly attached to the underlying epidermal *nail bed* or *sterile matrix* which is longitudinally fluted at its junction with the overlying nail and also at its dermal interface. Here the dermis is very vascular, accounting for the pink colour seen through the translucent nail. Under the distal border of the nail is a narrow crescentic zone of epidermis, the *hyponychium*, which is separated from the adjacent volar skin of the digital tip by a shallow *distal nail groove*.

Microscopically, nails are homologous with the stratum corneum, consisting of compacted, dead, anucleate keratin-filled squames, derived from the maturation of cells generated in the germinal matrix and underside of the proximal nail fold (Zaias & Alverez 1968). Both of these epithelial structures have mitotic basal zones which form typical keratinocytes. These undergo terminal keratinization without passing through a granular cell stage; the squames contain closely packed keratin filaments which lie transversely to the direction of growth and are embedded in a dense protein matrix. Marginal bands of dense protein, heavily cross-linked by disulphide bonds, lie beneath the cell membranes (Hashimoto 1971) and the desmosomes are numerous and persistent, giving nail its coherence; the cells are not shed from the surface as they are in the general epidermis. Very little lipid is present and there is usually a low water content, although nails are more than ten times more permeable to water than the epidermis. The ventral surface of the nail is formed by the matrix, while the dorsal strata are generated by the underside of the proximal nail fold; as new cells are formed, they keratinize and are then steadily extruded forward along the plane of the matrix and on to the nail bed. Growth occurs only in the root and lunule, so the thickness of the proximal end of the nail gradually increases as far as the lunule edge, after which it is constant.

The nail bed itself is lined by stratified squamous epithelium in which the surface layer is only parakeratinized, retaining its nuclei. The surface cells become firmly attached to the undersurface of the nail and move distally at the same rate, being shed imperceptibly at the distal border. This tight coupling, largely the consequence of the highly interlocking, longitudinally folded interface, is important, as it prevents the invasion of microbes and impaction of debris under the nail. Although there is a continual turnover of cells in the nail bed, they do not contribute to the nail substance, but provide a gliding surface for its growth. Beneath the epithelium is a richly vascularized dermis anchored to the periosteum of the distal phalanx and forming a distinct compartment. Because of this, infections of the nail bed or other sources

of local pressure rise (e.g. haematoma) may cause severe pain, relieved only by excision of part or all of the nail body.

As already stated, the lunule coincides with the externally visible part of the matrix lying beneath the nail body and obscuring the pink colour of the vascular dermis beneath. However, the nail itself is also cloudy in this area, probably because its keratin is not completely mature.

The rate of nail growth varies with digit, age, environmental temperature, time of day and other factors. Generally its speed is related to the length of the digit, being fastest (about 0.1 mm per day) in the third digit of the hand (medius) and slowest in the fifth (minimus). Fingernails grow up to four times faster than toenails. On average, nails grow quicker in the summer than the winter and faster in the young than the old. Disturbances of the growth pattern caused, e.g. by acute illness or by mechanical damage to its germinative cells, may result in transverse grooves (Beau's lines) or longitudinal furrows; psoriasis typically causes pits in the nail. These defects move forward with growth. More severe damage to the root may result in complete cessation of growth and the nail is then eventually shed, being replaced by a new one if germinative activity recovers. Minor disturbances of nail generation of uncertain origin result in other local defects, including minute air bubbles seen as white flecks.

The dermis beneath the nail is rich in blood vessels, including large arteriovenous shunts (glomera, p. 693). There are also numerous sensory nerve endings, including Merkel terminals (p. 910), and the nails subserve an important tactile function, aiding manipulation. Spatulate nails of this type are found in all the primate species, unlike other tetrapods where a simple keratinized claw typically terminates the digits, and appears to be an important aspect of the evolution of complex, manipulative hands and feet.

For further details of nail biology, see Forslind (1970) and Jakubovic & Ackerman (1985).

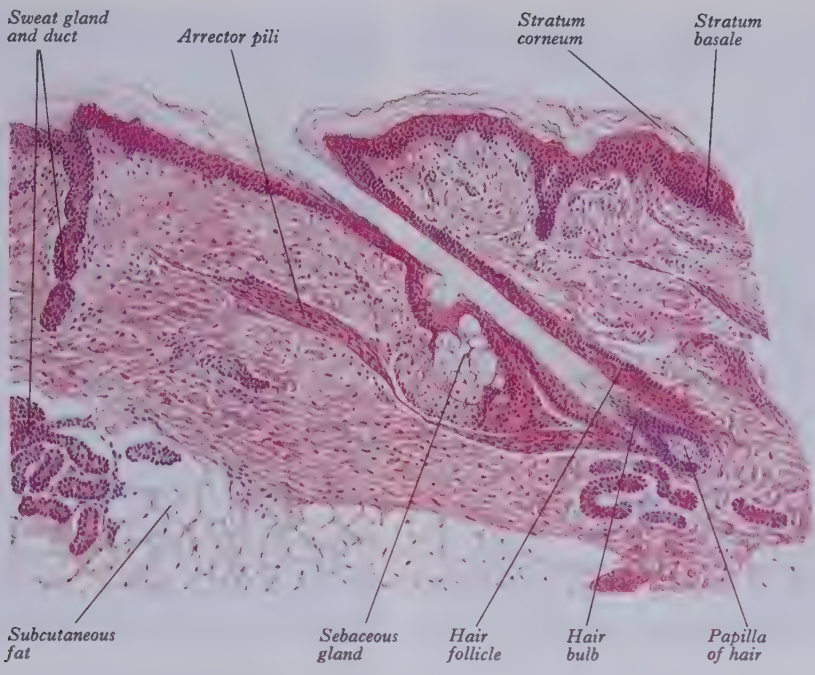
Hairs

Hairs (*pili*) are filamentous, keratinized structures present over almost all of the body surface (**1**.103–106) and are derivatives of the epidermis which assist in thermoregulation, provide some protection against injury, have sensory functions and subserve various subtle roles in social communication. Hairs are absent from a few areas of the body, including the thick skin of palms, soles and flexor surfaces of digits and certain other regions: umbilicus, nipples, glans penis and clitoris, the labia minora and the inner aspects of the labia majora and prepuce. Elsewhere, they vary from about 600 per cm^2 on the face to 60 per cm^2 on the rest of the body.

In length they range from less than a millimetre to more than a metre, in width from 0.005 to 0.6 mm. They vary in form, being straight, coiled, helical or wavy, and differ in colour depending on the degree and type of pigmentation. Such qualities differ with body region and between individuals of different ages, sexes and genetic constitution. In general, body hairs are longest and coarsest in Caucasians and least noticeable in Mongolian races.

Over most of the body surface hairs are short and narrow (*vellus* hairs) and in some areas such hairs do not project beyond their follicles, e.g. eyelid skin. In other region they are longer, thicker and often heavily pigmented (*terminal hairs*); these include the hairs of the scalp, the eyelashes, eyebrows and the post-pubertal skin of the axillae and pubis, and the moustache, beard and often the chest hair of males. The hairs of the nostrils and around the external ear canals are also coarser and of the terminal type. Curly hairs tend to have a flattened cross section and in general are weaker than straight hairs.

Each consists of a *shaft (scapus)* and a *root (radix)* lying within a tubular invagination of the epidermis, the *hair follicle (folliculus pili)*. At the proximal end of the root the hair is expanded to form the *hair bulb (bulbus)*, which is continuous basally with the epithelium of the hair follicle. The bulb is deeply indented on its deep surface by a conical vascular *dermal papilla*.



The hair shaft is composed of cells containing a particularly strong form of keratin in which many disulphide bonds cross-link the protein to form a resistant material with high tensile strength. In section, thick hairs show three concentric zones, the *cuticle*, *cortex and medulla* with different cellular constituents and types of keratin. In thinner hairs the medulla is usually absent. The *cuticle* forms the hair surface and consists of overlapping keratinized squames directed apically and slightly onwards (**1**.106). The *cortex* contains numerous closely packed, elongated cells, also filled with keratin and, except in white hairs, melanosomes (or phaeomelanin in red hair, see p. 78). In mature hair shafts these cells lack nuclei; between them are often air-filled spaces which may modify hair colour. Finally, the central *medulla* is composed of loosely aggregated and often discontinuous columns of rounded or discoidal cells containing vacuoles, keratin filaments, melanosomes and granular material. Air cavities lie between the cells, or even within them. The apical ends of uncut hair are usually tapered to a fine point.

The hair follicle may extend deeply into the hypodermis (**1**.103,104) with long hairs or may be more superficial within the dermis. Typically, the long axis of the follicle is oblique to the skin surface; with curly hairs, it is also curved. At its deeper end (*fundus*) it enlarges to accommodate the hair bulb and apically it receives the ducts of sebaceous (and sometimes apocrine) glands before expanding into a funnel-shaped aperture (**1**.103). The region above the sebaceous duct is the *infundibulum*, then basally as far as the attachment of the arrector pili muscle is the *isthmus* and deep to this, including the region enclosing the hair bulb, is the *inferior segment*. The follicle is surrounded by a thick perifollicular dermal coat containing type III collagen, elastin, sensory nerve fibres and blood vessels and into which blend the arrector pili muscles. Marking the interface with the dermis and follicular epithelium is a broad, PAS-positive basal lamina, the *glassy membrane*. Within this are arranged concentrically the epithelial *outer and inner root sheaths* surrounding the hair shaft.

The outer root sheath (**1**.105) is an invagination of the epidermis and has a similar although not identical stratification into basal and spiny cell layers which, in growing hairs, are rich in glycogen. Above the level of the inferior segment, its surface cells undergo keratinization, although no granular stratum is found. In deeper regions it is unkeratinized, forming a sheath a few cells thick. *The inner root sheath* occurs mainly in the inferior segment and is a three-layered structure formed basally in the hair bulb, moving apically with the growing hair and disintegrating in the isthmus of the follicle. Its three zones are, from outermost inwards: the *stratum epitheliale pallidum (Henle's layer)*, a single layer of keratinizing cells with pale, flat nuclei; then the *stratum epitheliale granuliferum (Huxley's layer)*, composed of two layers of partially keratinized cells containing strongly eosinophilic trichohyalin granules; and finally a single layer of flattened squames with atrophied nuclei, the *cuticle of the inner root sheath*, facing and loosely interlocking with the cells of the hair shaft cuticle. The keratin of the inner root sheath is soft and the cells of this structure disintegrate by the level of the sebaceous ducts, or before; they may play a part in protecting the incompletely keratinized basal regions of the hair root or in assisting its passage through the follicle.

The hair bulb (**1**.104) has at its base the *germinative matrix*, a zone of great mitotic activity which generates the hair and its surrounding inner root sheath, and more apically a *keratogenous zone* in which the cells undergo keratinization. The germinative matrix is composed of a mass of closely packed, pluripotent polygonal cells capping the dermal papilla. Cells arising mitotically from this group move apically and may differentiate along several different routes, depending on their position of origin. Those arising from the centre of the base may form the hair medulla; then, radially further out, successive concentric rings of cells will transform into the cortex and cuticle of the hair and, outside this, into the cells of the inner root sheath. The outer root sheath forms the walls of the whole structure but is apparently not derived from it.

This arrangement is of great theoretical interest, since the continuing activity of the whole root complex involves various morphogenetic processes in which different cell shapes, distinct chemical forms of keratin and migration patterns are produced, depending on which genes are being expressed. The entire unit

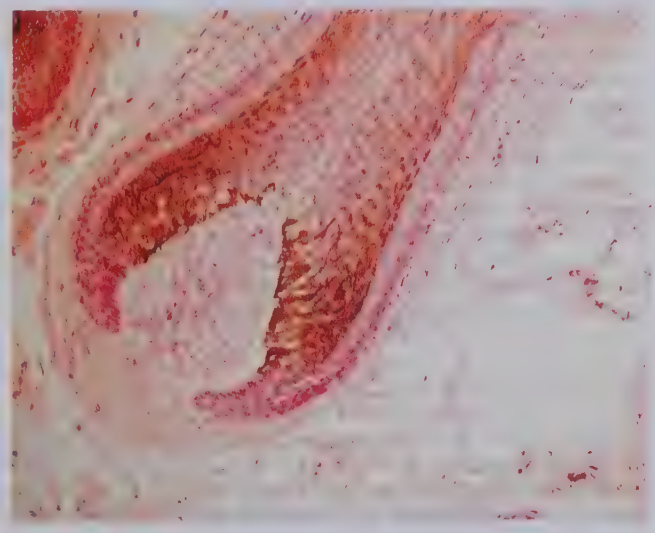
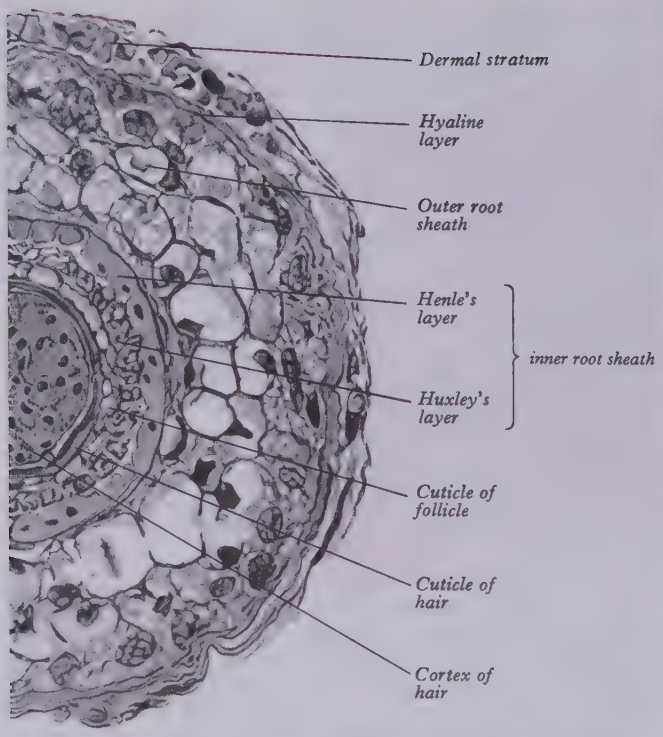
appears to depend on interactions with the connective tissue of the dermal papilla, whose presence is necessary for the hair to be formed and maintained; damage to the papilla results in abnormalities or loss of the hair.

Interspersed among the basal cells of the bulb are numerous melanocytes (1.104), their dendrites spreading and branching among the differentiating cells of this mass. Melanosomes (or in red hair, phaeosomes) are synthesized and passed on to the forming cells of the hair shaft, in the manner already described in the epidermis (p. 78), and so are responsible for hair pigmentation. Except in genetic albinism, white hairs have inactive melanocytes which do not contribute melanosomes to the hair root.



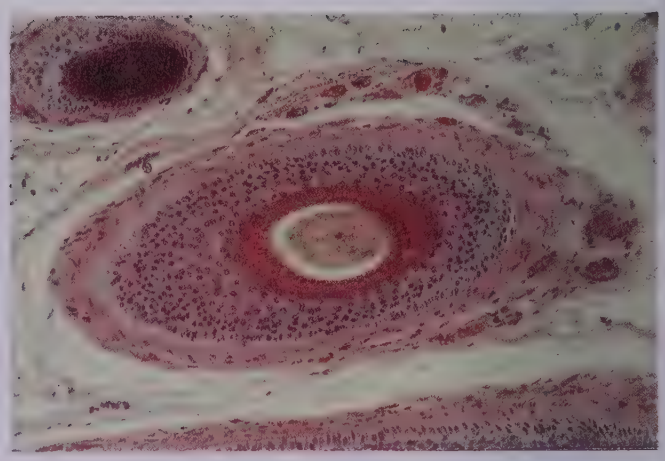
The growth rate of hairs varies with their site and thickness, ranging from about 1.5 mm (fine hair) to 2.2 mm (coarse hair) a week when actively growing. There are, however, cycles of growth and hair loss. Fast growing hairs are said to be in the *anagen phase*; this is followed by the involuting or *catagen phase*, when growth ceases, then the resting or *telogen phase*.

The anagen phase of large hairs such as those of the scalp lasts up to ten years, the catagen phase about three weeks and telogen up to four months, after which a new hair bulb is formed in the same follicle and a new hair also begins to grow. Hairs may be shed at any time after growth has ceased. In smaller hairs the growth cycle may be much shorter than this, as little as six months. During catagen, the germinative matrix ceases mitosis and the whole inferior segment of the follicle degenerates, so the expanded base of the hair moves upwards and is enclosed in an epithelial sac; such hairs are termed *club hairs*. During telogen the inferior segment of the follicle is totally absent and a new one has to be formed by interaction with a renewed dermal papilla before the next anagen can begin.



Cycles of growth and hair loss occur randomly in postnatal life, so that, e.g. in the scalp, about 85% of hairs may be in anagen phase. In some animals, hair growth and shedding is seasonally synchronized; this is also seen to a lesser extent in early development, as hairs of the fetus begin vigorous growth by the fifth month and tend to be shed in quantity during the third month of postnatal life.

Hair follicles are first seen as cord-like epidermal downgrowths into the mesenchyme at about the third month of gestation. Mesenchymal condensations then invade the base of these cords to form papillae; sebaceous glands bud off apically and arrector pili myocytes begin to differentiate to one side of the follicle. By the fifth month the body is covered by fine, often deeply pigmented primary hairs (collectively the *lanugo*); on the back these hairs are more frequent than those of the gorilla and chimpanzee at a similar age. Lanugal hairs are mostly shed before birth and are replaced by the secondary, *vellus* hairs, except on the scalp, eyebrows and palpebral margins. Since no further follicles are formed after birth, hairs become more widely spaced as the area of skin increases with body growth.



With puberty, hair growth and generation of much thicker hairs occurs on the pubes and axillae in both sexes and, under the influence of androgens, on the face and trunk in males. The actions of hormones on hair growth are complex but in general androgens stimulate facial and general body hair formation and, after about the first 30 years, tend to cause the thick terminal hairs of the scalp to change to small vellus hairs and may eventually cause complete baldness. In females, oestrogens tend to maintain vellus hairs in their formation of minute hairs, and in post-

menopausal life reduction in oestrogens may permit stronger facial and body hair growth. During midpregnancy, hair growth may be particularly active but some weeks later an unusually large number of hairs tend to enter the telogen phase and may be shed before the growth cycle recommences.

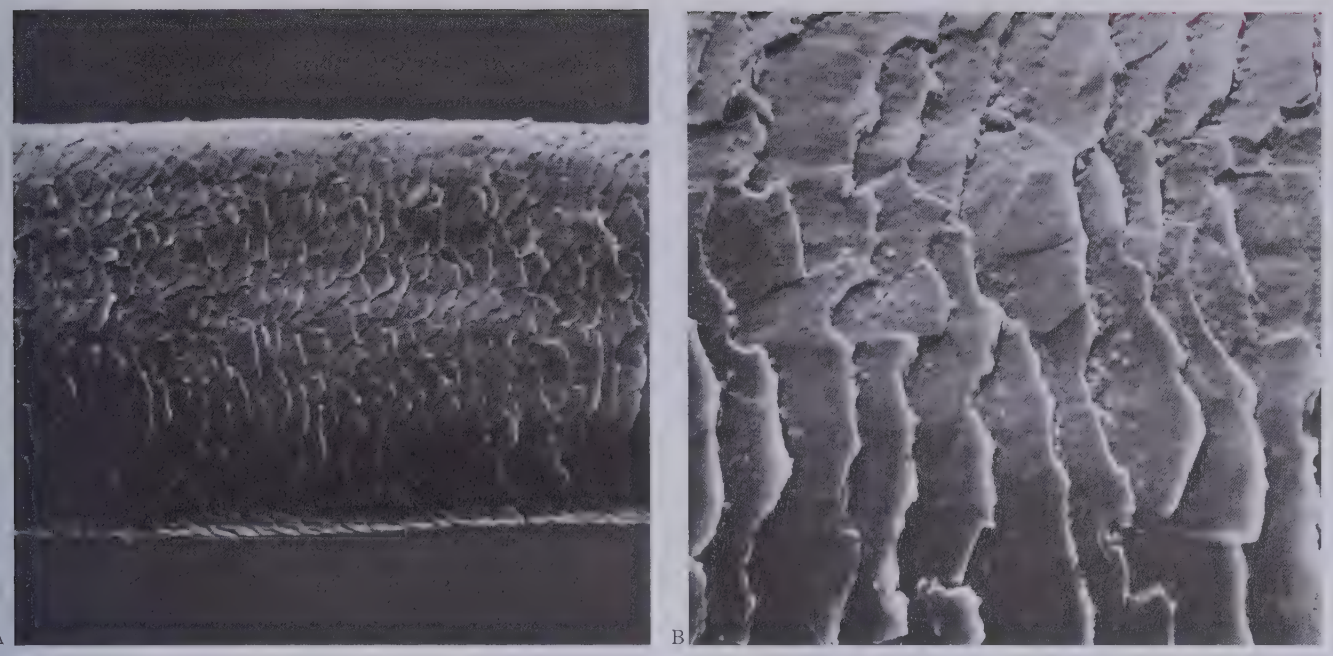
In older men, growth of hairs on the skin inside the eyebrows, nostrils and external ear canals tends to occur more rapidly, whereas elsewhere on the body growth slows and the hairs tend to become much finer.

Arrector Pili Muscles

These are small fasciculi of non-striated myocytes which form diagonal links between the dermal sheaths of hair follicles and the superficial (papillary) layer of the dermis (1.80,103). They are attached to the isthmus region of follicles, where the dermis contains many elastin fibres, and are directed obliquely and superficially towards the side to which the hairs slope. Contraction therefore tends to pull the hair more vertical and to elevate the epidermis surrounding it into a small hillock, while dimpling the surface where the muscle is inserted superficially, giving the appearance of 'goose flesh' on exposure to cold or emotional stimuli. The myocytes are innervated by noradrenergic terminals of cutaneous sympathetic nerves and may also respond to high levels of circulating catecholamines. Arrector pili muscles are absent from facial and axillary hairs and from eyelashes and eyebrows and the hairs around nostrils and external ear canals.

These muscles are believed to help express the secretions of sebaceous glands which occupy the angles between the arrector pili and the hair follicle. In many mammals, pilo-erection is a means of signalling aggression, fear and other social responses.

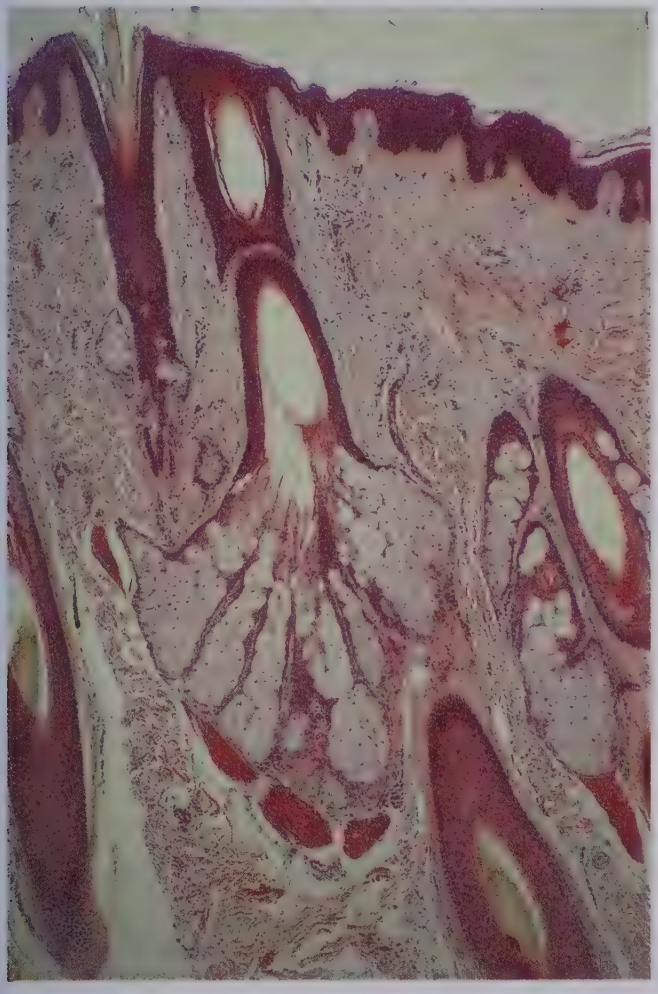
Sebaceous Glands



Sebaceous glands are small saccular structures (1.80,103) lying in the dermis and present over the whole body except the thick hairless skin of the palms, soles and flexor surfaces of digits; they secrete an oily substance, *sebum (sebum cutaneum)*, over the skin surface and on to hairs.

Typically, sebaceous glands consist of a cluster of two to five (occasionally up to 20) secretory acini opening by a short common duct into the apical portion of a hair follicle and can be considered together with the follicle and arrector pili muscle as part of an anatomical unit, the *pilo-sebaceous complex* (see the extensive review by Wheatley 1986). In some areas of thin skin lacking hair follicles, their ducts open instead directly on to the skin surface, e.g. on the lips and corners of the mouth, nipples, female mammary areolae (Montgomery's tubercles), glans penis, inner surface of the prepuce (glands of Tyson), glans clitoridis and labia minora; at the margins of the eyelids, the large, complex palpebral tarsal glands (Meibomian glands) are of this type (p. 1215).

In general, numbers of sebaceous glands in any given area reflect the distribution of hair follicles, ranging from an average of about 100/cm² over most of the body to as many as 400–900/cm² on the face and scalp. They are also numerous in the midline of the back. Individual sebaceous glands are particularly large on the face, around the external auditory meatus, chest and shoulders and on the anogenital surfaces (*sebaceous follicles*), and may become distended by their accumulated secretions. Those of much of the face are related to very small vellus hairs (p. 90), whose investing follicles have particularly wide apertures, usually filled with sebum.



Microscopically, the glandular acini are seen to be invested by a basal lamina supported by a thin dermal capsule and a rich capillary network (1.107). Within this, each acinus is lined by a single layer of small, flat, polygonal epithelial cells (1.108). These possess euchromatic nuclei and large nucleoli, keratin filaments, agranular endoplasmic reticulum, free ribosomes and rounded mitochondria and are attached to each other by desomosomes. Functionally, they are mitotically active stem cells whose offspring move gradually towards the centre of the acinus, increasing in volume and accumulating increasingly swollen lipidic vacuoles. Their nuclei become pycnotic as the cells mature and finally the relatively huge, distended cells disintegrate, filling the central cavity and its effluent duct with a mass of fatty cellular debris. This mode of secretion, involving the total destruction of the glandular cells, is described as *holocrine* (p. 57). For further information see Strauss et al (1976) and the comprehensive review of sebaceous gland biology by Wheatley (1986).

The secretory products pass through a wide duct lined with keratinized stratified squamous epithelium into the apical part of the hair follicle (the infundibulum) and thence on to the surface of the hair and epidermal surface. When first formed, sebum is a complex mixture of which over 50% is di- and triglycerides, with smaller proportions of wax esters, squalene, cholesterol esters and cholesterol (Stewart et al 1983). As sebum moves along its duct its glycerides are partly hydrolyzed by bacterial action to free fatty acids. The normal functions of these components are not yet understood but it is likely that, at least in some cases, they form a

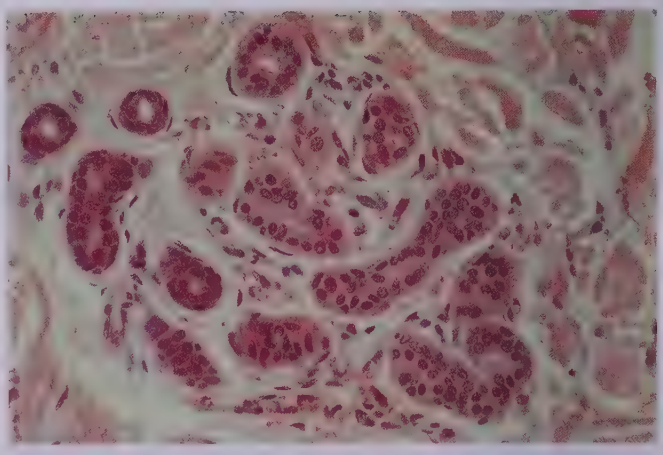
protective coating of lipid on hairs, possibly assist waterproofing of the epidermis, discourage blood-sucking ectoparasites and contribute to characteristic body odour, a feature which in our ancestral conditions may have possessed strong positive social connotations and in the new-born could play a part in the relationship between mother and child.

Prenatally, sebaceous glands arise by invagination from the epidermis between 13 and 15½ weeks' gestation and at birth are quite large, regressing later until stimulated again at puberty. At that time, sebaceous gland growth and secretory activity increase greatly in both males and females, under the influence of androgens, and possibly growth hormone from the adenohypophysis amongst other factors. Excessive amounts of sebum may become impacted within hair follicles, causing damage and inflammation of the surrounding area and thus causing acne. Secretory activity does not appear to be under nervous control but contractions of the neighbouring arrector pili muscles attached to hair follicles may compress them and stimulate their discharge.



Sudorific (Sweat) Glands

These are divisible into two types: *eccrine* glands, numerous and present over almost all of the body surface and *apocrine* glands confined to a few, restricted areas (see the reviews by Zelickson 1971). *Ceruminous glands* of the ear canal and *ciliary glands* (of Moll) in the margins of the eyelids are also modified sweat glands.

Eccrine sweat glands (1.80) are long unbranched tubular structures, each with a highly coiled, wider secretory portion (the *body* or *fundus*, up to 0.4 µm in diameter) situated deep in the dermis or hypodermis and a narrower, straight or slightly helical *ductular portion*, which in the deeper layers of the dermis is convoluted or twisted. The walls of the duct fuse with the base of epidermal (rete) papillae and the lumen passes between the keratinocytes often, particularly in thick hairless skin, in a tight spiral (1.80), to open via a rounded aperture on to the cutaneous surface. In thick hairless skin, they discharge by a regular series of punctae along the centre lines of friction ridges, incidentally providing markers of fingerprint patterns for forensic purposes. Eccrine glands are absent from the tympanic membrane, margins of the lips, nail bed, nipple, inner preputial surface, labia minora, glans penis and glans clitoridis. Elsewhere they are numerous, their frequency ranging from 80 to over 600/cm², depending on

position and genetic variation (Montagna & Parakkal 1974, Millington & Wilkinson 1983). Numbers are greatest on the plantar skin of the feet, but there are also many on the face and flexor aspects of the hands, while the surfaces of the limbs generally have the fewest. Racial groups indigenous to warmer climates tend to have more than those of cooler geographical areas.

In microscopic structure, the whole length of the gland is surrounded by a thin fibrous dermal sheath and an investing basal lamina. The secretory portion consists of a pseudostratified epithelium enclosing a wide lumen (1.109). There are three types of cell: *clear cells*, from which most of the secretion derives, *dark (mucoid) cells* and *myoepitheliocytes*.

Clear cells are approximately pyramidal in shape, with their bases resting partly on the basal lamina and their apices not reaching the lumen of the gland, but instead facing one or more small intercellular canaliculi which are confluent with the lumen. Their apical aspects bear numerous irregular microvilli; their bases are also highly folded where they abut on to the basal lamina. The cytoplasm is rich in glycogen granules and mitochondria, and some granular endoplasmic reticulum and a small Golgi complex are present. The nucleus is rounded and moderately euchromatic.

Dark cells are also pyramidal, with their narrow ends on the basal lamina and their broad ends facing the lumen. Their cytoplasm contains organelles associated with secretory activity—granular endoplasmic reticulum, Golgi complex and numerous dense carbohydrate-rich secretory vacuoles which discharge into the lumen.

Myoepitheliocytes (see p. 55) are numerous; they are elongated and lie among the foot-processes of the other types of cell, just within the basal lamina of the gland. A rich sympathetic efferent innervation, mostly cholinergic, surrounds the glandular portion and is responsible for stimulating myoepitheliocyte contraction, resulting in an immediate secretory response as well as the more delayed increase in glandular activity due to increased blood flow in the area.

Eccrine dermal sweat ducts are lined by two layers of basophilic cuboidal epitheliocytes, the inner of which has short microvilli bordering the duct lumen. A strongly eosinophilic layer lines the apices of the inner cells. The ductular cells have many mitochondria and rounded nuclei. Ductular cells within the epidermis migrate and keratinize in the same way as surrounding keratinocytes.

Sweat glands secrete a clear, odourless fluid, hypotonic to tissue fluid and containing small quantities of many substances, predominantly sodium and chloride ions but also urea, lactate, amino acids, immunoglobulins and other proteins, bicarbonate, calcium ions etc. When initially secreted, the fluid is similar in composition to tissue fluid but is modified as it passes along the duct by the action of its lining cells, which resorb sodium and chloride and some water too. The hormone aldosterone enhances this activity. Secretion is stimulated chiefly by temperature rise but, in certain areas of the body (hands, face and axilla), the glands react most strongly to emotional stimuli. These effects are mediated by the cholinergic sympathetic innervation surrounding the glands.

Apocrine sweat glands are particularly large glands of the dermis or hypodermis but, unlike the eccrine variety, they typically discharge into the apical regions of hair follicles. They are present only in a few areas of the body, namely the axillae, perianal region, areolae, peri-umbilical skin, prepuce, scrotum, mons pubis, and labia minora. Ceruminous glands of the external auditory meatus and the ciliary glands of the palpebral margins (glands of Moll) are also usually included in this category. However, their secretions are quite different and these glands should be considered as distinct, specialized subtypes (for details see pp. 1222 and 1215 respectively).

Although apocrine glands resemble the eccrine category in having a coiled basal secretory body and a straighter duct, the secretory region may be as much as 2 mm wide, being greatly distended by accumulated secretions; its coils often anastomose with each other to form a labyrinthine network. Their walls are lined by a single layer of cuboidal epithelium with rounded euchromatic nuclei and complex, microvillous apices which tend to protrude into the lumen. Among the bases of these cells lie numerous longitudinally orientated myoepitheliocytes, the whole complex of cells resting on a thick basement and, outside this, a connective tissue capsule, rich in capillaries.

The cuboidal cells have typical secretory cell contents—granular and agranular endoplasmic reticula, Golgi complex, dense secretory vacuoles—their numbers varying with the cycle of synthesis and discharge. The mechanism of secretion is still not entirely clear but may involve a number of different processes (see Hashimoto 1978), including merocrine secretion of granules, detachment of large volumes of apical cytoplasm (*apocrine secretion*) and occasionally complete, holocrine disintegration of epithelial cells.

The secretions within these glands are a proteinaceous, thick milky fluid which at first is sterile and odourless but undergoes bacterial metabolism to generate potent odorous compounds, musky or urinous in smell, including short-chain fatty acids, etc. In many animals these are potent pheromonal signals important in courtship, parental and territorial behaviour, as well as in various other aspects of social life. Their role in modern humans is less certain, although there has been much speculation on the potency of, e.g. axillary odours in the more subtle aspects of human interactions (see Gower et al 1987).

Apocrine glands are formed at the same time as eccrine glands and are at first widely distributed over the fetal body surface but from five months' gestation onwards are progressively lost, except in the small areas where they are occur in adults. At puberty they enlarge and become actively secretory. For reviews of this subject, see Hashimoto (1978), Tani et al (1980) and Jakubovic & Ackerman (1985).

GRAY'S ANATOMY

EMBRYOLOGY

2

Introduction

Distinguishing living organisms from inanimate objects intuitively seems simple and commonplace, but such distinction still defies concise scientific definition. This question is obviously central to any study of living forms, and biological texts commonly open by considering a series of attributes, such as irritability and other responses to environmental change, motility, ingestion followed by transformation (metabolism) of foodstuffs and excretion of end products, growth, reproduction and maturation.

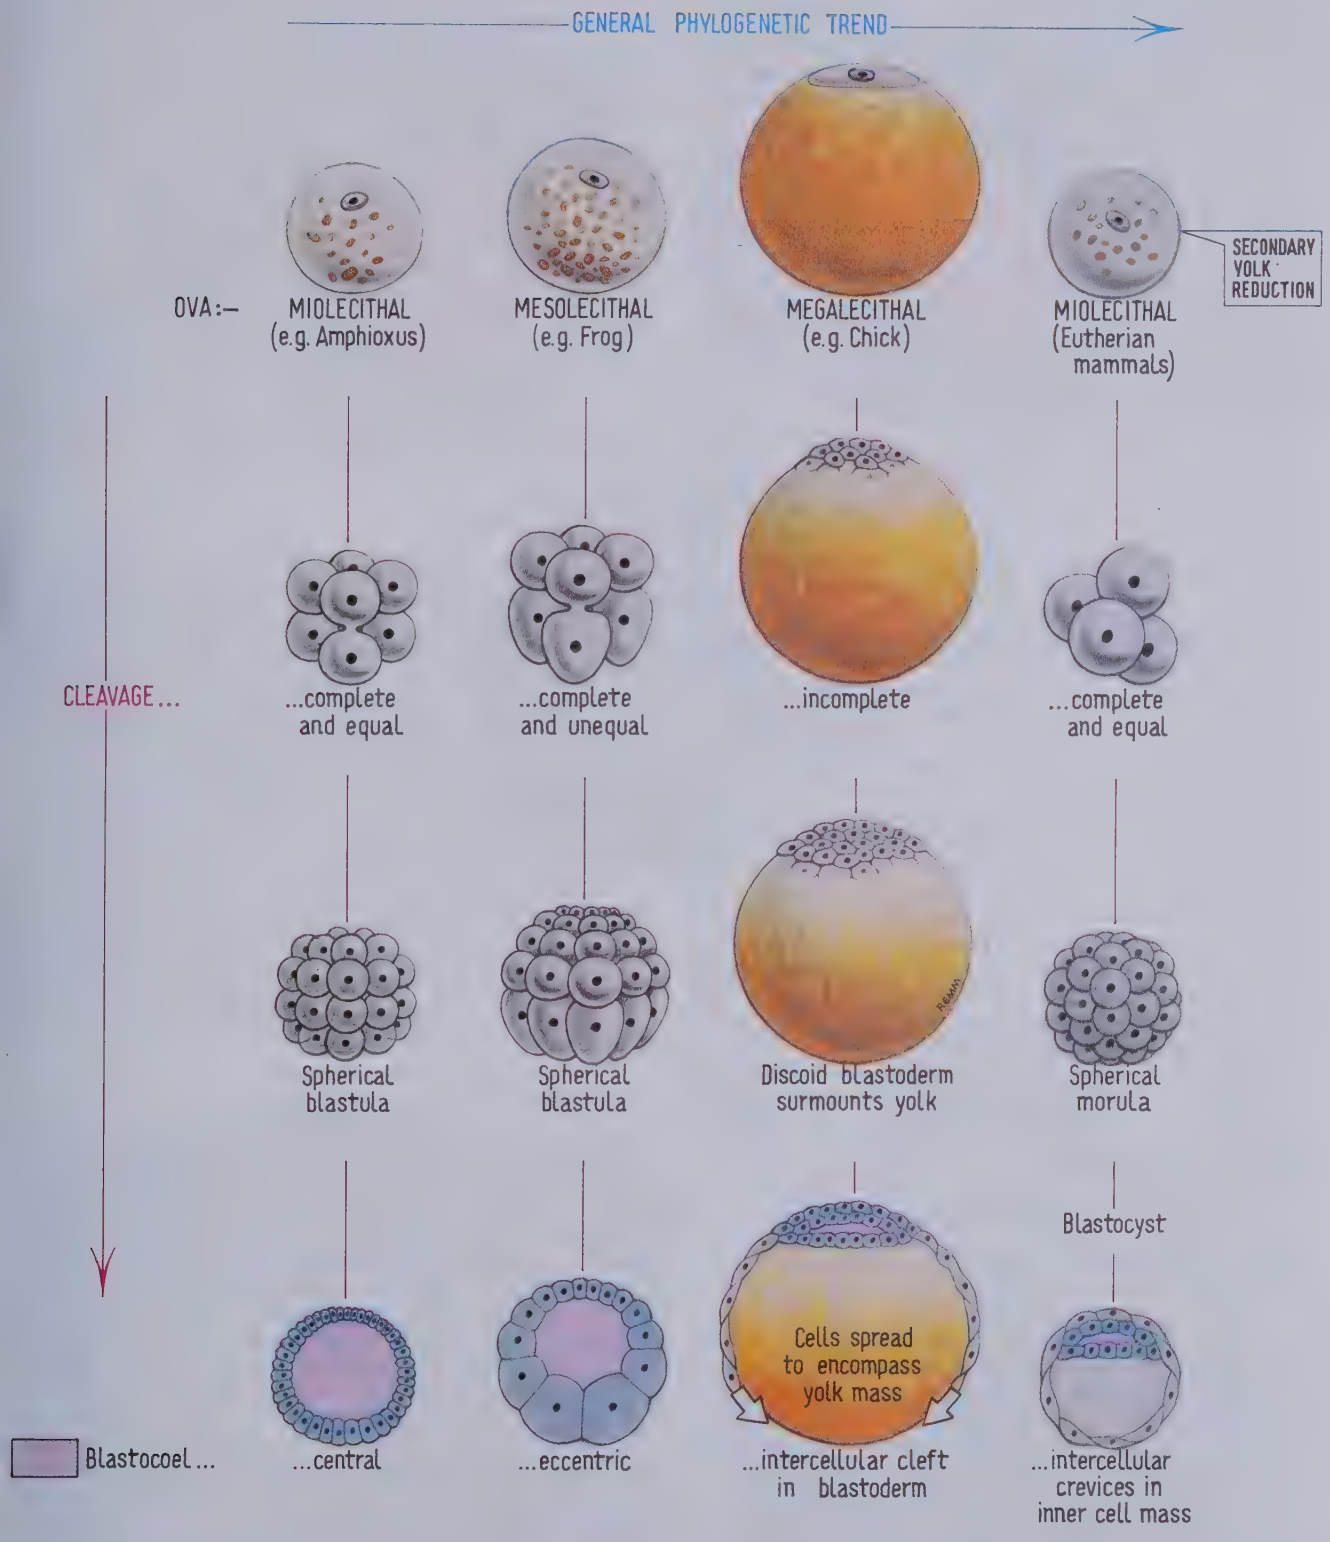
However, the basic building blocks of living things, sub-atomic particles, atoms and molecules and interblock forces, are common to all materials known to man; the animate attributes listed above appear as inevitable consequences of particular arrays or *organizations* of the building units.

THE DYNAMISM OF LIVING ORGANISMS

Examination of both the physical universe and the biosphere has led to widely accepted fundamental generalizations: firstly the relativistic nature of all forms of observation, and secondly the interrelation between matter and energy. The latter, stated explicitly in the *laws of thermodynamics*, holds that the total energy content of the universe is constant but that the proportion of disorganized, randomized or dissipated energy (*entropy* level) is steadily *increasing*. Living systems, however, appear locally to reverse this trend by their growth, reproduction and increasing structural complexity, that is to say, their entropy level is *decreasing*. This apparent paradox is answered by considering life forms as interlocked structurally, functionally and energetically with their environment, from which they are supplied by a constant flow of energy essential for their maintenance (Schrödinger 1967, Lehninger 1965, Young 1964). The ultimate source of this energy is the structural degradation of materials in the sun with the emission of radiant energy partly as light. This is trapped by green plants and used in photosynthetic processes whereby simple substances are energetically transformed into complex molecules incorporated into the plant tissues and eventually provide a source of chemical energy, or food, for the animal kingdom. (A minority of elementary organisms have energy provided by degradation of materials in the earth's core.) This absolute dependency upon supplies of environmental energy reflects the *dynamic* nature of life processes, which constantly undergo change. Further, continued success of an organism in any habitat implies that its structural/functional organization is complementary to features of its environment, and they can only be studied intelligently together, that is, as one system. Indeed, some hold that the various control systems of an organism necessarily embody a 'model' of their environment for effective responses to occur (Young 1971, 1978).

That living organisms are dynamic, of course, denotes changing states with the passage of time, but the temporal scale chosen for study may vary from millions of years to fractions of milliseconds. Examples of the latter include brief biochemical and biophysical interactions such as the activation of visual pigments by photons, conformational changes in cell membranes with consequent alterations in permeability, as during the transmission of a nervous impulse or the release of a neurochemical transmitter, and the formation and breaking of linkages between actin and myosin subunits during muscle contraction. A relatively short time scale is also involved in the multitude of feedback systems whereby the state of the internal and external environment is constantly monitored and appropriate adjustments are made to preserve the internal environment within the fairly narrow range of values necessary to the continued life of cells. Such a preservation of internal constancy, a comparatively rapid variety of *homeostasis* (p. 860), despite *short-term* fluctuations in the surroundings, is a central feature of the operation of all the principal bodily systems, e.g. the regulation of temperature, blood pressure, hydration, osmolarity, electrolyte and hydrogen ion concentrations, glucose and oxygen levels, etc. To these may be added somewhat *slower homeostatic cycles* of endocrine secretory control systems, the varying rates of cell growth, death and replacement in different tissues, the behaviour patterns associated with mating, rearing of young, searching for and securing food, and also the ill-understood processes which lead to the laying down of short- and longer-term memory traces. (Long-term homeostasis is discussed below.)

REPRODUCTION AND EVOLUTION



Contrasting with such changes of short duration all extant organisms' ancestries stretch back over hundreds of millions of years, a period involving great changes in the natural environment. The latter were paralleled by a gradually increasing diversity of form and complexity of organisms, each more or less well adapted to life in some particular pocket of the changing environment. The *long-term homeostatic mechanism* which enabled this diversification is intimately connected to another aspect of the dynamism of living organisms. Thus, in addition to securing an adequate flow of solar or chemical energy to drive its cellular machinery and continually replace its substance, each individual organism also passes through stages of *growth*, increasing *maturity* and, in complex forms, eventual *senescence* and *death*. Continuing life of the species is therefore dependent upon some mode of *reproduction*. Elementary life forms increase their mass and maturity until, at a critical point, they reproduce by simple equating division of their substance. Each successive organism has the same essential physico-chemical constitution as the parent, and part of its structure operates as an information store, i.e. a chemical (or genetic) *memory system*, so that the offspring grow into identical replicas of the parent. Occasionally, however, apparently spontaneous changes occur in the organization of the genetic memory store and such *mutations* lead to the emergence of organisms with altered characteristics. Often such *mutants* are less well fitted for survival under environmental stresses and they succumb, but sporadically a *favourable mutation* occurs. The transmission of this to succeeding generations leads to the establishment of a species with an enhanced probability of survival and, occasionally, the ability to populate new or changing environments.

Such **asexual** methods of reproduction occur in many relatively simple extant forms of life, but the great diversity and complexity of the remainder followed the emergence of **sexual** methods of reproduction, each offspring the outcome of welding of half of the genetic memory of *two* parents. In essence each parent *segregates* certain specialized *reproductive cells* in which there is a *rearrangement* of the genetic material, and a *reduction* to half the quantity found in the general cells of the body (p. 42). Two reproductive cells, one from each parent, approach and *fuse*, and their genetic material intermingles in a specific manner (p. 123). The offspring, whilst in part possessing certain characteristics which resemble those of one or other parent, and of course those of the species in general, also possesses unique features due to the new genetic combination and the previous genetic rearrangement. When the effects of occasional favourable mutations are added to the infinitely varied genetic combinations resulting from sexual reproduction over countless generations, the opportunities for the initiation of altered species are vastly increased. On this wide range of variants the forces of *natural selection* operate and result in the endless array of life forms which populate all corners of the earth's surface, oceans and skies.

Any organism, therefore, including mankind, is not only interlocked structurally and energetically with its environment, exhibiting transient homeostatic responses and rhythmic variations, but is also at some point in its individually unfolding life history (*ontogeny*). It is progressing towards senescence, and possesses a unique genetic apparatus, the result of innumerable generations of diversifying, sexually reproducing ancestors (*phylogeny*). All these grades of dynamic change should be considered when any study of the fabric and behaviour of mankind is undertaken.

The present section attempts a summary of the ontogeny of the human body. Comprehensive texts and papers are cited as frequently as space restrictions permit.

EARLY DEVELOPMENT OF CHORDATA

2.1 Variations in the patterns of cleavage in *Chordata* associated with differences in oöcyte size, yolk volume and distribution. Note that the overall phylogenetic trend is from left to right, and the progression of cleavage from above downwards. Note also the morphological *differences* and often proposed '*homologies*' between the various groups. Not drawn to scale. Consult text for further comment.

Sexual Reproduction

Sexual reproduction can conveniently be divided into several chronological stages, namely *gametogenesis, fertilization, cleavage, gastrulation* and *organogenesis*, whilst to the latter three stages the general term *embryogenesis* may be applied. This essentially reflects orderly temporal and spatial variations in *growth, morphogenetic movement* and *patterned differentiation*, balanced against *regional degeneration* and *death* of cells and tissues. A brief survey of these phases of development will be given before proceeding to a more specific account of human ontogeny.

GAMETOGENESIS

A multicellular organism which reproduces sexually consists mainly of general body (*somatic*) cells which, although exhibiting extreme ranges of variation in size, shape and specific functional as well as morphological characteristics, all possess certain common features of their genetic apparatus. This contrasts with the highly distinctive differentiation process and genetic changes which occur within the *gonads* and result in the formation of mature *generative (germ)* cells or *gametes*. General somatic cells usually possess a full or *diploid number* of chromosomes, a half of which was originally derived from each parent. However, the *activity* and *expression* of the many different gene loci on the chromosomes varies in different cell types in adult tissues, and during development as differentiation occurs. The somatic cells which are capable of dividing do so by the process of mitosis (p. 42). Each chromosome, having first made a faithful replica of itself and thus of its genes, divides longitudinally and each resultant cell is again equipped with the diploid number of chromosomes which are replicas of those in the parent cell. During gametogenesis, however, a complex series of changes termed *meiosis* are set in train (p. 42). Essentially, during this, the original chromosome number is reduced to a half, the *haploid number*, in which a *recombination* of the genetic material has occurred. (Details are considered on p.44.) The male gonad or *testis* produces many small motile gametes or *spermatozoa* in which the cytoplasmic machinery is much reduced; each consists of a nucleus bearing the genetic apparatus, the chromosomes, with a closely applied acrosome derived from a Golgi apparatus and succeeded by a long flagellum which is partly ensheathed by an energy-transforming mitochondrial sheath (p. 119). In contrast the female gonad or *ovary* produces fewer, larger non-motile *ova*, their cytoplasm containing a variable quantity of food reserves (*yolk* or *deutoplasm*) and exhibiting regional variations of the cortex (*oöplasmic segregation*) which are of importance in the initial stages of differentiation (p. 104 et seq).

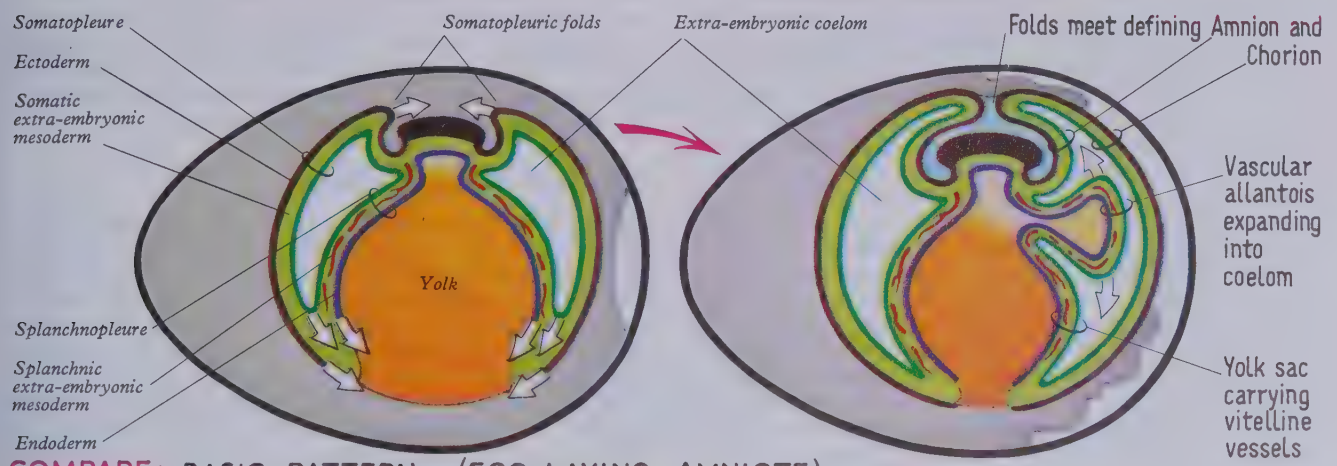
Types of Ova and their Influence on Development

Ova vary enormously in their size, amount of yolk and number shed, throughout the animal kingdom, and within the Chordata a broad evolutionary trend can be recognized (**2.1**). Elementary aquatic forms usually produce many small *miolecithal* (yolk-poor) ova, which, after fertilization, rapidly develop into independent larvae, many of which succumb to predators and other inhospitable features of the environment. The larger ova of the amphibia are *mesolecithal* (with greater reserves of yolk), but again, those fertilized ova that survive are *wholly* transformed into aquatic larval stages which forage for food independently and exhibit long periods of growth, differentiation and metamorphosis before the mature state is reached.

Colonization of dry land by forms not restricted by a periodic return to the water for reproductive purposes was necessarily paralleled by drastic evolutionary modifications in their ontogeny. Reptiles, birds (and prototherian mammals) produce a small number of large, heavily yolked (*megalecithal*) eggs enclosed by membranes and a hard shell, which may be laid on land. They have no larval stage and much of the fertilized ovum does not contribute directly to the body of the embryo, but is concerned with the elaboration of various *extraembryonic membranes*. The latter provide mechanisms for mobilization and transport of the massive yolk reserves to the developing embryo, deposition of waste end-products of metabolism, the provision of a local aquatic environment for the embryonic tissues and to allow exchanges of carbon dioxide and oxygen across the porous shell (**2.2**).

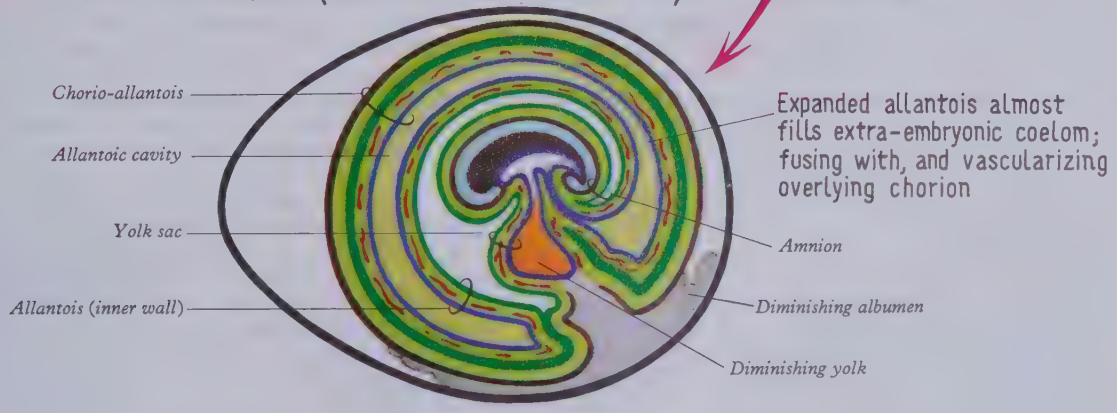
Eutherian mammals, including man, although derived from such ancestors with heavily yolked eggs, again produce *miolecithal* eggs, but these are few in number, possess no hard shell and development proceeds within the controlled environment of the female genital apparatus. Despite this drastic secondary reduction in yolk content, however, many features of mammalian development are only explicable by reference to such ancestry. Thus, although there are differences of detail between the various groups of mammals, they all develop the same array of extraembryonic membranes (yolk sac, allantois, amnion and chorion) with broadly similar functional associations. These membranes are, of course, modified in various ways for *viviparity*, i.e. development in utero, with nutritive, respiratory, excretory and immunological dependency upon the mother.

Recapitulation



Similarly, within the body of the mammalian embryo all the principal organ systems pass through stages which reflect fundamental patterns in the *ontogeny* of their ancestors. Such patterns are particularly clear in the basic metamerism of the trunk, the progression from a simple tubular heart to a complex, folded, double pump with intervening septa, the common plan of the early nervous system and special sense organs, the craniocaudal sequence of nephric tubules, the plan of the early chondrocranium and the succession of gill arches in the early pharyngeal wall. Such *recapitulation* during development was originally, and too simply, interpreted as if an embryo passed through sequential stages which mimicked the *mature* form of its main ancestral groups. Although this view was later modified to include only structural features during *embryonic life* of the ancestors, emphasis is now placed on the essential similarity of the *morphogenetic mechanisms* common to all chordates. Accordingly, the latter closely resemble each other in the early stages of development, and recognizable intergroup differences emerge gradually as development proceeds.

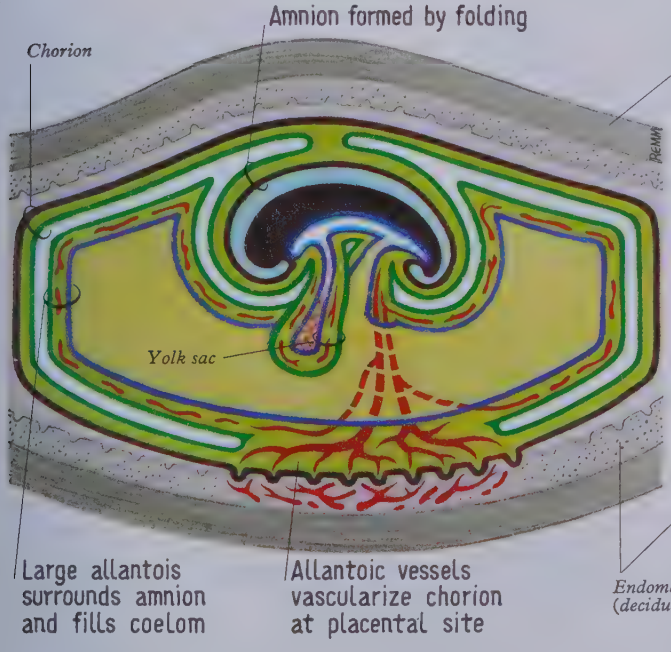
FERTILIZATION



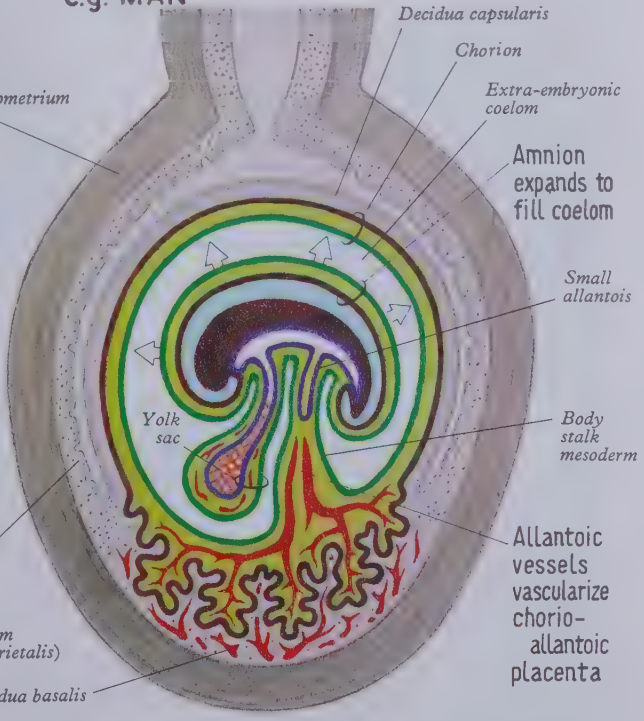
Fertilization includes those mechanisms whereby a sperm approaches, attaches to, then penetrates the surface of an ovum, and the early changes which follow. Briefly, the egg surface becomes modified preventing entry of further sperms, the oöplasmic segregation of factors in the egg cortex, important in subsequent processes of differentiation, are modified and finalization of the meiotic cycle of the ovum occurs. The latter involves completion of the second meiotic division with the expulsion of one set of chromatids into the second *polar cell*. (The first division had halved the number of chromosomes; each chromosome, however, consisted of two chromatids.) The male and female nuclear derivatives (pronuclei) swell, approach each other and then coalesce (*karyogamy*) to form a single *segmentation nucleus*. Thus the diploid number of chromosomes is restored, the chromosomal sex of the zygote established and a series of mitotic *(cleavage)* divisions are initiated.

Much evidence from comparative and experimental embryology has accumulated concerning the forms of symmetry exhibited by ova, the mechanism of sperm attachment and entry, the site of sperm entry and its influence on the distribution of formative substances in the egg cortex and their relative fixity or lability. For some prominent earlier contributors to this important area of biology see Needham (1942), Waddington (1956, 1962), Brachet (1960, 1965, 1967), Raven (1958, 1961, 1963, 1966a,b). All ova are *polarized* with an axis extending between the largely cytoplasmic *animal pole*, near which the nucleus lies, and the more heavily yolked *vegetative pole*. Whilst ova of some species possess a fairly simple *radial symmetry* around this axis with experimentally

FORMATION OF EXTRA-EMBRYONIC MEMBRANES



COMPARE: BASIC PATTERN (EGG-LAYING AMNIOTE)



WITH: EUTHERIAN MAMMALS —

SUPERFICIAL IMPLANTATION
e.g. PIG

INTERSTITIAL IMPLANTATION
e.g. MAN

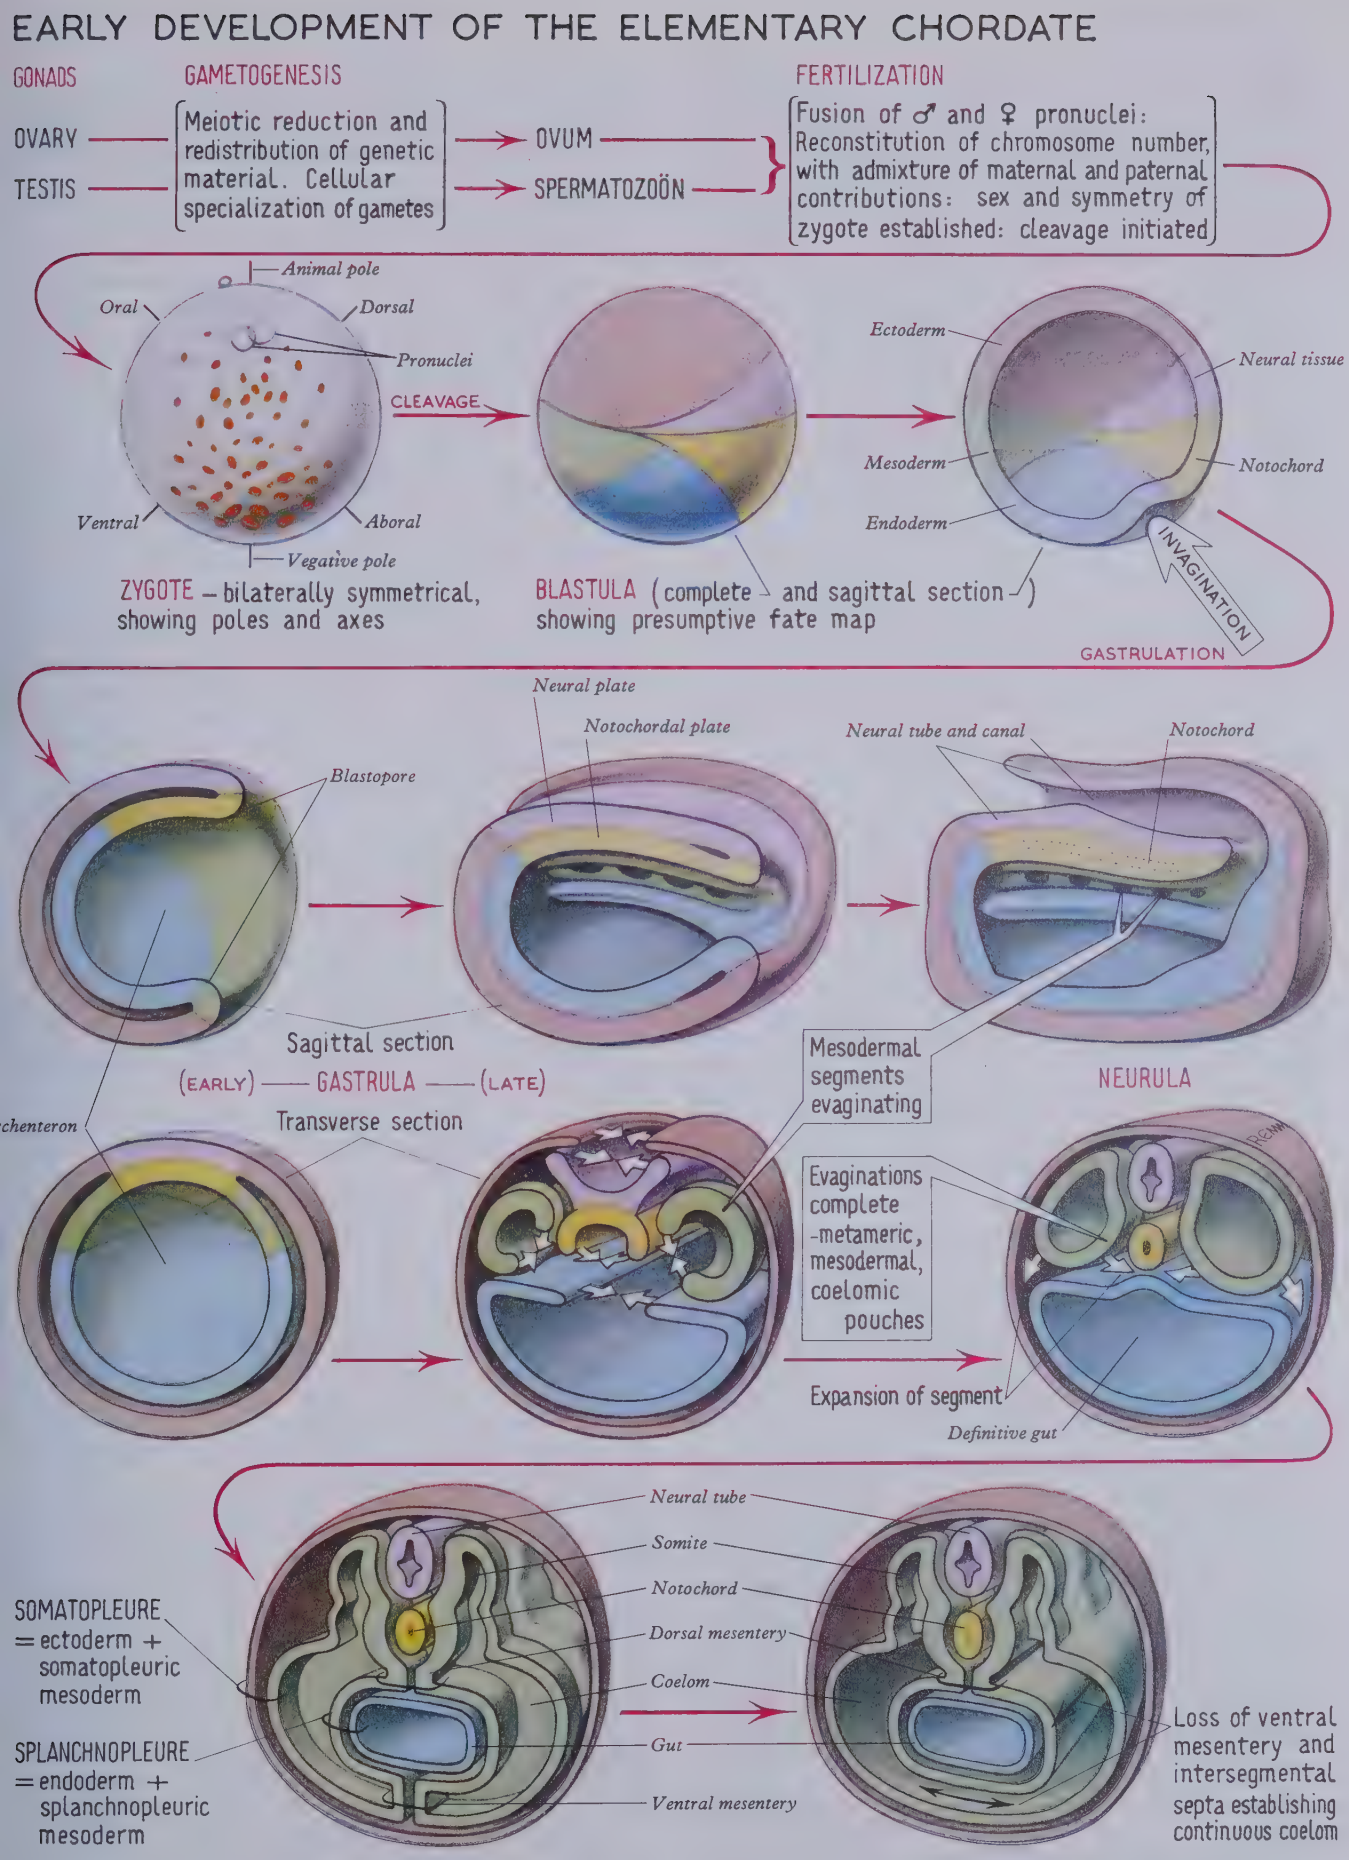
2.2 A generalized series of diagrams to allow comparison of the mode of formation of extraembryonic membranes in a megalecithal egg-laying amniote (e.g. chick) with that of a eutherian mammal exhibiting superficial implantation and a large allantois (e.g. pig), and a eutherian mammal showing interstitial implantation and a diminutive allantois (man). Note in each case the vascularization of the yolk sac, and the manner in which the expanded allantois (chick, pig) or its homologue in man, the body stalk mesoderm continuing from the small allantoic diverticulum, bear allantoic blood vessels which vascularize the overlying chorion. The latter is applied either to the shell, or to the uterine decidua.

demonstrable *gradients* of *developmental potential* extending between the poles, all others exhibit, in addition, further localizations of materials which confer a *bilateral symmetry* on the ovum. The time of appearance, degree and reversibility of this bilateral symmetry varies greatly between animal groups. Again, in occasional types of ova, the site of sperm entry is restricted by the egg coats to a small area on the surface whereas, in the majority, entry occurs at any point. Further, in some, the bilateral symmetry is reorganized in relation to the point of sperm entry whereas, in others, it is minimally affected. There is little evidence that sperms are specifically attracted towards ova by chemotropism, but in mammals it is often held that approach towards the egg surface, which initially is surrounded by granulosa cells of the corona radiata and the zona pellucida (p. 116), is facilitated by hyaluronidase and acrosin (acrosomase) produced by the acrosome of the sperm. However, the degree of development of an acrosome and its enzyme concentrations vary considerably—neither are prominent in man. In some instances the egg cortex and its coats have been shown to contain proteins (*fertilizins*) which can activate and agglutinate sperms, whilst the sperms contain *antifertilizins* which, when extracted, can agglutinate ova; penetration is assumed to involve an interaction of the antigen–antibody type. Finally, in some, the deeper part of the acrosome has been shown to extrude an *acrosomal filament* which, when it contacts the egg surface, becomes engulfed by a *fertilization cone* of cytoplasm which protrudes from the egg surface. The degree to which these postulated mechanisms, symmetries and rearrangements apply to human ova remains uncertain.

CLEAVAGE

Compared with the majority of somatic cells (excepting large neurons and certain other large cells), recently fertilized ova are unusual in possessing but a single diploid nucleus within a large volume of cytoplasm. The mitotic divisions of cleavage are, however, not accompanied by any substantial synthesis of cytoplasm and so the repeated replication and division of nuclear material, together with the partitioning of the existing cytoplasm, soon causes a return to the more usual *nucleo–cytoplasm ratio*. The resulting cells are called *blastomeres*, but their individual potentiality for further development varies considerably between animal groups; accordingly, a variety of terms have been used to describe cleavage 'types', which are briefly mentioned here.

TYPES OF CLEAVAGE (2.1)



Cleavage of miolecithal eggs is *complete* and *equal* since the whole zygote segments and resulting blastomeres are approximately equal in size. In contrast, mesolecithal eggs have a complete form of cleavage, which is *unequal*, with large yolk-laden blastomeres at the vegetative pole which grade into small yolk-free ones at the animal pole. In heavily yolked eggs the yolk mass does not segment (*incomplete*) and divisions are restricted to the discoid cytoplasmic accumulation at the animal pole. Such purely descriptive terms have been supplemented by others designed to summarize the *developmental potential* of the various regions of the zygote and the blastomeres derived from them. As has been intimated, experimental analysis of the *causal mechanisms* of early development has indicated that all zygotes exhibit some degree of segregation of cytoplasmic factors which, in their interactions with different blastomere nuclei, are fundamental in the subsequent emergence of different cell varieties. However, the degree, precision and lability of this segretation varies greatly between animal groups. In some invertebrate ova it is highly ordered and in such '*mosaic eggs*' cleavage often follows a fairly precise geometrical pattern (e.g. spirally cleaving forms) and is called *determinate*. The fate of each blastomere is relatively fixed and removal of blastomeres results in the development of a partial embryo. In contrast, in so-called '*regulative eggs*' with *indeterminate cleavage* the segregation, although present, is much more diffuse and flexible. In such forms, a blastomere when separated from its fellows often proceeds to develop into a complete, although small, embryo. However, such terms imply a distinction which is only one of degree. Many intermediate types exist and even the most mosaic ova show a small regulative capacity; conversely, the most regulative eggs are by no means equipotential systems; they possess some mosaicism, and only regions which include presumptive chorda-mesoderm (vide infra) continue to the formation of a complete embryo.

CLEAVAGE IN CHORDATA (2.1)

Cleavage of the miolecithal eggs of elementary chordates leads to the formation of a spherical *blastula*, i.e. a ball of cells with a central cavity or *blastocoele*, and the animal pole blastomeres are slightly smaller than those at the vegetative pole. The cleavage product of mesolecithal eggs is also a spherical blastula but, reflecting the large gradation in blastomere size from animal to vegetative pole, the blastocoele is eccentric and sited nearer the former. Cleavage in heavily yolked ova results in a circular *blastodisc* at the animal pole, several blastomeres thick and separated from the underlying yolk by a subgerminal cavity containing products of yolk degradation. The blastocoele is probably represented by a small cleft which develops between the superficial and deeper parts of the blastodisc (i.e. it is *not* homologous with the subgerminal cavity). Finally, cleavage of the miolecithal eggs of mammals leads first to a solid ball of blastomeres, the *morula* (Latin: *morum* = mulberry), soon to be transformed into a hollow *blastocyst* with an eccentric *blastocystic cavity*. The latter is surrounded on most aspects by a thin wall of cells (the early *trophoblast*) but at one point a localized group of cells, the *inner cell mass*, projects into the cavity. The mammalian blastocyst is to be carefully distinguished from the spherical blastula of the more elementary chordates. In the latter, the *whole blastula* undergoes a complex series of foldings, cell migrations and other *morphogenetic movements* and *interactions*, collectively termed *gastrulation*, and is then progressively transformed through early and late *gastrula*, then *neurula* stages, into the embryo. In contrast, only the *central cells* of the avian or reptilian blastodisc are engaged in these transformations. The peripheral blastomeres gradually grow to enclose the yolk, becoming arranged in several layers with an intervening cavity and, by complicated processes of differential growth, cellular changes and vascularization (2.2), form the various *extraembryonic membranes* (yolk sac, amnion, chorion and allantois) described more fully elsewhere. Similarly, in the early mammalian blastocyst, only a few *formative cells* in the centre of the *inner cell mass* are directly concerned in the future formation of the embryonic body. The remaining cells of the inner mass and the general walls of the blastocyst are destined to form the same extraembryonic membranes foreshadowed in their heavily yolked ancestors. The precocious segregation of blastomeres as extraembryonic structures in mammals contrasts with their later development in reptiles and birds and the detailed fate of the various membranes and their role in *placentation* shows a wide variation between the different mammalian orders (Mossman 1937, Amoroso 1952).

GASTRULATION

Gastrulation in simple forms (2.3) entails the conversion of a roughly spherical, hollow, single-walled *blastula* into a more elongated, double-walled *gastrula* containing a cavity, the *archenteron*, for reception and assimilation of food and with oral and blastoporic openings at opposite ends. This is achieved by the infolding of one half of the blastula into the other, the orifice formed by the invaginating material being the *blastopore*; the point where the first invaginated cells contact the inner aspect of the opposite hemisphere eventually breaks down to form an *oral orifice*. The addition of a third, intermediate, mesodermal layer in the wall is usual in most groups of animals and its origin is varied; in particular the fate of the walls of the primitive archenteron in the lower chordates is rather more complex (2.3). In these, the blastopore is regarded as presenting a dorsal, a ventral, and a pair of lateral *lips*. The material invaginated through the *dorsal lip* forms a midline strip in the roof of the archenteron which stretches from the blastopore to the margin of the future oral orifice; it underlies

2.3 Principal stages in the early development of an elementary chordate. The tabbing and illustrations proceed from left to right in a series of rows from above downwards. Note the poles and axes of the zygote, the presumptive fate map of the blastula, and the progression of gastrulation, neurulation, and coelom formation. Consult text for further details.

the external cellular wall and eventually folds off dorsally to form the *axial notochord*. Laterally placed strips, which flank the future notochord, form a series of paired outpouchings, the *metameric coelomic pouches*. The ventrolateral walls of the archenteron grow across ventral to the pouches and notochord to re-form a gut tube. The external wall of the gastrula dorsal to the mesodermal pouches and notochord thickens and folds in to form the primitive nervous system, whilst the remainder of the external wall forms the epidermis and its derivatives. In many types the lateral lips of the blastopore approach and fuse to form a *primitive streak* as they continue to bud off generations of mesodermal cells into the walls of the elongating gastrula. The dorsal lip continues to contribute notochordal cells and, with the fusion of the lateral lips, it rounds off and thus temporarily connects the archenteron with the caudal end of the early nervous system (i.e. a transient *neurenteric canal*). Similarly the ventral lip closes around a primitive cloaca, continuous with the gut tube and later with the urogenital ducts.

Accordingly, during gastrulation, originally widely separated cell masses in the walls of the blastula come into close secondary apposition, as the *presumptive organ rudiments* and tissue layers assume their definitive positions. *Presumptive fate maps* of the various regions of blastular walls have been produced by staining small regions differentially with vital dyes and following the stained regions during subsequent development. Much work has also been directed towards an understanding of the mechanics of gastrulation itself and, as we shall see, the profound morphogenetic significance of the secondary association between formerly separated groups of blastomeres (2.4,5, p. 104). Gastrulation, although necessarily modified in the blastodisc of heavily yolked eggs and within the inner cell masses of mammalian blastocysts, remains an essentially similar process. Ectodermal and endodermal layers become defined and, within the former, a linear proliferative zone of uncommitted cells, the *primitive streak*, persists and produces generations of mesodermal cells which pass between the two layers. Near the headward end of the streak a zone corresponding to the dorsal blastopore lip forms a notochordal process, which invaginates and breaks through to form a neurenteric canal, while caudal to the streak a cloacal membrane forms (cf. the transformation of the human bilaminar embryonic disc, pp. 131–136). The basic structural correspondence in these stages throughout the Chordata and in forms as diverse as *Amphioxus* and Mammalia is assumed to imply similar fundamental *morphogenetic mechanisms*—where experimental analysis has proved feasible, this has been confirmed.

Some General Aspects of Development

The development of a large complex organism from a single diploid cell, the zygote, entails an increase in mass and cell number of thousands of millions and the emergence of a bewildering variety of cell types, each with a characteristic constitution, shape, specific activities and welded into the distinctive tissue masses, sheets, tubes, liquids and so forth, which cooperate in the functioning of the whole.

The *developmental biology* of such an organism, while endlessly complicated in detail, and with as yet rather rudimentary proposals concerning the control systems involved, can nevertheless, in principle, be reduced to a limited number of basic processes, namely: temporo-spatial variations in *growth, pattern formation, morphogenetic movement, differentiation*, together with *degeneration* and *death* of some cells and their aggregates.

The *description, definition* and *causal analysis* of these basic processes, and the degree to which they are independent or interdependent, still hold the centre of attention of modern developmental biologists, although many of the fundamental questions were first formulated, and some of the most dramatic experimental observations made, many years ago (vide infra). In the intervening years, as fresh experimental data have accumulated, the questions have often been rephrased; the definitions and terms used have been constantly revised and modified and there has been a gradual change of emphasis concerning the conceptual frameworks currently in fashion.

Thus, in addition to attempting to describe and define the various forms, combinations and differential rates of *positive growth* exhibited by organisms, there has been a more recent upsurge of interest in simultaneous *cell necrosis* and removal and the factors which may control regional differences in balance between these processes. Similarly, the detailed analysis of the *specific intracellular events* exhibited by cells undergoing *differentiation* has been paralleled by numerous hypotheses concerning the *spatial patterning* of differentiation. Concepts such as *oöplasmic segregation* of *morphogenetic factors*, *'organizer' phenomena, competence* of tissues, *induction, determination, morphogenetic gradients* and *developmental field phenomena* and, more latterly, ideas concerning *intercellular communication and positional information* available to cells in an aggregate, have emerged. In contrast, other authors have placed greater emphasis on the probable morphogenetic significance of variations in the *cell cycle* (p. 37) with the establishment of *specific cell lineages* and the emergence of *cell clones* (vide infra). Intense research is directed towards the *regional genomic control mechanisms* implicit in all the foregoing. Much interest has also recently been aroused by the possible morphogenetic implications of the mathematical formulation of the *catastrophe theory*. An immense scientific literature has accumulated concerning these fundamental fields of biological study, which of necessity can only be touched upon in a volume such as this, and the interested reader should consult any of the readily available reviews, monographs or original papers.

GROWTH

Growth is a term widely used in everyday conversation and applied to both living and inanimate objects; it may, of course, within biology be applied to entire communities, individuals or parts of an organism such as a whole body segment, an organ, tissue, group of cells or even subcellular features such as mitochondria, cell membrane and so on. This variety in the application of the term is paralleled by the number of definitions for it—evidence that none is wholly satisfactory. They range from the over-simplified 'increase in mass and size' to lengthy, complex and sometimes incomprehensible descriptions. In general, during ontogeny, growth implies an increase in size and mass which results from synthesis of protoplasm and extracellular materials which are specific tissue components.

Growth of a tissue is classically considered to be either multiplicative, auxetic, accretionary or, quite often, a combination of these.

Multiplicative growth, as the name suggests, involves an increase in the number of cells (or nuclei and associated cytoplasm in syncytia) by a succession of mitotic divisions, and all mammalian tissues exhibit this form of growth at some stage. Its persistence, however, varies greatly between tissues with increasing differentiation and maturity. In some, multiplicative growth continues throughout life with continual replacement of senescent or dead cells, as in the epidermis, intestinal epithelium, and myeloid precursors of circulating erythrocytes. At the other extreme, cell division during embryonic and fetal life may lead to the full complement of a particular cell, e.g. oöcytes and neurons, and thereafter multiplicative growth ceases.

Much work has thus been directed at establishing the ranges of mitotic rates in many tissues throughout development into maturity and senescence, and towards an analysis of any cyclic (e.g. diurnal) variation in rate and the extreme differences in potential for further growth during regeneration exhibited by different tissues. Despite adequacy of such quantitative investigations in tissues of different age, sex and type, and the recognition of many general factors which influence such growth, e.g. genetic, nutritional (p. 156), endocrine, thermal, photic, mechanical, etc., little is known of the intimate processes which initiate, maintain, modify and terminate complex three-dimensional arrays of mitoses. In certain tissues (e.g. the epidermis and the growing nervous system) specific growth-promoting factors have been demonstrated (Levi-Montalcini 1967). Additionally, substances of widespread occurrence in many tissues termed *chalones* have received increasing attention (Bullough 1967, Bullough et al 1967). They have been defined as internal secretions produced by a tissue which, by inhibition, control the

mitotic activity of the cells of that tissue. It is considered that the chalone concentration is an important determinant of the balance which exists between mitotic rate, progressive cell differentiation and the assumption of a full functional role on the one hand, and the rate of cell ageing and progression towards senescence and death on the other. They are perhaps intermediaries between the general growth-influencing factors listed above and the differential activities of the genome (p. 109).

Auxetic growth involves an increase in the size of the specific individual cells characterizing a tissue. It is particularly prominent in certain invertebrate tissues such as the salivary glands of *Diptera*, but is also well shown by some mammalian tissues. For example, there is a vast post-natal increase of both surface area and cytoplasmic volume in many neurons and glial cells (p. 892); the growing striated muscle fibre (p. 553), the oöcyte, the myelinating Schwann cells, and the smooth muscle cells of the pregnant uterus furnish further obvious examples. The majority of other tissues, however, show some auxetic growth but of limited degree, while conversely, in some sites, continued multiplicative growth is accompanied by a *reduction* in cell volume (e.g. granule cells of the cerebellar cortex, and small lymphocytes in lymphoid tissue).

It is widely held that the general *nucleocytoplasmic ratio* to which most of the body's cells roughly approximate reflects the fixed quantity of DNA in their diploid nuclei which, in turn, imposes a rate limitation on the replacement of cytoplasmic proteins (each of which has a characteristic turnover rate). Thus, with continuing auxetic growth of a cell, its cytoplasmic volume eventually reaches a point beyond which the structural genes could not effectively replace the protein which is undergoing continual degradation. In some cases, growth ceases at this point, or nuclear replication with cell division occurs. The cases of auxetic growth cited above, however, often proceed far beyond the usual ratio of cytoplasmic volume to nuclear material and, in these, various methods of providing auxiliary nuclear support have emerged. The large dipteran salivary gland cells develop 'giant' *polytene chromosomes* containing some multiple of the diploid DNA content. The striated muscle fibre and other 'giant' cells such as megakaryocytes are, of course, *multinucleate syncytia*. Finally, the enlarging oöcyte and neuron (possessing but a single haploid and a single diploid nucleus, respectively) have their surfaces clothed by numerous *satellite cells* (follicular or glial cells). Such satellites probably provide auxiliary metabolic and nuclear support for the enlarged central cell, i.e. the two are functionally interlocked as a *cytophysiological unit*.

Accretionary growth denotes an increase in the amount of structural intercellular material between tissue cells—bone and cartilage are the most commonly cited examples. Further, perhaps less obvious, examples are the other fibrous connective tissues, tendons, joint capsules, aponeuroses and fasciae, the cornea, growing mesenchyme with its abundant intercellular matrix, and during the development of renal tissue and smooth muscle where the appearance of substantial basal laminae contributes significantly to the growing mass.

In practice, of course, these 'types' of growth as defined above are often welded together in various patterns, with differential growth rates and directions in different parts of the system; furthermore, they overlap with and merge into the phases of cell differentiation, full functional activity, ageing and senescence. These *differential growth patterns* with either *random* or *preferentially polarized* directions of mitotic division, together with alterations in cell size, shape and surface consistency, are central features of embryonic development and are responsible for the moulding of tissues into specific shapes whether solid masses, hollow balls, tubes, sheets and so forth. Equally important in some regions, however, is a process of tissue regression, with degeneration, cell death and tissue removal. Where multiplicative (and sometimes accretionary) growth continues throughout the thickness of a tissue mass and it grows as a whole expanding from within, its growth is termed *interstitial*. Experimental markers placed within such a tissue during growth are later found to have become increasingly separated—excellent examples are embryonic limb bud ectoderm (p. 174) and the interior of young masses of hyaline cartilage (p. 291). Alternatively, in *appositional growth* new generations of cells and intercellular material are added to the *surface* of the tissue by the repeated division of the cells of a *cambial layer* which surrounds the tissue, e.g. periosteum and perichondrium (pp. 291, 300, 461).

Differential growth rates, as intimated, are an essential feature of many aspects of embryonic development. For example, if in an area of loose mesenchyme, a locus with a high proliferative rate appears surrounded by 'shells' of tissue with progressively lower rates, a mass of tightly packed cells which grades into the surrounding tissue is formed, i.e. a so-called *mesenchymal condensation*. Two adjacent loci in subepithelial mesenchyme with an intervening quiescent zone lead to neighbouring elevations of the epithelium, and an intermediate furrow (cf. the development of the facial prominences or 'processes', p. 166). In many situations, mesenchymal condensations appear and their *blastemal shape* foreshadows that of the structure, bone, cartilage or muscle mass, into which they subsequently differentiate. Many other examples of differential growth will be encountered as development of individual organ systems is considered. Particularly clear-cut examples are seen in descent of the gonads (p. 256), formation of the cauda equina (p. 182), neck elongation, septation of the heart (p. 209) and in the emergence of asymmetrical arterial, venous and lymphatic systems from initially bilaterally symmetrical patterns.

MORPHOGENETIC CELL DEATH

Cell death and tissue removal are as much an integral element in embryogenesis as the positive forms of growth discussed briefly in the foregoing paragraphs. As we have seen, it is currently held that mechanisms of *tissue homeostasis* exist, possibly operated, at least partly, by the local concentrations of tissue-specific chalones, whereby a balance is achieved between cell division, differentiation, functioning and senescence. Death of cells has been recognized as early as the blastocyst stage in rabbits (Daniel & Olson 1966) and demonstrated at many later stages of ontogeny throughout the vertebrates (Glücksmann 1951). An obvious example is the retrogression of the amphibian tail at metamorphosis, but similar degenerations occur during the development of the axial nervous system (Hughes 1968) and in association with the mammalian primitive streak. At subsequent and postnatal stages, bone growth and remodelling, in particular, are accompanied by surface deposition in some regions and erosion and removal in others (p. 309).

Particularly well studied have been the integrated patterns of growth and death of cells during the shaping of the tetrapod limb (Saunders & Fallon 1966). Massive zones of what has been dramatically termed *cataclysmic necrosis* sweep the length of the developing limb as its contours are moulded. The process being especially prominent in some localities and finally occurs in the interdigital clefts as digital outlines become sculpted. Neighbouring mesenchymal cells become intensely phagocytic and engulf whole dying cells or any resulting cellular débris. It should be emphasized that the *normal prospective fate* of such a cell mass is to degenerate and die, and since, in modern terminology, it has become fashionable to regard ontogeny as the enacting of a *developmental programme*, ultimately encoded in the genome, such cells are described as succumbing to *programmed cell death*. Numerous experiments have been devised in attempts to analyse the precise roles of such necrotic zones in normogenesis and to elucidate what factors affect the enactment and timing of the so-called '*death clock*'. The *posterior necrotic zone* of the developing chick wing bud has, because of its predictable localization, timing and susceptibility to microsurgical experiments, become a favourite object for study (Saunders & Gasseling 1968), and its relationship to the establishment of *polarity* in the wing bud is firmly recognized. (See extensive review and bibliography by Hinchliffe 1982.)

DIFFERENTIATION

The appearance of many highly distinctive cell types which become blended in various ways to form the functioning tissues and the control mechanisms involved, has been for decades, and remains today, one of the central problems in biology.

The differences between fully differentiated cells in terms of their size, shape, ultrastructural appearance, chemical constitution and functioning (e.g. mature muscle, nerve and glandular cells) are plain: no intermediaries exist, and there is no known experimental situation in which one form changes into another. As we shall see, however, the cells of early chordate embryos may, under suitable conditions, *ultimately* form any one of many different cell types, i.e. they are widely held by some developmental biologists to be *pluripotent* and, as development proceeds, there occurs a step by step reduction in their potential for forming a variety of cells so that finally the fate of most cells is limited to one type of fully differentiated cell only. Even in the mature body, however, some cells retain some degree of flexibility and can still transform into a number of types—this is seen most powerfully in the ability to regenerate a whole body segment, e.g. limb or tail, shown by certain amphibia.

It may be mentioned here, however, and outlined further below that other groups of cell biologists contest the view just given of most early blastomeres as undifferentiated, totipotent or pluripotent cells with *immediate* access to a wide range of possible phenotypical fates and advance instead hypotheses of much more strictly compartmentalized cell lineages during development.

PREFORMATION AND EPIGENESIS

For centuries, a controversy raged concerning the form taken by the differentiation which occurs during embryogenesis, whether there was a *preformation* in the early embryo, or whether *epigenesis* took place. The former view held that all the structures of the mature body, although so minute as to be invisible, were present in the zygote and simply enlarged and were thus revealed in subsequent development. The epigeneticists, however, held that the various organ primordia appearing during development were essentially new formations. In a modern context both views, somewhat modified, have their place. In one sense, *the total information content* of both the cytoplasm and the nuclear genetic apparatus of a zygote is a 'preformation' which through a series of complex interactions directs the 'epigenesis' of new structures.

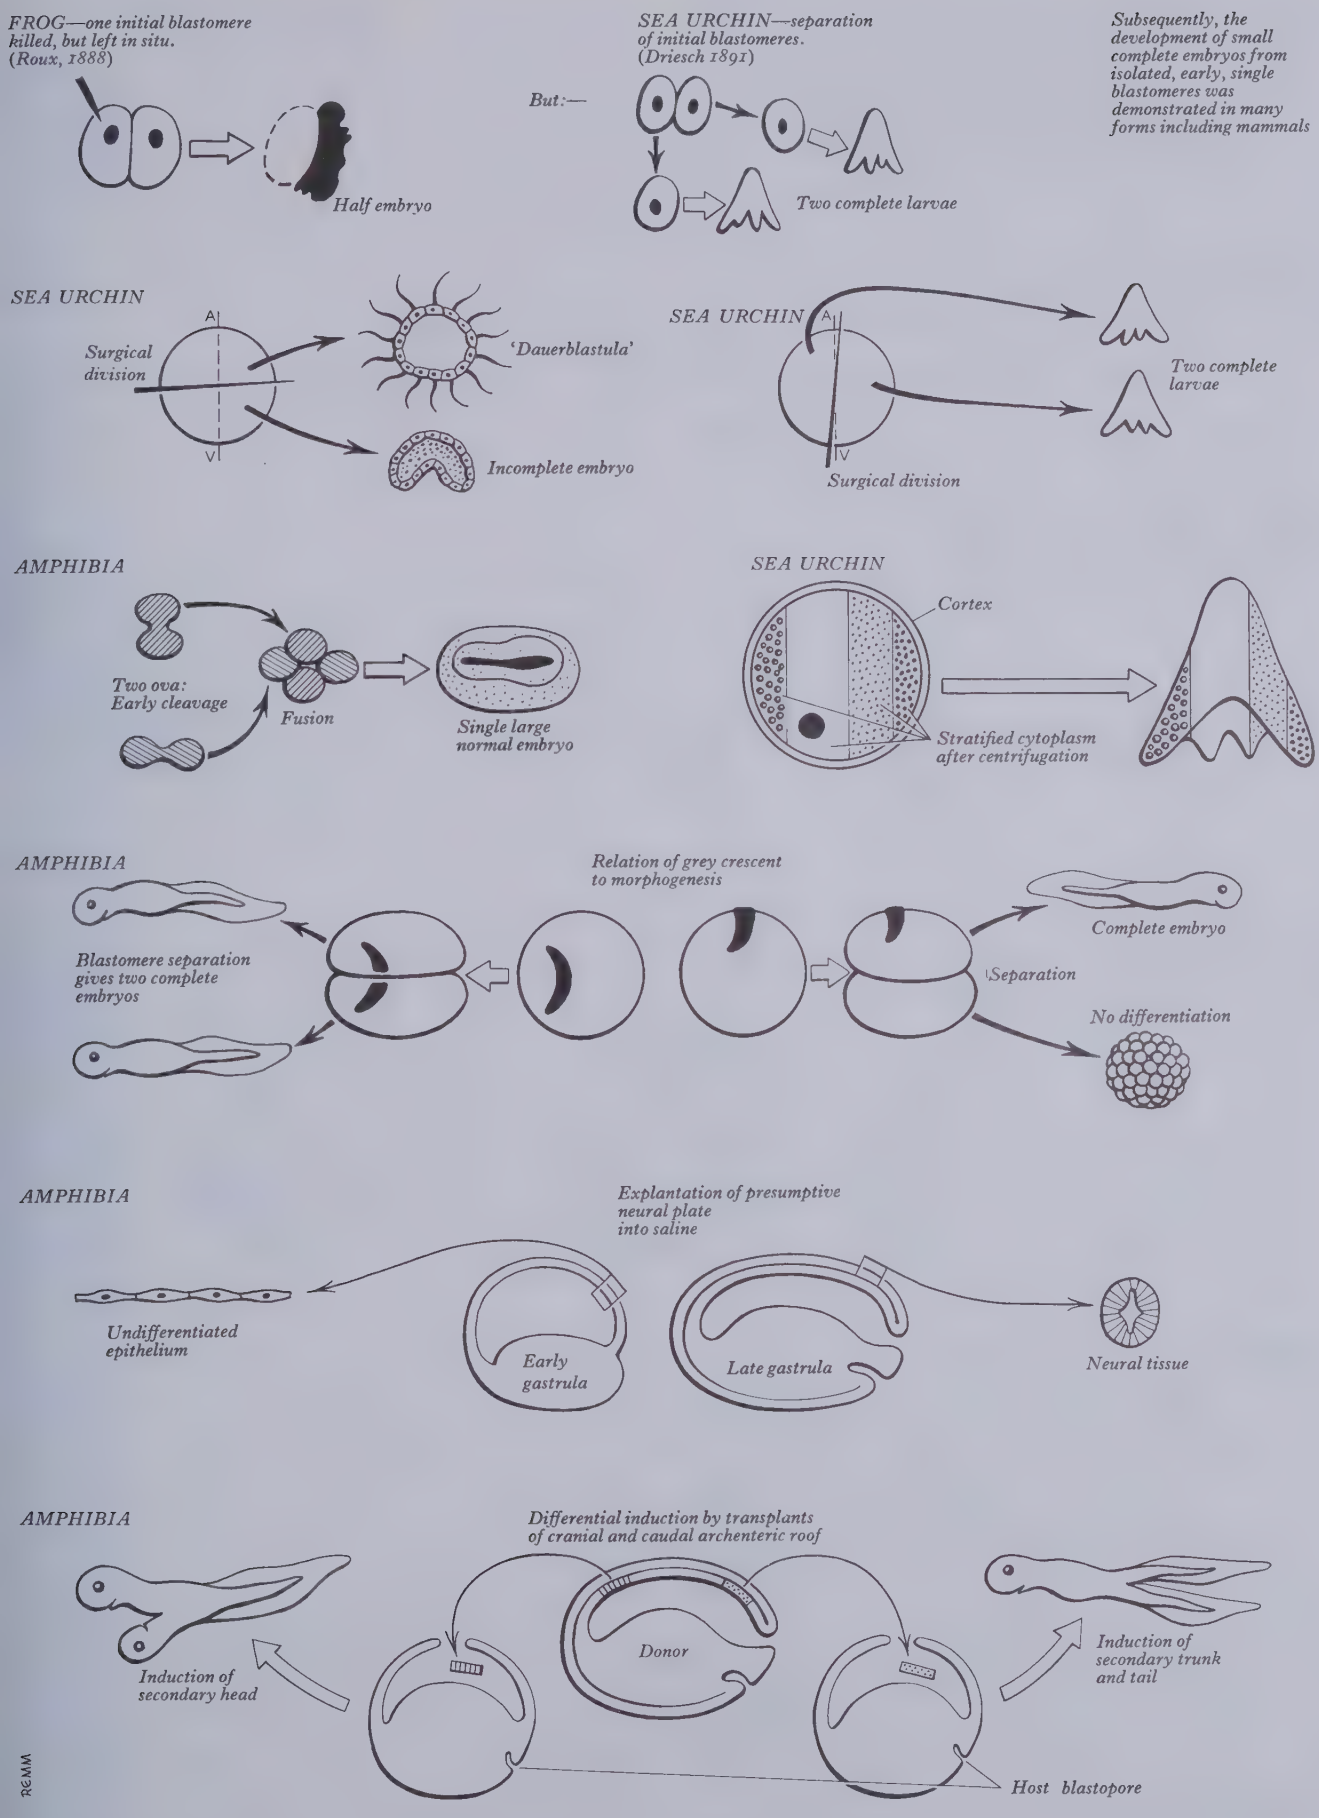
The classical studies of *descriptive embryology* in which times of appearance, shape and size of the various embryonic layers and organ systems at different stages of development were meticulously described in serial histological sections, and similar *comparative studies* of different species, although providing an invaluable framework, could make no contribution to an *understanding* of differentiation. An analytical approach was necessary (**2**.4, 5), and the foundations of 'developmental mechanics' or an *experimental embryology*, which sought to understand the *causal interactions* of development, were laid by Wilhelm Roux late in the nineteenth century. His experiments on frog development were paralleled by other observations of fundamental importance by Hans Driesch on the early sea urchin embryo. Then, passing into the present century, contributions of outstanding penetrance were made by such investigators as Hans Spemann, Ross G. Harrison, Sven Horstadius, J. Holtfreter and many others. Only the most cursory mention of this field of biology can be contemplated, and those with wider interests should consult the original writings of these pioneers and, as an introduction to the equally important researches of modern developmental biologists, specific monographs (e.g. Spemann 1938, Willier et al 1955, Hamburger 1960, Balinsky 1981, and subsequent text references).

EXPERIMENTAL EMBRYOLOGY

The final blow to rigid preformationist concepts was delivered when Hans Driesch showed that if the first two blastomeres of a sea urchin egg were separated, each could develop into a complete, although small, embryo (**2**.4). Thus, any idea of strict compartmentalism in the fertilized ovum had to be abandoned, since in normal development each of the blastomeres would have formed half an embryo but, when separated, each could *regulate* sufficiently to form a whole. On this basis Driesch supposed (mistakenly) that there existed *no segregation whatever* in the egg cytoplasm and that it constituted a '*harmonious equipotential system*' in all directions. Since subsequent differentiation occurred, he regarded this as evidence supporting revival of the Aristotelian *entelechy*, holding that such a phenomenon could not be explained by the laws of physics and chemistry and that a vital or spiritual '*internal perfecting principle*' was present.

However, as we have seen elsewhere (p. 100), much subsequent work showed that all ova and zygotes show some degree of *segregation of formative materials* in their cytoplasm, but its *degree* and *lability* varies between species. Ironically, had Driesch's separation been made in an equatorial plane rather than a meridional one, only partial embryos would have resulted!

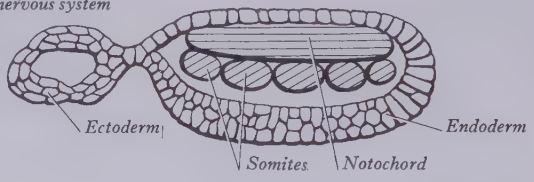
The experimental methods employed by the earlier investigators (**2**.4,5) included the preparation of '*presumptive fate maps*' of the blastula or blastodisc, *ablation* of regions of the blastula, *autotransplantation* of cell masses from one place to another in the same embryo, *explantation* of such masses or combinations of these into salt solutions and nutrient media, and finally the powerful methods of *heteroplastic* and *xenoplastic grafting* between different species. In the latter, the tissues of both the graft and the host are so distinctive that their relative contributions and aspects of their interactions in any complex development that occurs after transplantation can be followed.



The production of maps (**2**.3) showing the *presumptive fate* in normal development of different regions of the blastula or blastodisc, by the application of spots of vital dyes and following their subsequent history, was a necessary prerequisite of experimentation using microsurgical methods.

Self and Dependent Differentiation

From the earlier autotransplantation experiments, and later reinforced by explanation of blastula fragments into salt solutions (**2**.4), the first concepts of two distinct tissue states emerged, i.e. those that exhibited *self-differentiation* and the remainder in which *dependent differentiation* was the rule. In the former, as the name suggests, a fragment, when transplanted to an apparently 'indifferent' region of the blastula or, more critically, into salt solutions, proceeded to develop into the tissues it would have formed if undisturbed. Regions with dependent differentiation, however, if transplanted early, failed to continue development and only did so if combined with some neighbouring mass of cells. If such a region, which at an early stage showed dependent differentiation only, was not transplanted until a later stage, it was often found to have become self-differentiating. Furthermore, when such an early region was combined with different regions of the embryo, development would often result in a changed final tissue (e.g. muscle rather than kidney).

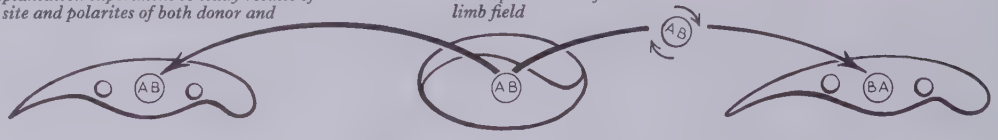


From such work, it was realized that the *prospective significance* or *normal fate* of the various regions of the blastula did not reflect the *prospective potency* of these regions (i.e. the *various fates possible* under different experimental conditions). Further, it was found that from the earliest moments, certain *restricted regions only* exhibited *self-differentiation*, i.e. *determination* of their fate had occurred. The remaining regions with dependent differentiation, originally 'pluripotent', suffered a stepwise restriction in their possible fates, i.e. an increasing fixity of determination occurred as development proceeded.

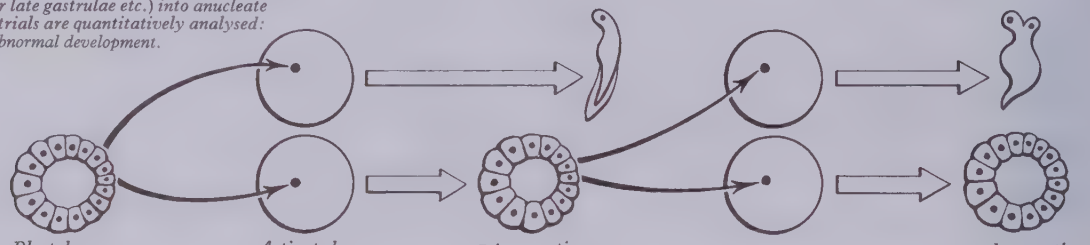
Later, the features of dependent differentiation were more clearly defined. Classical experiments with many variations were performed showing the dependency of the development of the lens vesicle (which transforms into the ocular crystalline lens) on the approach and close apposition of an evagination from the primitive nervous system (the optic vesicle). These experiments showed that, in the absence of an optic vesicle, no lens formation occurred, that many different regions of 'indifferent' ectoderm, if exposed to the influence of the vesicle, could form lens tissue and similarly, if the same ectoderm was used to replace that covering the hindbrain, it would develop into a membranous labyrinth. In this manner, the concept of *embryonic induction* developed. This held that for a restricted period a particular region of pluripotent tissue was *competent* to react to an inductive influence exerted by an adjacent tissue.

2.4 A selection of the classic manoeuvres, which were milestones in the development of experimental embryology as a science. Consult text.

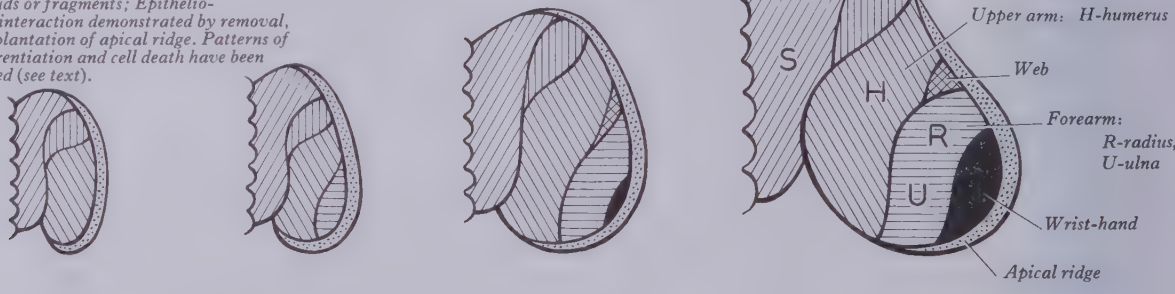
Differentiation after exogastrulation. Note absence of nervous system



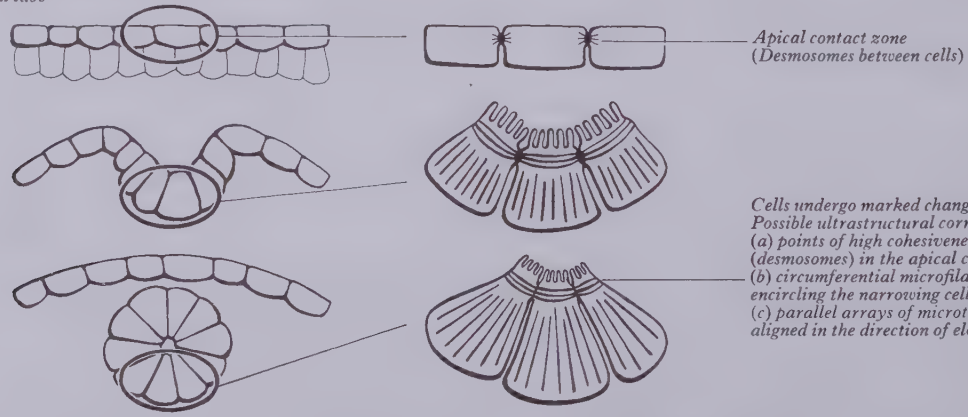
Mutual interaction of cell masses despite intervening millipore filter



Example of transplantation experiment to study results of variation in age, site and polarites of both donor and host.



Transplantation of limb field



Analysis of development after establishment of nuclear clones by serial transplantation of donor nuclei (from blastulae, early or late gastrulae etc.) into anucleate eggs. Numerous trials are quantitatively analysed: normal/partial/abnormal development.

Presumptive fate maps of sequential stages in the development of chick wing bud. Note proximo-distal emergence of mesodermal patterning. A widely studied system: progressive determination demonstrated by culture or chorio-allantoic grafts of whole buds or fragments; Epithelio-mesenchymatous interaction demonstrated by removal, reversal or transplantation of apical ridge. Patterns of cell mitosis, differentiation and cell death have been extensively studied (see text).

An example of morphogenesis: formation and closure of amphibian neural tube

Primary Organization

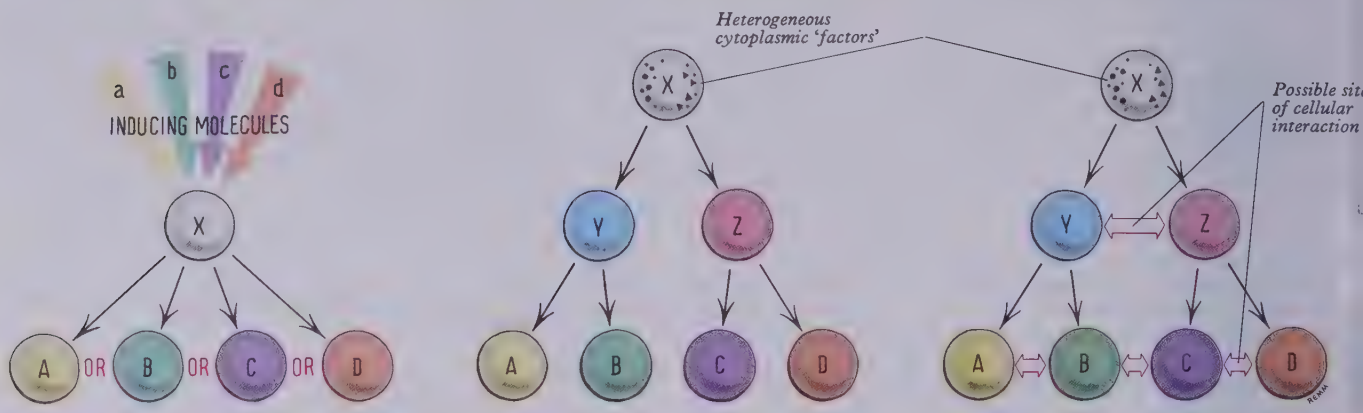
Experiments by Hans Spemann involving the ablation, or the auto- or hetero-transplantation, of the future dorsal lip of the blastopore region, further clarified the process. In the absence of a dorsal lip, continued development of an organized nature ceased. When, however, such a region was transplanted to the flank of another gastrula a dramatic series of changes ensued. The *graft* proceeded to proliferate, invaginate and develop into a notochord, surrounding skeletal structures and adjacent muscle masses, showing that extremely early determination had occurred, and it followed its normal course of self-differentiation. In addition, the surrounding *host tissues* displayed an equally dramatic series of responses to the inductive influences of the graft. The superjacent ectoderm developed into a remarkably complete nervous system, with recognizable subdivisions of brain and spinal cord, laterally placed host mesoderm formed musculature and kidney tissues whilst, on occasions, a subjacent gut tube was induced. Host and graft tissues often continued to interlock in the development of what was virtually a complete second embryo, attached to the abdomen of the host. Because of the early determination and self-differentiating nature of the tissues of the dorsal blastopore region, and their profound inductive influence on surrounding tissues which lead to the development of an embryonic axis and adjacent tissues, it was called the *primary organizer region*. Then followed a series of experiments which demonstrated regional differences in the inductive capacity of the tissues sequentially invaginated through the dorsal lip (**2**.4); thus so-called head, trunk and tail 'organizer' regions were recognized. Subsequently, however, a wide variety of substances, including some inorganic compounds which do not exist in developing embryos, were shown to have inductive effects and similar effects followed the microsurgical killing of a few blastomeres or the introduction into the blastocoele of powdered glass. Interestingly, extracts of adult tissues produced varied responses, either a *mesodermalizing* effect or a *regional neuralizing* effect (with the formation of predominantly forebrain, hindbrain or spinal structures; see Toivonen 1967, Nieuwkoop 1967). Thereafter, many subordinate inductive systems were shown to operate in coordinated sequences throughout chordate development. In some cases competent tissue was separated from its relevant inductor tissue by a 'millipore' filter which prevented the passage of cells (**2**.5); inductive effects still occurred, presumably because of the passage of chemical messengers between the two. (It should be mentioned, in this context, that since the advent of the scanning electron microscope the full effectiveness of such filters has been subjected to a critical reappraisal.) Since the turn of the century much effort and ingenuity have been expended in attempts to isolate and identify specific intercellular chemical inducers but, despite many claims, none have been substantiated in the embryogenesis of metazoa (Grobstein 1967).

In contrast, considerable detail has now accumulated concerning the differential activation and repression of the genome in microorganisms associated with the *induction of enzyme synthesis* (vide infra) and also concerning the two-stage inductive events which firstly transform an uncommitted lymphoid stem cell to a committed cell (p. 670) and secondly express this committal by the production of specific antibody (Feldman & Globerson 1974). In the latter case the second stage inducer, the antigen, is of course often a chemically well-defined molecule. Whilst such studies may well have parallels with events in embryogenesis, direct extrapolation is premature, and it is perhaps unfortunate that the term induction has been applied to all these situations.

In recent years there has occurred a great change of emphasis when developmental biologists consider inductive phenomena. The dramatic responses demonstrated by Spemann following blastopore transplantation, coupled with his all-embracing term 'primary organizer', led for many years to the following view of early embryogenesis: namely, that the majority of early blastomeres were *undifferentiated, totipotent* cells, with highly labile control mechanisms and with *numerous* alternative developmental paths *immediately* available to them. A *master organizer* region, or regions, was assumed to produce complex organizer or inducer molecules of *high information content* which passed to, and *directed*, the subsequent developmental path of the reactive cells. Naturally, great interest focused on the possibility of isolating and characterizing physico-chemically these *instructive molecules*. Gradually, however, as data have accumulated concerning other possible modes of interaction of cell aggregates (vide infra), the use of the term organizer has fallen into disuse, and the search for complex instructive molecules has slackened. Perhaps the inductive phenomena of embryogenesis are mediated by slight variations in ubiquitous molecules of relatively simple chemical constitution (e.g. metabolites) of low, or absent, intrinsic information content, and the developmental path followed is largely determined by the currently available metabolic options provided by the *cytoplasm* and *genome* of the reacting cells.

MODERN VIEWS OF DIFFERENTIATION

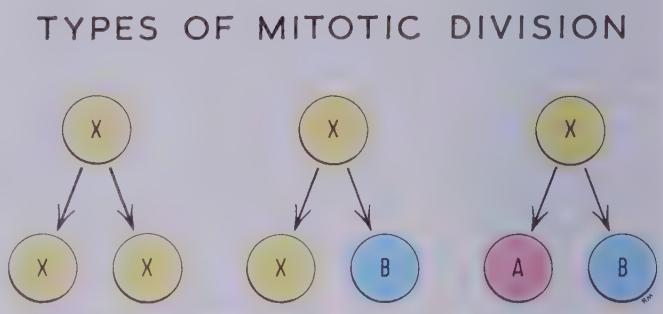
Differentiation has often been defined as the emergence of *irreversible, inheritable* differences between cells, in contrast to the many *reversible* changes shown by cells in response to changed local environments, termed *modulations*. However, the apparent irreversibility seems to be a feature only prominent in cells of vertebrates in the relatively few experimental situations so far studied. Further, many changes in the cells of plants and higher invertebrates closely resemble processes of differentiation, but are in fact reversible (see below). Perhaps the terms differentiation and modulation imply a rigid distinction between two states exhibited by cells, when in fact a range of states with varying degrees of reversibility exists.



It has been held (Sager 1965) that from the earliest times the simplest, non-nuclear (*prokaryote*) units of life consisted of '... a stablized tripartite system: nucleic acids for replication, a photosynthetic or chemosynthetic system for energy conversion and protein enzymes to catalyse the two processes'. To these essential ingredients common to all living forms were later added the enzyme systems which accompanied a dependency on environmental oxygen, and then a greater variety of cellular form paralleled the appearance of *eukaryote cells* with a well defined chromosome-bearing nucleus. It is in the *interactions* between these different phases of one cooperative system, the cell, that clues to the nature of differentiation are currently sought (De Reuck & Knight 1967, Bullough 1967, Toivonen 1967, Nieuwkoop 1967, Grobstein 1967, Wolstenholme & Knight 1970, Harris 1970, Ashworth 1973, et seq.).

As we have seen (p. 15 et seq.), proteins are of fundamental significance in the construction and operation of all prokaryote and eukaryote cells. In great variety they are essential constituents of cytoplasmic matrix, nucleoplasm, cytomembranes including the plasma membrane and walls of membrane-bound organelles and, with nucleic acids, as nucleoproteins of the genetic apparatus. Most significantly, they form the basis of the innumerable enzyme arrays which catalyse all the steps in the structural and energetic transformations which constitute 'life'.

Thus, it has been stated quite simply that when cells with the same genome synthesize different proteins, differentiation has occurred (Jacob & Monod 1961, 1963). This implies, therefore, that an understanding of the processes of differentiation lies not in the details of the protein synthetic pathways as such, but rather in the various control systems to which these are subjected. The latter are currently believed to involve varieties of chemical messengers which operate within and between cells.



The foregoing definition of differentiation, however, does not specify which gene products may be regarded as indices that differentiation has occurred and disregards the phases of the cell cycle. On such a view, early 'pluripotent' embryonic cells have a *wide repertoire* of possible responses, any one of which would *immediately* follow a local change in the operative control system, during any phase of the particular cell cycle occurring at the time. Thereafter, the early, labile control systems would become progressively stabilized in subsequent generations as the cells differentiate (**2**.6A).

Other groups of cell biologists, in contrast, propose an alternative set of hypotheses (Holtzer & Abbott 1968, Holtzer et al 1972, 1975, **2**.6A, B). These authors class materials synthesized by

2.6A Theories of mitosis and progressive differentiation. The tabbing is further explained in the accompanying text.

cells as either '*essential molecules*', i.e. those synthesized by most cells and required for their viability, or '*luxury molecules*' which are 'those cell-unique molecules responsible for the state of differentiation of the cell that either synthesizes them or has inherited them'. Secondly, cell mitotic cycles are regarded as of two fundamentally different types (2.6B): *proliferative cell cycles* with amplification of cell numbers, the progeny having precisely the same synthetic capacity as the parent cell; and *quantal cell cycles* which, at some point, make available for synthetic activities regions of the genome in subsequent cells which were *not available* in the mother cell. Such a view securely links essential steps in differentiation to particular phases of a *critical series* of quantal mitoses, perhaps interspersed by proliferative cycles and at each quantal cycle the parent cell is maximally *bipotential*. Thus, the division may be *symmetrical* giving derived cells with identical synthetic capacities or *asymmetrical* in which their capacities differ (2.6B). In one particular type of asymmetrical division, one of the progeny retains the synthetic capacity of the parent cell (2.6B), persisting as a *stem cell* (p. 40). A quantal cell division, therefore, is a *decision point* at which the progeny enter one of two new paths of differentiation. A series of such divisions would clearly lead to diversification of cell types, each ultimate *clonal type* being the product of a precise and strictly compartmentalized *cell lineage*. This hypothesis, presented here in the barest outline, rejects the conventional view of the pluripotentiality of early blastomeres, holding that all cells are optimally differentiated for the stage of development they have reached and, further, relegates the inductive capacities of exogenous molecules to a relatively minor role (Holtzer et al 1972, 1975). Such views are, however, not wholly in accord with those proposed by other groups in relation to the spatial patterning of differentiation (vide infra). These contrasting views are summarized in illustrations 2.6A, B.

2.6B Varieties of mitotic cell division: these include a symmetrical proliferative mitosis, and two types of asymmetrical quantal mitosis. Consult text for discussion.

THE CONTROL OF GENE ACTION

The general structure and role of nucleic acids in the form of nuclear and extranuclear deoxyribonucleic acids (DNAs) and various ribonucleic acids (RNAs) in relation to protein synthesis has been discussed elsewhere (p. 39). Mention was also made of the concept of the *operon* which emerged from elegant investigations on microorganisms (Jacob & Monod 1961, 1963). Essentially, an operon is a functional grouping of DNA loci including several *structural genes*, an *operator segment (o)*, a *promotor region (p)* and a *regulator gene (i)*. Each structural gene carries the information necessary for the specification of a particular polypeptide (which forms part of either a structural or an enzymatic protein). In the case of the *lac operon* of *Escherichia coli* —the first to be thoroughly analysed by the study of the activities of mutant forms (Ashworth 1973)—the linear sequence of DNA loci was demonstrated to be: *i p o z y a* (*z*, *y* and *a* denoting structural genes which encode for the synthesis of β-galactosidase, a permease and a trans-acetylase respectively). The prefix *lac* indicates that lactose is the physiologically important substrate for β-galactosidase. Subsequently, further examples of more complex operons have been analysed, with many features in common with the lac operon but with alternative controlling mechanisms. Such studies have led to rapid advances in our knowledge of the main variations in gene activity in *prokaryotes*.

In general the activity of the structural genes is dependent upon the state of their associated *operator*; they are active only when it is 'free' and they become inactive when it is 'blocked' by combination with a specific chemical group. The neighbouring *regulator gene* produces a *repressor protein* which, depending on local conditions, may exist in an active form capable of binding with the operator, or in an inactive form when it cannot do so. In this manner the activity or otherwise of a particular group of structural genes is dependent upon the production of a *first order* chemical messenger or repressor protein. In turn, specific *second order* messengers (*effectors*) determine the state of the repressor molecules. Some repressors can only block the operator when combined with effectors termed *co-repressor* molecules. In some instances it has been shown that low molecular weight end products of certain *biosynthetic pathways* act as co-repressors, thereby providing a negative feedback system controlling the synthesis of enzymes essential to the biosynthetic path. Thus, heightened activity in the biosynthetic path leads ultimately to gene *repression*, whereas diminished activity leads to *derepression* of the relevant genes.

Other effectors, such as *enzyme inducers*, act in a converse way —by combining with the repressor protein they so modify its structure that it is unable to combine with the operator and consequently the related structural genes become active. The *promotor region*, which lies adjacent to the operator, is now known to be the site where binding of DNA-dependent RNA polymerases (*transcriptases*) occurs, when the operator is not blocked by repressor protein. These determine the *loci* for the

initiation of transcription and, further, variations in a number of factors entering into the constitution of the transcriptases (e.g. the σ-factor) result in *modulation of the rate* of transcription.

Thus, through the balanced activities of *negative* (repressor/operator) and *positive* (transcriptase/promotor) controls, a great flexibility of gene action may be achieved varying from *on/off switches* to delicate *adjustments of transcription rates*.

Certain gene loci have also been considered to control the *mitotic* behaviour of cells; on this view, when the loci are active, multiplicative growth persists and, when inactive, the cells are channelled into avenues of differentiation and ageing. The *tissue-specific chalones* mentioned previously have been proposed as co-repressors of such mitosis-initiating genes (Bullough 1967). The activities of the tissue chalones may be modified by the concentration of general circulating hormones and thus act as intermediaries between the endocrine system and the state of the genome in the tissue cells. (In certain invertebrates a further class of substances called *pheromones* even pass between different individual members of a community, and affect the reactions of their tissues and also their behaviour patterns.)

However, as indicated previously, some cell biologists would not regard the foregoing as an adequate view of the role of mitosis in cell differentiation. Firstly, many would prefer to consider the delicate on-going quantitative controls of protein synthesis as more the province of the cell physiologist, and regard true differentiation to occur only at certain definite phases of *quantal cell cycles* (p. 40). As stated, in the latter, regions of the genome of derived cells become available for synthetic activities which were *not available* in the parent cell. In this regard, mention must be made here of the elegant researches on the structure, distribution and possible roles of varieties of the basic proteins called *histones* (see reviews by Zubay 1968, Cooke 1975, Wasserman 1973, Borun et al 1975). Five principal classes of histone are present in eukaryote cells, and these form strong, stable complexes with each other, and with DNA, thereby being important structural and functional components of the chromosomes (see the discussion on the *nucleosome*, p. 37, and 1.30). It has been proposed that in combination with certain 'operator-like' regions of the chromosomes the histones provide a powerful *non-specific repression* of these regions and their associated structural genes. Such regions, it is thought, become *unblocked* by the cooperation of *non-histone components* only at specific times during chromosome replication in quantal cell cycles. It is possible that such non-histone components, or their precursors, form the basis of the so-called *morphogenetic substances* which many workers have indirectly demonstrated to be differentially distributed in the cortex of the oöcyte, thereafter being unequally partitioned in the various blastomeres at cleavage and, further, they may form the substrate for cell–cell interactions in later development. Experimental analysis of the components that may interact with the histone complexes is still in its infancy. Particular interest has been centred upon the structure and metabolism of certain *'acidic' non-histone chromosomal proteins* (Borun & Stein 1972, Stein & Borun 1972, Borun et al 1975) which may be responsible for the production of specific RNA transcripts and, accordingly, be closely related to aspects of the control of cellular differentiation. (Over 400 varieties of such proteins have been demonstrated in mammalian cells.)

Some authors have stressed that the genome of *prokaryotic cells* is permanently *unblocked* but can be repressed or derepressed (Tsanev & Sendov 1971, Tsanev 1975), while in metazoan *eukaryotic cells* the genome is initially *blocked* and during embryogenesis *sequential unblocking* of different gene combinations occurs. The *functional state* of the fully differentiated cell is thereafter determined by repression and derepression 'within the limits of the unblocked regions of the genome'. Computer simulation of model systems of metazoan development indicates that the final stages of cellular differentiation can be reached only through 'a chain of events in which both processes of repression–derepression (realized by embryonic induction) and of blocking–unblocking (realized by the mitotic cycle) are successively involved'.

It should be noted that many of the control systems described above seem to be mediated by that ubiquitous regulator molecule cyclic adenosine monophosphate (3′5′cAMP), which therefore also appears to have a central role in cellular differentiation.

An abbreviated account such as the foregoing can do little justice to the numerous elegant and rapidly expanding researches in these fields. Nevertheless, enough has perhaps been said to emphasize that the earlier evidences stemmed largely from work with microorganisms, and although considerable advances have now been made (Lewin 1970), the positive identification of the specific roles of intra-cellular and intercellular chemical messengers in advanced metazoan tissues is still awaited. However, as a working hypothesis it is considered that the patterns of growth, differentiation and functional expression in metazoa result from the varied activation and repression, coupled with sequential unblocking, of gene groups which stem from an interlocked hierarchy of chemical messengers—repressors, corepressors, inducers, transcriptases, blocking/unblocking proteins, tissue chalones and circulating hormones (and in some communities pheromones), which act in coordinated sequences in space and time as integral parts of cell cycles. Many modifications of this scheme will undoubtedly prove necessary. Furthermore, the informational role of extrachromosomal nucleic acids and other self-replicating cytoplasmic substances (or *plasmagenes*) which may have major roles in normal development have as yet been little investigated in the higher metazoa.

CONCEPTS RELATING TO PATTERN FORMATION

The events outlined in previous sections dealt largely with hypotheses concerning *intracellular* mechanisms controlling cell differentiation, but neglecting two fundamental aspects of development, *pattern formation* and *morphogenesis*. The latter, acting in concert with cell differentiation, are the means by which the total genetic information available to the zygote is ultimately expressed in the mature functioning phenotype.

Pattern formation concerns the processes whereby the individual members of a mass of cells, initially *apparently* homogeneous, follow a number of different avenues of differentiation precisely related to each other in an orderly manner in space and time. The mechanisms by which such temporo-spatial differences are initiated and maintained currently engage the attention of many developmental biologists. The 'patterns' embraced by the term, of course, not only apply to regions of *regular* geometrical order such as the retina, crystalline lens, cerebellar cortex, etc., but all aspects of metazoan development including ordered but *asymmetrical* structures such as the tetrapod limb, mammalian liver, etc. Thus, e.g. in the case of the limb, the intimate *intracellular* events leading to the emergence of chondroblasts, myoblasts, osteoblasts and so forth will be identical in right and left sided limbs, forelimbs and hind-limbs, and their counterparts in different species; nevertheless, the *patterned arrangement* of these elemental processes differs in each case.

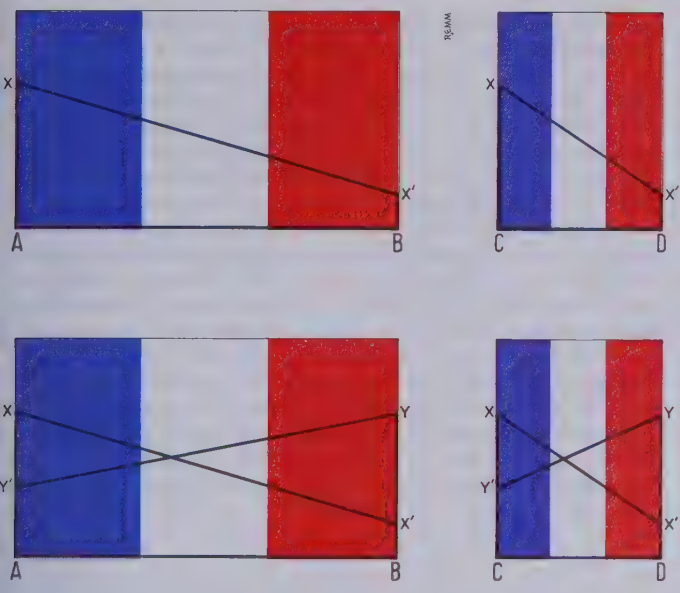
Morphogenesis, or the assumption of form by the whole, or part, of a developing embryo, is often for convenience treated as a separate field of study, involving differential rates of growth or degeneration of cell groups but, particularly in early embryogenesis, also the relative *morphogenetic movements* of cells or cell aggregates. The movements involved in gastrulation (p. 100) or the wide dispersal of neural crest cells (p. 183) are dramatic examples. Thus, the study involves an analysis of the *mechanisms* and *forces* responsible for cell movement, migration, changes in shape of individual cells and the differential adhesiveness of their surfaces (see pp. 22, 115). However, despite the conveniences for research groups, these facets of development are necessarily *interdependent*. Whether it is differential growth balanced against areas of degeneration, morphogenetic movements and migration or cellular differentiation under consideration, it is necessary first to *specify* within a group of cells *which particular ones* shall divide, degenerate, migrate or differentiate, and this is the province of *pattern formation*. As an example, when a cell group migrates to a distant location in normal development, mechanisms clearly exist to *locate* the group about to migrate, in relation to the remainder of the embryo. After a prelude of growth, the selected group enters the initial stages of differentiation, which lead to the development of those organelles, surface specializations and

changes of cell shape responsible for the mechanics of migration; further, these events must follow in correct *sequence* and *orientation*. Following migration, the group is in a new cellular environment and further periods of growth and differentiation follow, with crucial interactions between the migrated group and the cells forming its new environment, often affecting the particular avenues of differentiation followed by *both*.

It should be noted that pattern formation is an essential ingredient not only of normal embryogenesis but of processes of *regeneration*, good examples being the regeneration of new heads and tails in transected flatworms, new apical and basal regions in transected *Hydra* or the replacement of a whole severed limb, or an appropriate part thereof, in adult Amphibia. In general, regeneration follows one of two main types: *morphallaxis*, in which the whole reforms by rearrangement and differentiation of the existing tissues without further growth, or *epimorphosis* in which there is new growth of blastemal tissue which subsequently matures into the full regenerate. Whatever control mechanisms are proposed for embryonic pattern formation, they must be sufficiently flexible to also account for morphallaxis and epimorphosis.

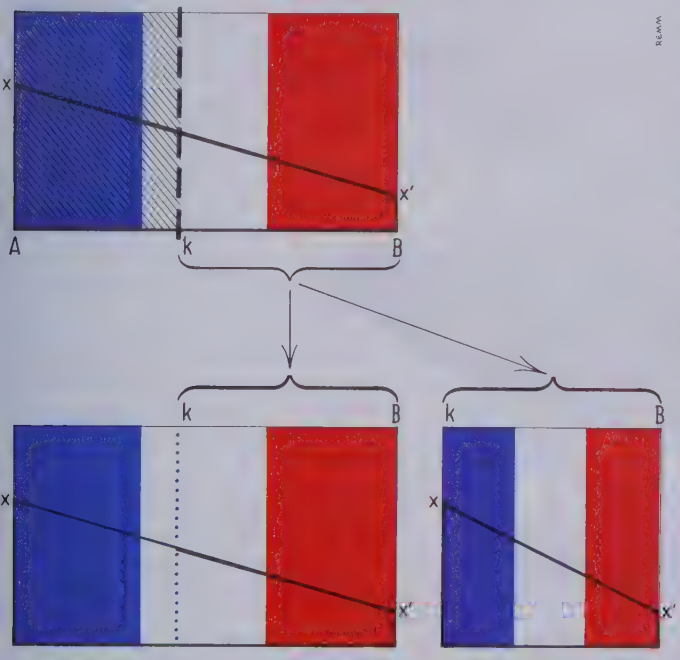
(For an extensive entry into the literature consult the chapters collated by Malacinski & Bryant 1984.)

It should be emphasized that the approach to the problems of pattern, form and differentiation contrasts sharply between workers. Some (Holtzer et al 1975) assume that finer and finer probing of the genome and the detailed control of protein synthesis, leading to a reasonably complete understanding of the *intracellular* molecular events of cytodifferentiation, would, in its turn and with little addition, provide an adequate explanation of changes in form and pattern. Others (Wolpert 1969, 1971 a,b, 1978, 1981, Wolpert and Stein 1984), whilst conceding the importance of the molecular aspects of cytodifferentiation, hold that the laws and principles of control of pattern and form must initially be sought at the *cellular* and *intercellular* level and that they will prove to be 'as general, universal, elegant and simple as those that now apply to molecular genetics'.



Since the closing decades of the last century, a series of concepts concerning pattern formation have emerged, but with time these have been rephrased and redefined, often resulting in differences of definition and terminological confusion. These concepts, mentioned earlier (p. 98), include ideas of polarity, axes, gradients and fields and suggestions concerning the coordinates necessary for their specification.

In the physical sciences, a notional system possessing two regions of opposite tendencies or qualities, the *poles*, which are considered joined by a linear *axis*, is commonplace, e.g. in magnetism and electrostatics. At each point in space along and around the axis and poles, a force exists having a specific intensity and direction, i.e. a *vectorial force field* is present in three-dimensional space and a *linear axial gradient* exists between the poles. Similar terms were adopted by developmental biologists, but whilst some authors (Wolpert 1971 a, b, 1978) stressed the analogy with the physical sciences, others (Waddington 1966) considered that, except for particular purposes, such approaches were grossly oversimplified. Descriptions of systems exhibiting forms of polarity, axes and gradients, abound in biology. Classic examples include regeneration following the transection of *platyhelminths* or *Hydra* at different levels. The details will not be followed here, but in general the presence of an axial gradient concerning the form and frequency of successful regeneration was demonstrated, together with gradients of metabolic activity and susceptibility to toxic materials. Further, the *apical region* (head in flatworms and hypostome in *Hydra*) regenerated first and subsequently inhibited the formation of additional apical structures, and appeared to coordinate the regeneration of succeeding parts (a phenomenon termed *apical dominance*). Similar poles, axes and gradients have been described in many *oöcytes*, e.g. the animal–vegetative, oral–aboral and dorso–ventral axes (see p. 98 and **2.3**). The term axis has, however, been used in rather different ways in different situations. Thus, the animal–vegetative axis of oöcytes is often an obvious structural and cytophysiological feature, reflected by the eccentricity of the nucleus and the differential distribution of yolk platelets, other organelles, pigment granules, metabolic levels, etc. Further, in some forms which have been thoroughly analysed, e.g. the sea urchin (Gustafson & Wolpert 1963, Gustafson 1965), there exists an experimentally demonstrable 'morphogenetic gradient' along this axis, although it is as yet uncertain what are the relevant 'morphogenetic factors' which are distributed along the axis, although tentative suggestions have been made (see p. 109), and of course the mechanisms controlling their distribution are completely unknown. However, it is clear that the animal–vegetative axis is determined early and once formed is extremely stable; in contrast, the dorso–ventral axis is determined much later, is more difficult to demonstrate and is more labile. Similar concepts of polarity and axes have often been applied, e.g. to the developing tetrapod limb, and here again the proximo–distal, cranio–caudal and dorso–ventral 'axes' are determined at different times and vary in their lability.

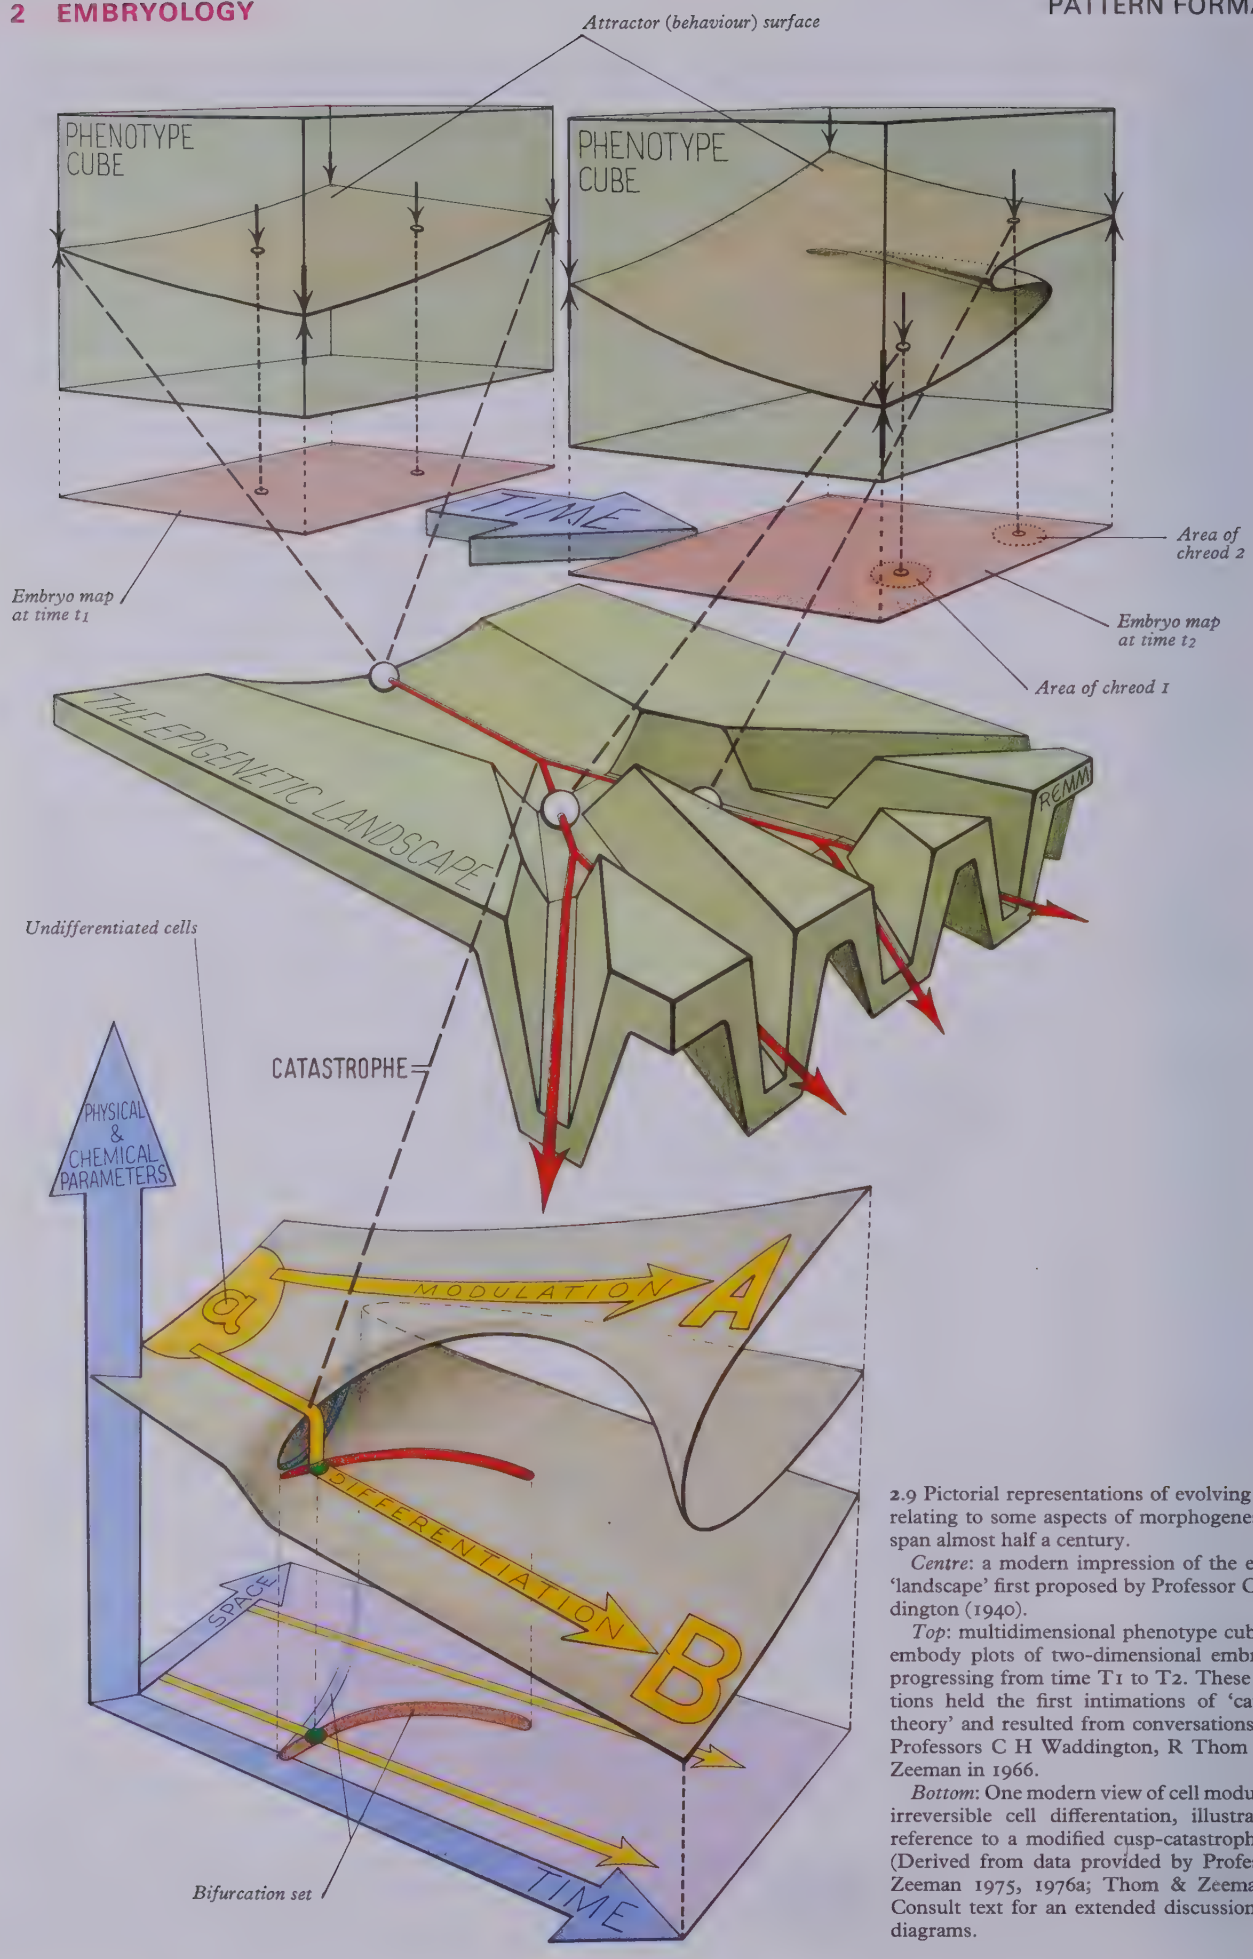


Such concepts are central to many of the hypotheses relating to pattern formation and may be considered in association with the two forms of development mentioned earlier (p. 100) termed *mosaic* and *regulative*. In a mosaic system, removal of a part results in a specific defect in the final embryo, whereas removal of part of a regulative system is followed by a total proportionate reorganization of the remainder, with the formation of a small but complete embryo. Further, division of a regulative system often results in duplication, with two small complete embryos. Similar considerations also apply not only to whole zygotes, but also to presumptive organ rudiments. Although no animal groups are wholly mosaic or regulative, some, such as the annelids and molluscs, show a high degree of mosaicism, whereas the sea urchin and chordates are predominantly regulative.

During oögenesis, and variably modified at fertilization, it has been demonstrated (Raven 1958, 1963, 1966 a,b, Austin & Short 1984) that morphogenetically important substances are localized (oöplasmic segregation) in the cortical zone in geometric patterns related to the principal axes of the oöcyte. It is assumed that the distribution gradients of such substances are differentially parcelled between the blastomeres during cleavage. In *mosaic systems* it is thought that the cytoplasmic parcelling which results from their highly ordered and specifically orientated cleavage is almost wholly responsible for directing subsequent pattern formation, morphogenesis and cytodifferentiation, as a series of independent localized events with relatively little intercellular communication. In contrast, it has been proposed that while the blastomeres of regulative eggs also necessarily differ qualitatively and quantitatively, the phenomenon of *regulation* exhibits *global features* wherein the mass of cells reorganizes *as a whole*, and there must exist avenues of *intercellular communication* of crucial significance in development. Such ideas led to the early formulation of the concept of the *morphogenetic field* (Huxley & DeBeer 1934, Child 1927, 1941) defined as 'a region throughout which some agency is at work in a coordinated way, resulting in the establishment of an equilibrium within the area of the field'. Subsquent years saw the rather sporadic (and occasionally inappropriate) use of the term embryonic field, and then for a period its use was largely abandoned by many developmental anatomists. Only quite recently has the phrase been subjected to critical reappraisal and restatement; two provocative but contrasting views have emerged.

The first concerns the idea of *positional information* being available to individual members of a mass of cells by virtue of the presence of *reference points* at its borders, the whole constituting a *morphogenetic field*. Essential to the idea is that *gradients* of activity (information) extend from the reference points throughout the cell mass by *cell–cell communication:* accordingly, the unique position of each cell is specified, and subsequently each differentiates appropriately within the limits of the metabolic options provided at the time by the state of its genome. The picturesque model adopted to present this hypothesis is the so-called 'French Flag Problem' (**2.7**A,B). In this, a line of cells with channels of intercellular communication between them are considered to have three possibilities for molecular differentiation —blue, white or red—and they form a correctly proportioned French Flag whatever the number of cells in the line and even if parts of the original line are removed. It is assumed that each cell is assigned a positional value by appropriate signals with respect to reference sources at the ends of the line. Reference to

2.7A Diagram illustrating one hypothesis concerning positional information in relation to pattern formation, by reference to the so-called 'French Flag' problem. A-B and C-D indicate long and short rows of cells respectively, X, X' and Y, Y' the concentrations of morphogenetically active substances. Above: (X-X') shows the gradient of a single substance; below: (X-X' and Y-Y') the gradients of two substances. In each case a similar triple differentiation occurs. See text for discussion. (Modified from, and kindly provided by, Professor L Wolpert 1971 a,b, 1978.)



2.7B Diagram using the 'French Flag' analogy to illustrate application of the hypothesis of positional information advanced to explain regeneration, after ablation (cross-hatch), of part of an array of cells, either by morphallaxis (right), or by epimorphosis (left).

illustration 2.7A,B will make it clear how such a proposal could successfully explain proportionate differentiation, not only with lines of different lengths but also to include epimorphosis and morphallaxis. A number of model systems proposing possible mechanisms for the mode of operation of the signalling system have been examined. Briefly these include, most simply, a source of a metabolic product at one end of the line, a sink at the other, with the establishment of a linear diffusion gradient between them. More complex models have proposed signalling gradients of two or more substances, or the reversible operation of multiple sources and sinks depending upon local conditions (the so-called homeostatic model), whilst others have invoked active transport mechanisms or the presence of paths of selective permeability. An interesting alternative mechanism suggests (Cooke & Zeeman 1976) that a reference point may be provided by a *pacemaker cell* which emits two wave-like periodic propagations of biochemical activity which are transmitted from cell to cell throughout the morphogenetic field. Positional information would then be signalled by the *phase angle difference* between the arrival of the two waveforms at the cell in question. In a detailed analysis of amphibian gastrulation it was suggested that *two* such pacemaker regions were present, one at the animal pole and the other at the grey crescent. Their mutual positions change during gastrulation providing a dynamic *two-dimensional grid* of positional information in the mesodermal mantle, thereby specifying its subsequent pattern of cytodifferentiation. (For further discussion of these and related hypotheses consult Kitchin 1949, Muchmore 1951, Waddington 1956, Deuchar & Burgess 1967, Johnson 1970, Zeeman 1976b, Elsdale & Pearson 1979, Burgess 1981, 1983.)

Despite the fact that all the foregoing signalling mechanisms are relatively simple in principle, it has been stressed that such systems, when coupled with variations in the 'rules for interpretation of the signals' on the part of the genome of the reacting cells, could result in the production of highly complex, even asymmetrical patterns. Nevertheless, although universality has been claimed for the theory throughout biology (Wolpert 1971a, b, 1978), currently there is no direct evidence for the precise nature of the boundary zones (reference points or pacemaker cells), the detailed mechanisms of intercellular signalling and the manner of cellular interpretation of the signals. As yet, therefore, the hypothesis of a coordinate system which specifies positional information, whilst providing a powerful stimulus for new thought and experiment, must for the present remain the province of tentative theoretical biology.

During the period of emergence of theories of positional information in relation to morphogenetic fields, there has also occurred the convergence of ideas from two other sources. The first constituted a critical reappraisal of the definition of the term '*morphogenetic field*' and associated terminology by the eminent developmental biologist C. H. Waddington (1940, 1966). The second was the evolution of a new set of descriptive and explanatory mathematical models which have been grouped under the dramatic name of *catastrophe theory*.

During attempts to redefine the term 'field' as applied to embryology, it was stressed that much confusion had arisen because of the original combination of the ideas of organization and induction (Waddington 1966); confusion was reinforced by the use of terms such as 'organization centre' and 'organizer substance'. Thus it was originally supposed, as indicated above, that such a centre, during an act of embryonic induction, produced organizer substances which transmitted the instructions necessary for the subsequent complex organization of a neighbouring mass of competent cells. In order to avoid this confusion it was proposed that *evocation* should be used for 'induction that does not *transmit* organization'. *Individuation* was suggested for organization of a mass of cells *per se*, whether preceded by an inductive *triggering mechanism* or not. In this sense it was proposed that a morphogenetic field was only appropriately named when applied to an *individuation field* and it was indicated that some authors had used the term too loosely, denoting merely the *locality* of a normal presumptive organ rudiment. It was also considered that to view a morphogenetic field as the manifestation of the presence of gradients of one, or at most a few, simple diffusable substances, was almost certainly a naive over-simplification. Emphasis was placed on the fact that when attempts are made to describe a system in developmental biology, cognizance must be given not only to the three dimensions of *space*, but also to the essential dimension of *time*, to embrace the dynamic progressive changes involved. Further, at successive intervals it would be necessary in such a *multi-dimensional function space* to establish coordinates allowing vectorial analysis of the *concentrations* and *directionality of interaction* of a large number of relevant chemical families. The mathematical concepts appropriate to a study of multidimensional space–surface transitions constitute *topology*. Those facets of topology which are of wide application in both the physical and biological sciences, including developmental biology, constitute

2.9 Pictorial representations of evolving concepts relating to some aspects of morphogenesis which span almost half a century.

cardiac cycle, nerve impulse propagation, cell differentiation (**2.9**) and for amphibian gastrulation (Zeeman 1976a,b, Poston & Stewart 1978), but as yet experimental validation is lacking (and indeed, occasional authors view with scepticism the over-enthusiastic acceptance and application of the theory in the presence of incomplete data—see Croll 1976).

NUCLEAR CHANGES DURING DIFFERENTIATION

Two main lines of investigation over some decades have attempted to demonstrate changes in the nuclei of tissues which have undergone differentiation—firstly, experiments using nuclear transplantation techniques and secondly, an examination of the phenomenon of chromosome 'puffing' shown by some species. More recently the modern techniques of genetic manipulation ('engineering') have started to focus, with some success, on the regional variations in activity of short segments of chromosomes (see p. 39). Currently, immunofluorescence techniques are proving valuable methods of demonstrating the location and timing of first appearance of antigenic new gene controlled products during differentiation.

Many kinds of transplantation experiment have been carried out (King & Briggs 1965, Gurdon 1967, 1968) but in principle, the nucleus is removed from an activated egg and replaced by one removed from a particular site in, e.g. an early blastula, early or late gastrula or more highly differentiated post-gastrulation tissue, and then any subsequent development which proceeds is analysed. In practice more reliable quantitative results can be achieved by the *serial transplantation* of donor nuclei before proceeding to a developmental analysis (**2.5**). Although the results show considerable variation, in general, the transplantation of early nuclei is often followed by the formation of a complete embryo, whereas nuclei from the later stages are sometimes only able to support the development of incomplete embryos or cell masses of a restricted tissue type. However, in contrast, it has been shown that nuclei from advanced tissues such as amphibian neural plate cells and ciliated gut epithelial cells of the tadpole can still support the formation of complete embryos, although the proportion of successful experiments is reduced, whilst nuclei from fully adult tissues fail to do so (Gurdon 1967, 1968). Whilst such results may reflect some stable changes occurring in nuclei as differentiation proceeds, more work will be necessary before clear-cut interpretation is possible.

Direct visualization of differences between the chromosomes of various tissues and times is provided by the giant polytene chromosomes of the *Diptera* and the 'lampbrush' chromosomes of the newt. At certain loci such chromosomes exhibit hazy thickenings of their outlines (*'puffs'* or *Balbiani rings*). It is widely held that throughout inactive regions of chromosomes the DNA threads are closely coiled and supercoiled, but at sites of activity the threads become unwound and spread laterally from the axis of the chromosome and form the basis of the puffs. Each puff may include a number of active operons at which transcription and synthesis of messenger RNA is occurring. In short, although many details of the process of puff formation remain to be elucidated, the puff patterns of all the functional nuclei of a particular cell type in a tissue are identical but differ significantly from the patterns in other tissues. The patterns also change as development proceeds; e.g. there is a regularly repeating sequence of changes accompanying the 'moult' and 'intermoult' stages in the life of larvae. The latter system is particularly interesting since moulting is a response to a hormone, *ecdysone*, which has been isolated and which affects the activity of the genome—details of the process are under intense analysis.

It is important to emphasize the fundamental question posed by such investigations, namely—during the growth, patterning and differentiation of complete multicellular organisms, is the *essential sequence* of instructive molecules in the genome of the different emergent cell types *altered*, e.g. by deletion of segments? Alternatively, is the overall sequence *preserved* and the *expression* of its various segments *modified* appropriately? The consensus supports the latter, with the reservation that the *degree of reversibility of expression control* varies widely with site and species.

Occasional examples of alteration of genomic sequences have been quoted, e.g. the early segregation of gonocyte and somatic cell nuclei in *Dipterans*, with the apparent deletion of sex-determining loci in the latter; another case involves the *amplification* of repetitive gene sequences during oögenesis at the other extreme; it has proved possible, by careful tissue culture techniques, to grow a complete carrot plant from a single isolated parenchymal cell from a mature carrot.

SURFACE INTERACTION BETWEEN CELLS

Further properties of developing cells, which reflect some aspect of their state of differentiation and have important implications in morphogenesis, concern the selective interactions between their surfaces when in contact. Such surface modifications are closely related to the formation of the cellular sheets, hollow balls, tubes, invaginations, solid masses and so on which characterize embryonic life. Following earlier tissue culture studies (Weiss 1941, 1961, 1970, Abercrombie 1961, Abercrombie & Heaysman 1953, 1954), two important principles were enunciated. Numerous experiments showed that some cells, when explanted on to a matrix with an heterogeneous, polarized substructure, often migrated along preferential paths determined by its architecture. This led to the concept of *contact guidance* of cells—particularly well shown in the preferred regeneration of nerve fibres along the surfaces of Schwann cells or, during ontogeny, the growth of later generations of nerve fibres along the surfaces of the earlier pioneer fibres.

In contrast, when similar cells which were migrating freely in tissue culture approached each other and made contact, all movement and often cell division in the plane of contact ceased and this phenomenon of *contact inhibition* was proposed as an important morphogenetic factor. For a brief account of the mechanisms of cell movement see p. 49, and for reviews on morphogenetic movements consult Ede (1976), Abercrombie & Heaysman (1953, 1954), Hinchliffe & Johnson (1980).

Since that time many experiments involving the *disaggregation* of tissue cells have been made (Townes & Holtfreter 1965). For example, if the cells of a neurula or those of a developing kidney are disassociated to form random cell suspensions, they often subsequently reaggregate and similar cells reassociate so that a recognizable neurula or a fragment of kidney tissue is reformed. Again, if cell suspensions from developing liver and kidney are intimately mixed, similar cells gradually reassociate and organize into kidney and liver tissue. In this manner, using different cell combinations, the potential of different cell types for mutual recognition, reorganization into tissues, sheet formation, invagination and so forth have been analysed. An adequate interpretation of the phenomena would, of course, necessitate an intimate understanding of the physico-chemical properties and control systems of cell surfaces. Until such become available, the investigators in this active field of research are pursuing quantitative variations in the *specific adhesiveness* between cells and proposing various models for further examination, such as *stereochemical surface configurations* which can only interlock with complementary surfaces. For reviews consult Curtis (1967, 1973), Karfunkel (1971).

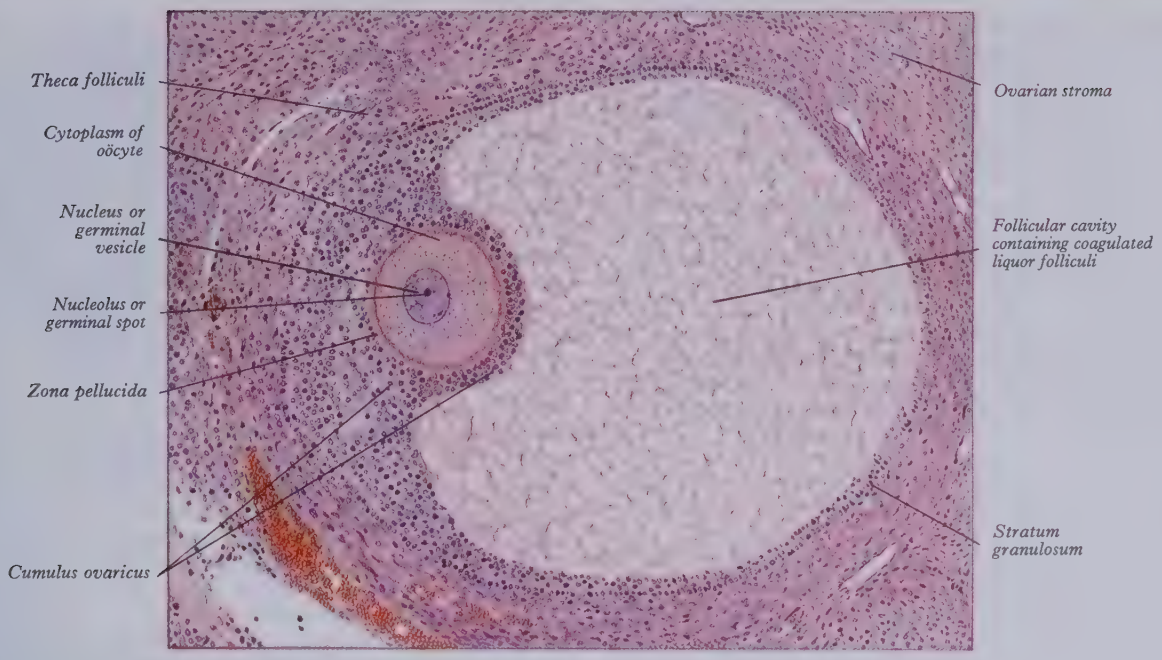
In the subsequent sections a brief account of *human* development is given and, as such, is necessarily and solely *descriptive embryology*. When reading such an account of the emergence of primordial organs and subsequent changes in shape, the reader should constantly be aware of the many continuing fields of *experimental analysis* in other forms, which are daily adding to our comprehension of the *causal processes* of the almost incredible and beautiful phenomenon of development.

The Female Gamete: The Ovum

The precise origin of the primordial germ cells, from which both ova (Shettles 1960, Austin 1961, Austin & Short 1984) and spermatozoa are derived, remains uncertain (p. 254); but those which reach the genital ridge in the female, the *oögonia*, proliferate and differentiate into *primary oöcytes*. Their number maximizes at about 6 000 000 in each ovary by the fifth intra-uterine month (Baker 1963, 1966). Subsequently, before birth, widespread degeneration occurs, leaving a complement of about 2 000 000 primary oöcytes (Block 1953). However, many of these become atretic before puberty, when only some 40 000 oöcytes persist in each ovary (Pinkerton et al 1961). A mere 400 or so of these will be shed at ovulation with the potential of fertilization during the reproductive years of the average woman. (Each primary oöcyte passes through a series of changes, becoming a *secondary oöcyte* just before ovulation and mature *ovum* at, or just after, fertilization. The term ovum is nevertheless used with a confusing vagueness for all three and even for later stages, a practice which is best avoided.) Immediately after formation and still before birth, primary oöcytes enter the initial stages of prophase of the *first meiotic (reduction) division* in the process of *maturation*, which is not completed until shortly before ovulation. This reduction in the genetic apparatus and the recombination of genetic material are, of course, central features of maturation (p. 42). A primary oöcyte is distinguishable from other cells in the ovary by its large size, being about 35 μm in diameter, and by the fat granules in its cytoplasm. Its nucleus is relatively large, vesicular and usually eccentric, with a prominent nucleolus. The nuclear eccentricity confers a visible polarity on the cell which is emphasized to some degree during subsequent growth and maturation. The Golgi apparatus is well developed and consists of parallel cisternae and numerous small vesicles; the latter also appear throughout the cytoplasm. Juxtanuclear anulate lamellae occur interspersed between spherical or slightly elongate mitochondria. At first the endoplasmic reticulum is vesicular and displays few ribosomes. As the oöcyte grows all these organelles increase in number and usually in size, and they disperse from the juxtanuclear zone throughout the cytoplasm. (Although described as isolecithal—vide infra—this dispersal is not entirely uniform, varying with nuclear position.) Granular endoplasmic reticulum and free ribosomes, though not prominent, also increase. Lipid granules begin to appear; they correspond to the yolk platelets of earlier vertebrates but are smaller and less frequent in primates. By the secondary or antral stage of follicular growth (vide infra) the oöcyte has completed its increase in size. Usually each ovarian follicle contains one, but two or even more may be present. In some strains of certain animals polyovular follicles are more frequent. The oöcyte is surrounded by a single layer of cubical cells and at this stage electron microscopy shows that the relationship is one of close apposition; adjacent plasma membranes are smooth and separated by 12.5–14.0 nm.

THE OVARIAN FOLLICLE

During the earlier and subsequent stages of maturation considerable growth of the primary oöcyte and enlargement of the follicle occurs. By accumulation of cytoplasm, particularly its lipids, the oöcyte reaches a diameter of 117–142 μm—a volume increase of about a thousand times; this is achieved before follicular enlargement is complete. The follicular cells first multiply and form several layers; at, or even before, this stage electron microscopy reveals the accumulation of interrupted masses of amorphous material between the cells and the oöcyte. These soon fuse into a complete membrane around the oöcyte, seen with light microscopy as a PAS-positive, thick and radially striated envelope, the *zona pellucida* (z. striata). The zona contains considerable amounts of carbohydrate and neutral glycoprotein (Braden 1955). Sialic acid residues also occur and may contribute to its elasticity (Soupart & Noyes 1964, Soupart & Clewe 1965). Electron microscopy reveals an intricate filamentous structure at the time of ovulation. The origin of the zonal membrane, whether from the oöcyte, follicular cells or both, is still undecided (Hope 1965); an outer layer, consisting of acid mucopolysaccharide, has however been attributed to the follicular cells (Wartenberg & Stegner 1960, 1961). Coincident with the development of the zona, the surface of the primary oöcyte presents numerous microvilli which project into the zona: less frequent processes from the follicular cells pass through the zona pellucida to make contact with the plasma membrane (oölemma) of the oöcyte, without actual cytoplasmic continuity. These intimate relationships may be concerned with transport of materials between the follicular cells and ovum (Shettles 1958, 1960, Chiquoine 1959, Sotelo & Porter 1959, Odor 1960).

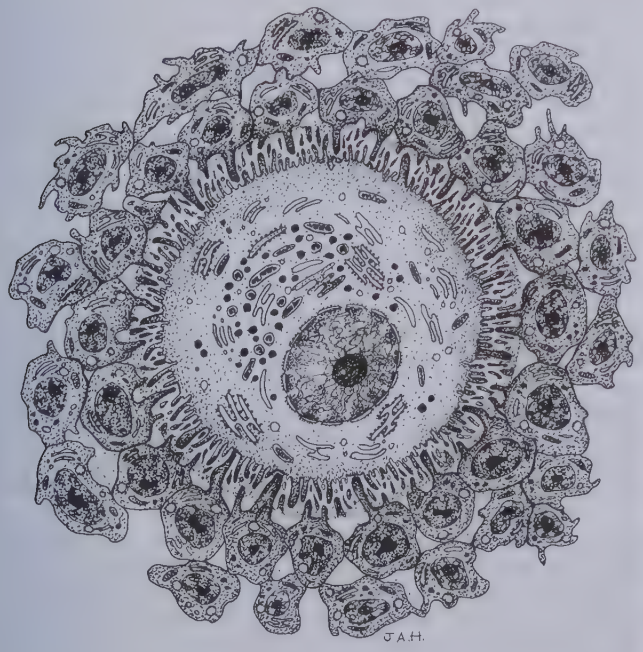


The zona pellucida is semipermeable, is slowly lysed in alkaline media and degraded by the proteolytic enzyme acrosomase. It is best developed in placental mammals and persists until the blastocyst stage of development. It is probably the source of fertilizin in mammals (Bishop & Tyler 1956).

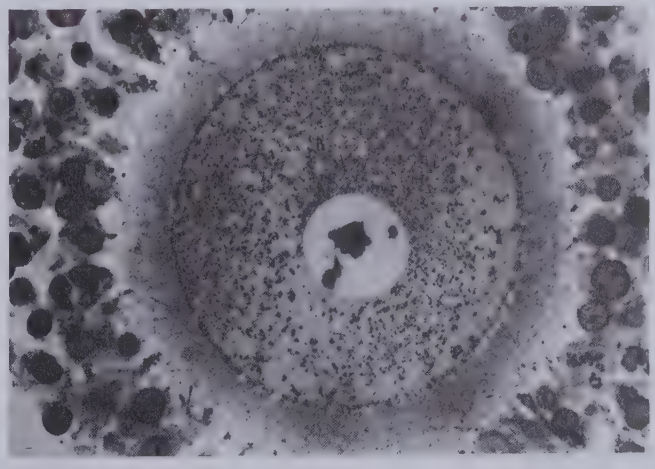
Dense extracellular granules, *Gall-Exner bodies*, develop between the maturing follicular cells. They are PAS-positive and display a complex ultrastructure. They may be derived from the Golgi apparatus but are of uncertain significance. They occur in human follicles but rarely in other mammals.

OVULATION

When the follicle is multi-laminar, a fluid-filled *antrum* appears among its proliferating cells, gradually dividing them into an internal stratum, the *cumulus ovaricus* (oöphorus), and an external *stratum granulosum*; but at one site the two strata maintain continuity (**2.10**). The primary oöcyte is in the cumulus; the granular stratum forming an envelope around the fluid gradually thins as the *liquor folliculi* accumulates. (Antral development has been analysed in particular detail by Zamboni et al 1972.) The primary oöcyte, which has remained in the prolonged prophase of the first meiotic division, retains its microvilli and its complex interrelationship with the follicular cells outside the zona pellucida (**2.11A**) until shortly before ovulation, when continued formation of the first polar cell is resumed (vide infra) and completed. Now a *circumvitelline space* appears between the zona and what is now a secondary oöcyte. The processes of the follicular cells are also withdrawn from the zona, which therefore loses the striation seen earlier with light microscopy and becomes more homogeneous. The follicular cells show an increasing abundance of mitochondria, granular endoplasmic reticulum and free ribosomes and their Golgi organelles become more prominent, indicating increasing activity. The stratum granulosum becomes enveloped in a cellular and fibrous sheath derived from the ovarian stroma (**2.10**), termed the *theca folliculi* (p. 1436). By enlargement, and perhaps also translation through the ovarian stroma, the ripening follicle projects from the surface of the ovary and finally ruptures, releasing the secondary oöcyte, surrounded by the zona and cells of the cumulus, into the peritoneal cavity, from which it rapidly enters the uterine tube; thereafter, slow transit to the uterus is aided by contractions of the fimbriae of the tube and of the tube itself, together with ciliary movements of its epithelium (Austin 1963). It has been noted that the secondary oöcyte cannot be strictly regarded as an 'ovum' until after completion of its second division and release of a second polar cell.



The follicular cells adherent to the liberated oöcyte are now termed the *corona radiata* and they form two or three irregular and loosely arranged layers (**2.10, 11**). Between them is a matrix containing hyaluronic acid, and in some species there is strong evidence that seminal hyaluronidase brings about the disintegration of the corona which soon occurs. As mentioned, the zona pellucida is partly degraded by seminal proteolytic enzymes derived from the acrosome of the sperm head, including acrosomase (acrosin). Unless fertilization occurs, the secondary oöcyte is discharged from the uterus in the debris of the next menstrual period; if it is fertilized, the zygote which results is



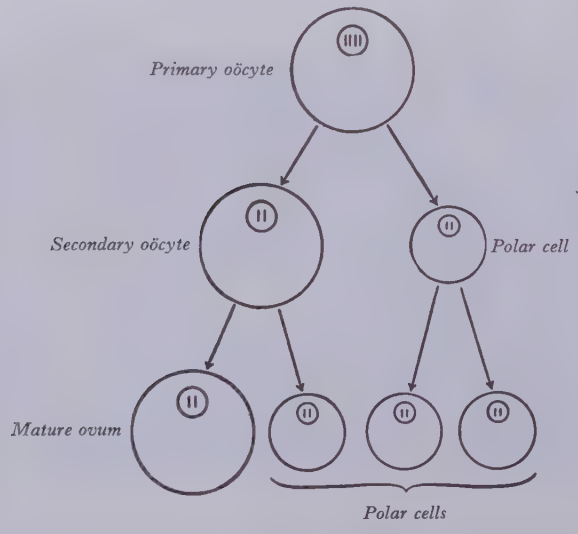
2.10 Ovarian follicle from a woman aged 28 years. Haematoxylin and eosin. Magnification × *c.* 90.

retained and pregnancy begins. (For details of fertilization see p. 123.) Usually only one follicle matures fully and ruptures in each menstrual cycle in mankind, but multiple ovulation does occur (p. 125). Hence only a small fraction of the primary oöcytes which persist in the ovaries of the newborn female are destined to survive to ovulation, the remainder degenerating. Atresia occurs before birth, as stated above, and even at birth about half of the surviving oöcytes are abnormal. Several follicles usually develop normally to some extent in each reproductive cycle, but only one commonly completes the process, the others becoming degenerate, being invaded by blood vessels and connective tissue which ultimately replaces them as *atretic follicles* (eventually contracting into small white fibrous *corpora albicantia*, see p. 1437).

Although an oöcyte is exceedingly large compared with other general body cells, it resembles them in general structure; some of its parts are given specific names. Thus, the cytoplasm is the *yolk* or *oöplasm*, the nucleus is termed the *germinal vesicle* and the nucleolus the *germinal spot*. The cytoplasm is also often known as the *vitellus* and hence the plasma membrane of the cell is the *vitelline membrane*. The yolk comprises two major components: (1) cytoplasm bearing organelles that characterize many other cells, termed *formative yolk*; (2) the *nutritive yolk* or *deutoplasm*, which consists largely of fatty droplets containing lecithin. In mammalian ova the deutoplasm is small in amount and is only partly sufficient for the initial stages of embryonic development prior to implantation in the uterus. Over this period the deutoplasm is supplemented by nutritive tubal secretions (p. 141) and 'uterine milk' (p. 146). In contrast, as we have seen (p. 98), the eggs of birds contain a supply which nourishes the

2.11A Drawing constructed from electron micrographs of a primary öocyte surrounded by its zona pellucida, outside which are aggregated follicular cells of the corona radiata. Note extensive invasion of the zona by microvilli of the oöcyte interdigitating with cytoplasmic processes of the follicular cells. Where some of the latter approach the plasma membrane of the oöcyte, desmosomoid junctions are visible. Note the organelle-rich cytoplasm of the oöcyte. (Modified from Anderson & Beams 1960, with kind permission.)

2.11B Human oöcyte photographed in transverse section. Follicular cells surround it, the zona pellucida intervening. Epon-embedded, osmic-acid fixed, toluidine blue stained. Magnification × 550. (Baca & Zamboni, 1967)



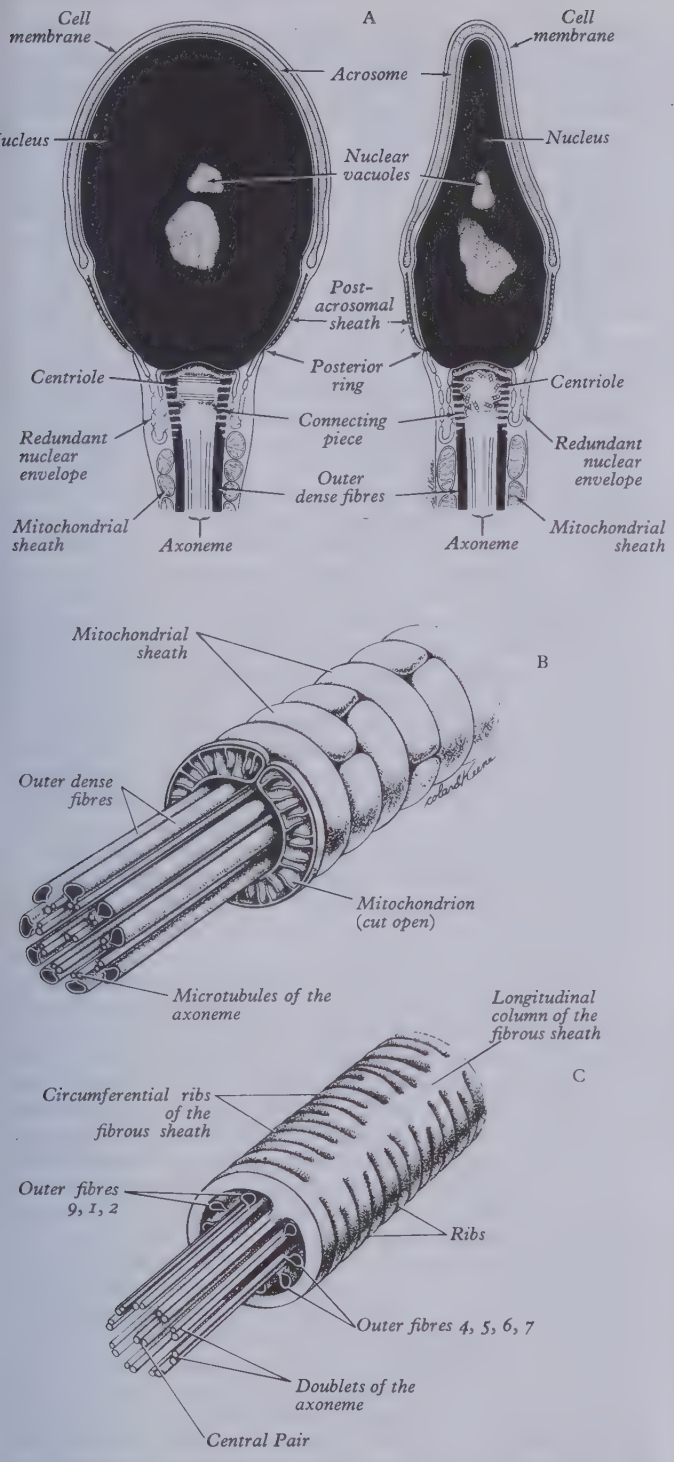
chick throughout its entire development up to hatching. The distribution of the deutoplasm varies in different animal groups; the abundant deutoplasm of certain ova tends to accumulate in one part of the cell, which is therefore termed *telolecithal*. In human oöcytes the dispersion is rather more, but not completely, uniform or *isolecithal*. The formative yolk contains some of the organelles characteristic of cytoplasm, such as mitochondria, Golgi apparatus and centrosome, rough and smooth endoplasmic reticulum, varieties of lysosomes, microbodies granules, filaments and tubules; centrioles are sometimes visible in the neighbourhood of the nucleus, but they disappear when the female pronucleus is formed after fertilization (p. 124). (For a detailed analysis of the fine structure of the developing human oöcyte in vitro consult Zamboni et al 1972.) By analogy it is presumed that crucial, active, morphogenetic substances are differentially concentrated in various parts of the cytoplasm, particularly in the cortical zones.

MEIOTIC DIVISION OF THE OÖCYTE

The series of changes which produce a fertilizable 'ovum' are known as maturation (Monroy & Tyler 1967), some features of which have already been mentioned above. The primary oöcyte's initial period of growth by accumulation of deutoplasm is followed by two successive cell divisions (**2.12**), the first being *heterotypical*, *reduction division* or *meiosis*, during which the so-called *diploid* or full complement of chromosomes is halved, the second division being *homotypical* and involving no such reduction (p. 98). Unfortunately, both forms of division, intimately linked in the formation of mature ova (and spermatozoa) from their precursors, are, in current practice, grouped together under the term meiosis (which strictly implies a reduction or lessening), a custom which may be misleading. (The equally fundamental nuclear changes involving interchange of chromatid segments leading to *genetic reassortment* or *recombination* are detailed on pp. 42–46).

The primary oöcyte, which is already in the prophase of the first meiotic (true reduction) division, contains the diploid number of chromosomes. It should be emphasized that most, if not all, the primary oöcytes have completed the prophase stage of the first meiotic division before the individual's birth (Manotaya & Potter 1963, Ohno & Smith 1964). Instead of proceeding to metaphase, they enter the so-called *dictyotene* stage, a resting state between prophase and metaphase, which is characterized by a reticular arrangement of chromatin and lasts until the first meiotic division is resumed and completed shortly before ovulation. As this division recommences, the nucleolus disappears, the nuclear membrane disintegrates, the chromosomes appear and become arranged in homologous or *bivalent* pairs at the equator of a spindle radially orientated at the animal pole of the oöcyte. The phenomena constituting *cross-over* of chromatid segments has now occurred. The chromosomes separate and one member of each pair passes centripetally into the central region of the cell, while the others move centrifugally, forming a projection at the animal pole of the oöcyte which becomes separated off as the *first polar cell* or 'body'. Unlike that of the nucleus, the division of the cytoplasm is highly *unequal*, the polar cell carrying with its numerically equal (but constitutionally altered) chromosomal complement an exiguous share of the cytoplasm. The larger cell resulting from this reduction division is a *secondary oöcyte* and it is not fully reconstituted before it divides again. Its haploid complement of chromosomes (22 autosomes + an X sex chromosome) is again rearranged around the equator of a second polar spindle at the animal pole of the cell. A nuclear membrane is not reformed before this second maturation division commences. A similar division may occur in the first polar cell but is abortive, since all polar cells degenerate. At the moment of spindle formation the secondary oöcyte is shed from its mature follicle to enter its uterine tube. The division is only completed after fertilization, as had long been suspected (Allen et al 1930, Hamilton 1944, 1949). *If fertilization ensues*, the haploid group of chromosomes split longitudinally so that each of the resultant two cells receives an equal amount of genetic material, although the chromosome content has been halved. The larger cell is the (sperm penetrated) ovum, which retains almost all the cytoplasm, a small amount only of which enters into the formation of the *second polar cell*. The first polar cell may not undergo division in every instance, but three, theoretically the full complement, have been observed in association with fertilized ova within the zona pellucida (Shettles 1955). Thus, in the human ovary, there is no true, free, non-sperm penetrated *ovum* stage: unfortunately, as mentioned elsewhere (p. 116) the term ovum is widely but imprecisely used for many stages of early development.

The chromosomes of the fertilized ovum now lose their visual identity and appear as a reticulum near the centre of the cell and constitute the *female pronucleus*, around which a nuclear membrane reappears. The cytoplasm shrinks a little so that a distinct circumvitelline space develops, in which the polar cells may be visible. At this stage the mature ovum is characterized by its chromosome content—half the typical number for the somatic cells of the species—and its large size, due to the great accumulation of deutoplasm. Its pronucleus is now ready for union with the male pronucleus, already in the cell, in the last act of fertilization, the formation of a zygote (p. 123). (The above remarks concentrate upon chromosomal and nuclear organization; for the equally essential organization of the *cytoplasm* of the oöcyte prior to fertilization and further development, see p. 98 et seq.).



2.12 Diagram showing the reduction in number of the chromosomes during the maturation of the ovum. The first division is heterotypical, the second homotypical. The latter follow sperm penetration.

The Male Gamete: The Spermatozoön

Gametogenesis in the male exhibits both marked similarities and differences in comparison with the development of ova. During maturation there is the same reduction of chromosomes to the haploid number and genetic recombination, but in the testis there is a continuous formation of spermatocytes and spermatozoa during reproductive life, linked with the enormous number of gametes which are formed. In each ejaculate there are many times more spermatozoa than there are germ cells in both ovaries at their peak content before birth; whereas the latter is of the order of 10 to 12 million, a single ejaculation may contain 300 million spermatozoa (**2.13A-C**), only one of which may fertilize an ovum. (The nomenclature of male gametes is not yet unified officially; spermatozoön, spermatoid, sperm and spermium are all used.)

THE MORPHOLOGY OF SPERMATOZOA

A spermatozoön, or sperm (Fawcett 1961a, 1975, Pikó 1969, Rothschild 1957), is a smaller cell than an oöcyte, highly specialized to reach the latter and to carry to it its own haploid chromosome complement. Its expanded *caput* or *head* contains little cytoplasm and is connected by a short constricted *cervix* or *neck* to the *cauda*

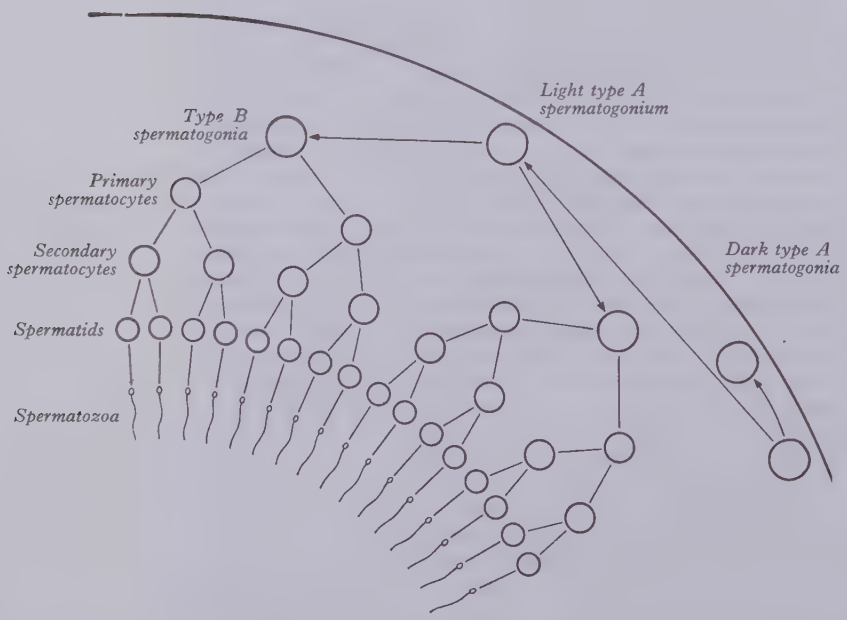
2.13 Diagrams of human spermatozoön showing; A. the head, viewed in its major (left) and minor (right) diameters; B. the middle part and C. the principal part or tail. (By courtesy of Fawcett & Hafez and C V Mosby Company)

or *tail*. The latter is a flagellum of complex structure, usually divided into *middle*, *principal* and *end parts* or *pieces*. Volumetrically the tail much exceeds the head, which varies greatly in different species (Rothschild 1957, Phillips 1975), being ovoid or piriform in man, somewhat flattened at the tip in lateral profile, with a maximum length of about 4 μm and a maximum diameter of 3 μm. The tail, about 45–50 μm in length, displays a greater uniformity between species.

The head (2.13A) is an extreme example of chromatin concentration, consisting largely of a dense and visually uniform nucleus, with a distinct bilaminar nuclear membrane and a bilaminar *acrosomal cap* (head cap), the latter covering the terminal two-thirds of the nucleus and partly derived from the spermatid Golgi apparatus. The acrosomal cap is thin in a human spermatozoön but in other species it is often large and more complex in shape. The acrosome has been shown to contain several enzymes including acid phosphatase, hyaluronidase and a protease (*acrosomase*), which are probably involved in penetration of the oöcyte. The nucleus and acrosome are enveloped in a continuous plasma membrane without intervening cytoplasm (Fawcett & Burgos 1956, Anberg 1957). The chromatin is stabilized by disulphide bonds, as if to protect its genetic content during the spermatozoön's journey (Fawcett 1975). So densely packed is the chromatin that it appears homogeneous even under electron microscopy. It has a strong affinity for basic stains, consisting of about 40% (dry weight) deoxyribonucleic acid and a protein rich in arginine (Daoust & Clermont 1955). It is also resistant to physical stress, e.g. ultrasonication (Henle et al 1938), and to mechanical shear (Mann 1949). Defects in condensation of nuclear material may be visible under light microscopy as relatively clear areas or *nuclear vacuoles*. Attempts to discover structural details in the nucleus in a variety of species, by polarization microscopy, X-ray diffraction and freeze-fracturing techniques, have shown a lamellar structure which cannot yet be equated with chromosomal content. The human Y chromosome has been identified using fluorescence microscopy (see **1.46**).

Between the head and the middle part or body of the spermatozoön is a slight constriction, the *neck*, about 0.3 μm long. In its centre (**2.13**A), close to a shallow recess in the base of the nucleus, is a well-formed centriole, corresponding to the *proximal* centriole of the spermatid from which the spermatozoon differentiated (**2.15**). The axial filament complex (axoneme) is derived from the *distal* centriole, a funnel-shaped *connecting piece* or *basal body* from which the outer fibrils of the tail extend (vide infra). (The *nuclear recess*, or *implantation fossa*, is the region of attachment of the complex filamentary structure of the tail. It is continuous with the postacrosomal part of the nuclear envelope concerned in fusion with the ovum and its nucleus.) A small amount of cytoplasm exists in the neck, covered by a plasma membrane continuous with that of the head and tail.

The middle part or piece is a long cylinder, about 1 μm in diameter and 7 μm long. It consists of an *axial bundle of microtubules (fibrils)* or *axoneme* (the axial 'filament' of light microscopy), surrounded by a *mitochondrial sheath* in which the mitochondria of the spermatid have become arranged in a helical manner (**2.13**B), the whole being enveloped by cytoplasm and a plasma membrane, as in the neck. The axoneme consists of a central pair of microtubules within a symmetrical set of nine doublet microtubules, as in a typical cilium (p. 31), and outside this is a second ring of nine coarser fibres, less symmetrical in arrangement and unequal in size. These external fibres are also less regular in cross-sectional profile (vide infra), showing marked interspecific variations. They appear to be non-contractile despite showing a surface striation. Their function is obscure. The mitochondrial helix exhibits 10–14 turns (Reed & Reed 1948) but this sheath is subject to considerable variation in abnormal spermatozoa (Fujita et al 1970). The number of mitochondria seems excessive in some species, including *Homo sapiens*, when related to the energy requirements of the axonema. Their close relation to the external coarse fibres is suggestive but, as noted, these are apparently not contractile. At the caudal end of the middle part of the cell, immediately anterior to the tail, is an electron-dense body, the *annulus* (**2.15**). The mitochondria of the sheath are much compressed, but it is now certain that they retain their individuality (Fawcett & Ito 1965).



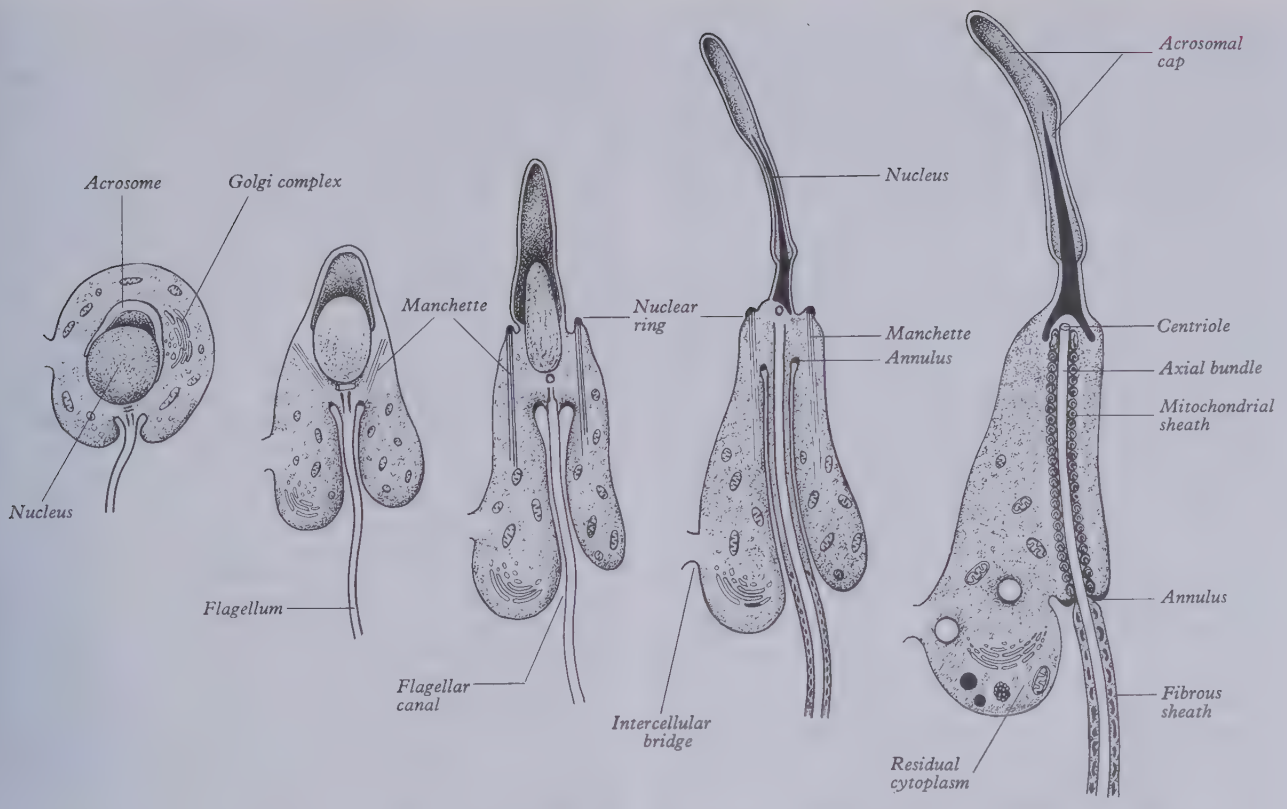
The principal part or tail of a spermatozoön is the motile part of the cell. Being about 40 μm long and 0.5 μm in diameter, it forms the greater part of the spermatozoön. The axial bundle of fibrils and the surrounding array of coarse fibres are continued uninterruptedly from the basal body through the mitochondrial sheath and through the whole length of the tail except for its terminal 5–7 μm, in which the axial bundle alone persists, the coarse fibres ceasing before them. It is only in this terminal *end part* or *piece* that the tail has the typical structure of a flagellum; the coarse fibres are peculiar to mammalian spermatozoa, which also display other specializations. External to the fibres and

fibrils, coarse and fine, is a circumferentially orientated dense *fibrous sheath*, whose individual elements branch and re-unite to form a tight reticulum. A small amount of cytoplasm and a plasma membrane complete the major elements in the structure of the tail. The finer details of the structure have been studied intensively in mammals such as the guinea-pig (Fawcett 1965) and, while there is little doubt that the human spermatozoön is highly similar (Pedersen 1969), the following summary of these findings is based perforce on appearances in the guinea-pig.

MOTILITY OF SPERMATOZOA

In cross-section the tail is oval and tapers caudally and its central area is typical of a flagellum or cilium. The surrounding coarse fibres are obovate or petal-shaped and unequal in size, one being consistently the largest. This is given the number 1 and the rest are numbered from this in a clockwise manner. These fibres are separated into two unequal groups by slender *longitudinal* columns in the fibrous sheath which interrupt its circumferential fibres and extend inwards to meet the coarse fibres numbered 3 and 8. This divides the interior of the tail into *major* and *minor compartments*, containing respectively coarse fibres 4, 5, 6 and 7, and 9, 1 and 2. The plane through the two columns also passes through the central pair of the axial bundle of fibrils and can be used as a reference datum for other structural details. For example, the transverse diameter of the head has been considered to lie at right angles to the plane of the columns, but it has now been shown in the guinea-pig that the angle between the two planes is 20–30 degrees less than a right angle (Fawcett 1968). Such details may be instrumental in elucidating the motile activities of the tail. It is now generally accepted that the tail executes undulatory movements in one plane (p. 32), but it has also been suggested that a helical component is superimposed upon this, there being perhaps two separable mechanisms, one involving flat waves travelling along the tail, the other associated with torsional activity (Gray 1958, Bishop 1962, Lindahl & Drevius 1964).

The latter variety of movement has been linked with the unequal size and distribution of the coarse fibrils; it has also been suggested that the central pair of fine fibrils act as axial stiffeners. The asymmetry of the spermatozoan head has also been invoked to explain supposed helical movement. However, it has to be admitted that the full details of the mechanisms of spermatozoal motility are unknown.



2.14 Diagram showing the stages in the maturation of the spermatozoön. The division of the primary spermatocyte is heterotypical; the remaining divisions are homotypical. Some have described a further division of spermatids in the human testis, but this is unconfirmed—see text for further details and compare with illustration **8.194**.

Some further details deserve mention. The dense outer fibres have been shown to exhibit an oblique or helical striation in replicas of dried whole mounts of rodent spermatozoa (Phillips & Olson 1975). The central axoneme (**2.13**), consisting of the usual ciliary pattern of nine double fibrils or 'doublets', has been intensively studied (see p. 31 and Fawcett 1975 for survey of literature). Each fibril is a microtubule, itself constructed of a regular number of protofibrils. Protein bridges connect adjoining doublets at regular intervals and radial links extend centrally to the central doublet of the axoneme (p. 31).

Maturation of spermatozoa (**2.14**, 15) is a complex process which has received much attention. Spermatozoa show little independent motility while still in the male genital tract, though when removed from the epididymis they may display circular swimming movements or even directive movements if taken from the cauda epididymis near the beginning of the ductus deferens (Blandau & Rumery 1964). From the results of artificial insemination of rabbits with spermatozoa from the caput and cauda of the epididymis, it has been postulated that some form of maturation process takes place in this organ, during which the spermatozoön attains its specific pattern of motility (Gaddum 1968). Apart from these incomplete activities, spermatozoa are largely transported through the genital tract by ciliary action, by fluid currents set up by localized secretion and absorption and by muscular contractions. Associated with the maturation of spermatozoa in the genital tract in some mammals is the extrusion of a small mass of cytoplasm, the *kinoplasmic droplet* or *residual body*, which migrates backwards along the surface of the head and middle part of the spermatozoön before disappearing. It consists of membrane-enclosed cytoplasm containing fine tubules and vesicles (Bloom & Nicander 1961, Guraya 1963). Human spermatozoa have not been shown to undergo any demonstrable structural changes during passage through the epididymis, but there is evidence of an increase in sulphide cross-linking between proteins (Bedford & Calvin 1974). Moreover, restorative surgery after vasectomy indicates that at least part of the human epididymis is essential for motility (Bedford et al 1973).

As soon as they are ejaculated the spermatozoa display their full pattern of motility. The precise factors which trigger off these movements enabling human gametes to travel at a rate of 1.5–3 mm/min are not yet clear; but the other constituents of semen, derived from the epididymis and testis and from the seminal vesicle and prostate, are generally considered to exert an activating influence. The motility varies greatly in different species, disappearing in minutes in some fish but usually persisting in mammals for hours and even days when introduced into the female genital tract. Exact figures for its persistence in the human female are uncertain and are of doubtful value, since it is likely that, as in other mammals, human spermatozoa quickly lose their potency for fertilization, although still motile. They have been recovered in a motile state in human cervical mucus several days after insemination and will survive in this condition for as long as 7 days when implanted into such secretions in vitro. These survival periods may, however, be of little significance, in view of the speed with which spermatozoa reach the infundibulum of the uterine tube and the brevity of their fertilizing power. Spermatozoa have been shown to reach their tubal destination in a manner of minutes after ejaculation in some mammals and experiments on recently excised human uteri and tubes indicated a time of about 70 minutes (Brown 1944). The conclusion must be that factors other than their own motility are responsible for the transport of spermatozoa from their site of deposition in the vaginal fornix to the ovarian end of the uterine tube and there is considerable evidence that contraction of the uterine and tubal musculature is responsible (Bickers 1960).

It is not usually recognized that a spermatozoön must be adaptable to a wide range of environments in its long journey from the seminiferous tubule to the uterine tube, encountering major changes in the electrolyte and non-electrolyte constituents in the fluids with which it is successively surrounded. Nevertheless, a collectively vast amount of observation and experiment has been recorded in connection with the effects of the multitude of factors, both physical and chemical, in the natural media involved regarding the behaviour of these cells and particularly their motility and

2.15 Differentiation of the spermatid (guinea pig), from left to right. Note nuclear condensation and elongation, appearance of the *manchette* and fibrous sheath, caudal movement of the annulus, and development of the mitochondrial sheath. (Modified after Fawcett in Bloom & Fawcett 1975)

fertility (Nelson 1967, Mann 1967); e.g. the effects of respiratory gas tensions, reaction, various ions, antibodies, vitamins, hormones, inhibitory substances, temperature, different forms of radiation and other factors have been studied in remarkable detail, for which monographs and original papers must be consulted. The effects of low temperatures in preserving spermatozoa and perhaps prolonging their vitality have attracted much research in connection with artificial insemination, both in stock-breeding and in infertile human marriage. Mammalian semen, including that of human beings (Parkes 1952), can be stored at temperatures of about $-70°C$ for weeks and even months, the motility and fertility of its suspended spermatozoa reappearing when the suspension is unfrozen. However, storage of human semen presents difficulties (Polge 1957).

Seminal plasma, the fluid component of *seminal fluid* or *semen*, contains a remarkable array of substances, including muco-proteins, a dozen or more identified proteolytic enzymes, the bases spermine, glycerylphosphorylcholine and ergothioneine, a group of organic acids called prostaglandins (which have pharmaco-dynamic actions on the uterus and smooth muscle in general), acids such as citric, ascorbic, uric, lactic and pyruvic, and the sugars sorbitol, inositol and fructose. The fructose added to the fluid by the secretion of the seminal vesicle is an essential substrate in the anaerobic glycolysis by which spermatozoa survive the low oxygen tensions existing in semen itself and in the female genital tract. Prostaglandins are now believed to play a role, perhaps by modulation of neurotransmitter release, in the contraction/ relaxation activity of the non-striated muscle in the testicular capsule and interlobular septa adjacent to the seminiferous tubules (as suggested by von Euler 1936). Consult Ellis & Hargrove (1977) for literature.

CAPACITATION

After ejaculation into the female, the spermatozoa undergo the final step in their maturation, a process known as *capacitation*. It has been shown that spermatozoa are not able to fertilize ova until they have been within the genital tract of the female for a period of time, usually of hours but varying with the species (Austin 1951, Chang 1951, Austin & Walton 1960). The mechanism of capacitation, whereby the spermatozoön is activated to enter and fertilize the ovum is still uncertain. A confusing array of findings with regard to the interactions of the two gametes immediately prior to this event have been described, unfortunately in widely different vertebrates and invertebrates. It is probable that hyaluronidase hastens the separation of corona radiata cells from the ovum, and thus facilitates the spermatozoön's approach to the zona pellucida. The origin of hyaluronidase from the acrosomal cap is associated with subsequent loss of the cap (Leuchtenberger & Schrader 1950), at least in part (Austin & Bishop 1958). 'Capacitated' spermatozoa observed in the zona pellucida or perivitelline space have invariably lost most of their acrosomal material (Leuchtenberger & Schrader 1950, Pikó & Tyler 1964) and it is clear that capacitation is some process of activation which precedes penetration. Antigenic 'coating' substances on the surface of mammalian spermatozoa, including those of man (Weil 1965), have been recorded and it is possible that an immunological reaction may be involved. Interaction between a *fertilizin*, derived from the ovum or elsewhere in the female genital tract, and a spermatozoan *anti-fertilizin* has been associated with capacitation, but the interrelationship between the various events is still sub judice, as comprehensive reviews show (Metz & Monroy 1969, Chang & Hunter 1975). Capacitation may be regarded as the terminal event of maturation of the spermatozoön, prior to actual fertilization, for which it is preparation.

Spermatogenesis

This is the complex series of changes by which spermatogonia are transformed into spermatozoa, similar in some general features —particularly in reduction division and genetic recombination —to the evolution of ova from oögonia, but differing in the more profound morphological metamorphosis involved. Spermatogenesis may, for convenience, be divided into three phases. During the first, **spermatocytosis**, spermatogonia proliferate by

mitotic division to replace themselves and to produce primary spermatocytes. In the second phase, **meiosis**, two successive maturation divisions, the first a true reduction division as in the case of the oöcyte, produce *secondary spermatocytes* and then *spermatids*, all with the haploid number of chromosomes. In the third phase, **spermiogenesis** or **spermateliosis**, the spermatids become spermatozoa; it is during this period that the greatest visible transformation of structure occurs.

SPERMATOCYTOSIS

During embryonic, fetal and perhaps also early post-natal life, *primordial germ cells* (p. 254) in the tubules of the testes divide mitotically to produce spermatogonia (Witschi 1948, 1951, Mintz 1960), from which, at and subsequent to puberty, the development of spermatocytes and spermatozoa commences. It is the cyclic divisions of these cells, the details of which have attracted much attention in recent years, that form the starting place for production of the huge numbers of spermatozoa discharged into the seminal plasma to form the seminal fluid. The series of changes involved do not occur in a synchronous manner in all seminiferous tubules at the same time, although they do in considerable parts of an individual tube, with variations in different mammalian species, including mankind. As the cycle of change from spermatogonia to spermatids proceeds at any particular locus in a tubule, a succession of varying cell associations can be observed and measured; the process is termed the *cycle of the seminiferous epithelium* (Clermont & Leblond 1955) (p. 1427).

In man, three types of spermatogonia can be distinguished and are termed the *dark type A*, *light type A*, and the *type B* (Clermont 1963). Spermatogonia are large rounded cells, the three types showing little difference in size or in their cytoplasm, but the A series, light and dark, are distinguishable by their nucleoli which are eccentric and attached to the internal aspect of the nuclear membrane. The type B spermatogonia have a more constantly spherical nucleus, in which the nucleolus is central in position. The dark type A is distinguished from the pale type A by its dark nucleoplasm and a large pale-staining nuclear vacuole. The dark type A is now considered, largely on morphological grounds, to be the progenitor or stem spermatogonium (Clermont 1963). Such cells, peripherally situated in the tubule and often in pairs, divide mitotically at the beginning of a seminiferous cycle, some to produce two further dark type A spermatogonia, thus replenishing the complement of stem cells, others into two light type A spermatogonia. Mitotic division of a light type A spermatogonium furnishes two type B spermatogonia. On theoretical grounds, it is probable that in man a larger series of spermatogonial divisions may occur, so that the ultimate spermatocyte progeny of a stem cell may in fact be more numerous than is here indicated (Clermont 1966). Each type B spermatogonium then divides again mitotically into two *resting primary spermatocytes* or preleptotene spermatocytes. The dark type A cells remain arranged along the basement membrane of the tubule, whereas the pale type A, type B spermatocytes and the spermatids derived from them lie closer to the lumen, into which the free end-product, spermatozoa, will be discharged (**8**.191). These events constitute spermatocytosis, which is now followed by meiosis.

MEIOSIS OF SPERMATOCYTES

The primary spermatocytes soon enter the prophase of the *first maturation (reduction) division*, which is prolonged over several days through the successive stages of leptotene, zygotene, pachytene, diplotene and diakinesis (p. 44) (Clermont 1963, 1966). As the nuclear membrane now disappears in metaphase, the bivalent chromosomes are arranged on the equatorial plate, separating into two groups and moving to opposite poles in anaphase, followed in the usual manner by reformation of the nuclear membranes in telophase and division of the cell. These three phases occur much more rapidly than prophase and during the whole process there is a considerable increase of nuclear and cytoplasmic material, bringing the primary spermatocyte back to a size comparable with that of the stem spermatogonium. The two *secondary spermatocytes* thus formed contain, of course, the haploid number of chromosomes, this *first* maturation division being the one which is strictly speaking *meiotic*. After a brief interphase each secondary spermatocyte now undergoes a *second maturation division*, which is by mitosis. The two resultant cells are spermatids and with their formation the phase of meiosis may be considered to end, being followed by their maturation into spermatozoa (spermiogenesis). Theoretically each primary spermatocyte may be expected to produce four spermatids but in mankind the yield is less than this, presumably because some spermatocytes degenerate during maturation.

Criticism of the traditional view that spermatids do not divide has been expressed (Roosen-Runge 1952) and tentative corroboration of this came from electron microscope and other studies (Fawcett et al 1959, Fawcett 1961b). These interpretations have subsequently been subjected to critical rescrutiny. Electron microscopy has also shown that the division of the cell body (cytokinesis) in spermatocytes may be delayed, so that fine cytoplasmic bridges remain interconnecting such cells even beyond the stage of the next nuclear division (Fawcett et al 1959). These bridges, which may remain in the case of spermatids until a late phase in their transformation into spermatozoa, are short, devoid of spindle fibres or other remnants and are enclosed in annular thickenings of the plasma membrane. They probably permit interchange of organelles, may be involved in synchronization of development and may contribute to the mechanical stability of the spermatid-Sertoli cell complexes. Such cytoplasmic interconnection may also help to explain the formation of multinucleated masses when the seminiferous epithelium is injured, as in making teased preparations. Except where connected together by bridges the developing spermatids are very closely associated with Sertoli cells, whose processes are insinuated between them.

During the differentiation of some rodent spermatids a fusiform conglomeration of microtubules, the 'spindle-shaped body', appears between the annulus and fibrous sheath. The same structure has been observed in human spermatids; its functional significance is uncertain but an association with the development of the fibrous sheath has been suggested (Pedersen 1969, Wartenburg & Holstein 1975).

SPERMIOGENESIS

During *spermiogenesis* (spermateliosis), spermatids go through a complex series of changes to become spermatozoa (**2**.15) and this metamorphosis has been studied in particular by light microscopy, using preparations stained by the periodic-acid Schiff technique (PAS) (Leblond & Clermont 1952, Clermont 1963). Electron microscopy has confirmed these observations (Fawcett & Burgos 1956). In the newly formed spermatid the Golgi apparatus (idiosome-Golgi complex) is large but otherwise typical, consisting of flattened membrane-enclosed vesicles, usually stacked in a parallel array, together with rounded minute vesicles which are possibly nipped off from the flattened variety, the whole complex being juxtanuclear. A few electron-dense homogeneous *paracrosomal granules*, which are intensely PAS-positive, develop in separate Golgi complex vesicles and the latter coalesce into a single large *acrosomal vesicle*, the separate granules fusing into a single spherical *acrosomal granule*. This vesicle, with its granule attached to its juxtanuclear wall, becomes adherent to the nuclear membrane over an area which will be anterior or 'leading' in the maturing spermatozoön. The granule flattens, but its central part bulges slightly into a shallow depression in the nucleus, which becomes progressively more ovoid (**2**.15). By successive absorption of further vesicles from the Golgi complex, the material in the acrosomal vesicle increases and the vesicle expands as a bilaminar cap over the anterior two-thirds of the nucleus. Coincident with these changes, the spermatid elongates and the Golgi complex and associated cytoplasm migrate to the posterior part of the cell, bringing the external wall of the acrosomal vesicle into contact with the plasma membrane at the anterior aspect of the cell. The acrosomal granule now spreads out between the layers of the vesicle until it is uniformly distributed and no longer a localized structure. When the centrioles begin to separate (vide infra),

microtubules develop forming an inverted conical array, *the manchette*, perinuclear in position and expanding from the region of the acrosomal cap; its precise significance is not yet explained.

In the early spermatid the nucleus is of relatively low density, containing finely dispersed granules which aggregate into larger and denser masses as development proceeds. These finally agglomerate into a homogeneously dense mass, usually containing one or more regions of low electron-density and variable in size, position and shape—the *head vacuoles* (Fawcett & Burgos 1956). Correlated biochemical and ultrastructural studies indicate a considerable variation in the chromatin content of spermatozoa, this heterogeneity being more marked in mankind than other primates or rodents; it probably indicates a lower fertilizing power (Bedford et al 1973).

The two centrioles are near the posterior aspect of the nucleus from an early stage. One remains unmodified; the other becomes modified into the basal body of the spermatozoon (see p. 119). The anulus arises close to the latter (the distal centriole) but its origin from it is doubtful. The axial fibrils begin to develop from the basal body, extending 'caudally' into the cytoplasm of the cell as it becomes progressively more elongated. Only the proximal part of the bundle of fibrils remains surrounded by cytoplasm, to form the definitive middle part of the spermatozoön. In this, the mitochondria of the spermatid assemble to form the helical sheath. The detailed development of the fibrous sheath of the tail part is unknown. These changes complete what might be called the period of 'organogenesis' of the spermatid, whose further development into a spermatozoön is largely concerned with enlargement of the tail.

During the final maturation of spermatids into individual spermatozoa some of the cytoplasm is detached as a *residual body*. This contains some mitochondria, Golgi membranes and vesicles, RNA particles, lipid granules but of course no nucleus. Residual bodies are prominent when spermatozoa are being released into their tubule. They are engulfed by Sertoli cells, which accounts for the increase in lipid content of these cells at this period (Lacy 1960).

As already stated, there is a close relation between developing spermatids and Sertoli sustentacular cells. The spermatogonia are external or basal to the Sertoli cells in the tubule and the spermatocytes which develop from the former are embraced by Sertoli processes; the spermatids are even more deeply embedded in the supportive cells. (For further details see p. 1425.) These associations have been regarded as symbiotic, a single sustentacular cell being grouped with several spermatids. The Sertoli cells are phagocytic and absorb not only residual bodies but also degenerating germ cells. They have been attributed a metabolic role and may form, or at least transmit, hormones involved in the maturation of germ cells. Until released into the seminiferous tubule, spermatozoa are very firmly held by the Sertoli cells. Their release is sometimes termed *spermiation* and is followed by rapid translation of the spermatozoa to the epididymis.

Spermatogenesis is an orderly and complex sequence of events, with characteristic time constants and cell associations for each mammalian species. The details of these in the human testis will be discussed with that organ (p. 1427).

Fertilization—Union of the Gametes

It has become customary to speak of an ovum as being fertilized by a spermatozoön and, in view of the apparent passivity of the former and the extreme specialization of the latter for motility, it is tempting to consider the ovum as being merely stimulated to further development, in which the part played by the sperm nucleus may be consequently overlooked. It is of interest to note that in some of the earliest organisms to propagate by sexual reproduction, such as primitive algae, the gametes are all alike, except presumably in their genetic content, whether chromosomal or cytoplasmic. The profound differences which have nevertheless evolved in the gametes of the great majority of plants and animals—vertebrate and invertebrate—appear to depend on a conflict between adaptation for carriage of nutriment and improvement in motility. The effectiveness of *syngamy*, the bringing together of two gametes to produce a new individual, has been furthered by the development of this marked dimorphism between them. This dimorphism has, in turn, entailed the evolution of equally profound differences between the individuals producing the two kinds of gametes, males and females, in regard to the organs concerned in bringing together these dissimilar gametes and ensuring the development of their fused product, the *zygote*, until able to undertake a separate existence. Strictly speaking, therefore, the expression 'fertilized ovum', insofar as it appears to assign a merely stimulatory role to the spermatozoön, is misleading and hence undesirable. However, it should be noted that almost all the cytoplasm of the zygote is derived from the ovum and, as indicated elsewhere (p. 98 et seq), its organization has a profound morphogenetic significance.

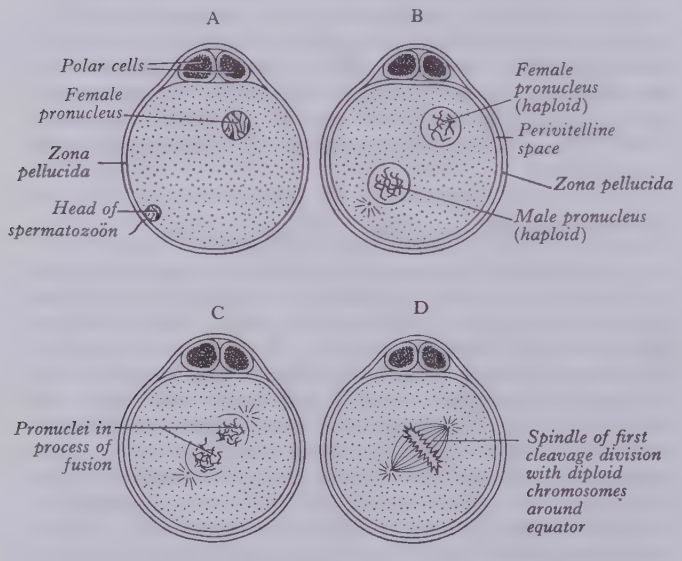
The occurrence of parthenogenesis in a very small fraction of animals, mainly invertebrates, does not invalidate the fact that *fusion* of two gametes, from separate parents, is the central feature of reproduction in most animals and plants (Tyler 1967b). There is also abundant evidence that the critical element of this fusion is the conjunction in one cell of two haploid complements of the particular species' chromosomes, these being sufficiently identical to entail the development of a viable new unit in the species. Differences involving a number of genes, arising during the phenomena of crossover and segregation of the chromosomal material or (very rarely) by sporadic mutation, are thus also able to express themselves in individual variation, with all its implications in evolutionary reactions between the species and its environment (p. 96 et seq).

Nevertheless, it would be equally misleading to regard the union of the ovum and spermatozoön as little more than restoration of the diploid number of chromosomes, because other events, of equal significance in the further development of the zygote, also occur. The ovum immediately resumes and completes its second maturation division; without fertilization this does not occur and the ovum begins to degenerate within 24 hours (Allen et al 1930, Hamilton 1949). A second polar cell is thus produced and, if the first has divided as it sometimes does in human beings (Shettles 1955), three may be present in the circumvitelline space. In many mammals, and probably in mankind, what is apparently a small excess of nutritive yolk or deutoplasm is extruded from the ovum into the same space after fertilization (*deutoplasmolysis*). This event is followed at once by segmentation, which is also dependent upon fertilization for its initiation.

(For overall reviews on mammalian reproduction see Austin & Short 1984.)

ACTIVATION AND SEX DETERMINATION

The phenomena which ensue upon the entry of the spermatozoön can thus be conveniently divided into those described in the preceding paragraph, which together constitute *activation*, and those concerned in the intermingling of the separate hereditary influences of the two parents and associated with the fusion of the nuclei of their gametes, a process described as *amphimixis*. The latter really falls within the scope of genetics, but a particular aspect—the determination of the sex of the zygote—may be mentioned here, because the actual determination is in a sense effected as soon as a spermatozoön has entered the ovum. In approximately equal numbers, spermatozoa of many animal groups, including mammals, contain either an X or a Y chromosome, whereas mature ova contain only an X chromosome. If both gametes contain an X chromosome the resultant individual is female; but when the spermatozoön contains a Y chromosome, the cells of the new individual will each contain an X and a Y chromosome, which is characteristic of the male. This may not, however, be the only factor involved in the determination of sex (p. 260).



UNION OF THE GAMETES

In mammals, generally only one spermatozoön pierces the vitelline membrane to enter the ovum, although numbers usually penetrate the corona radiata and even the zona pellucida. Enzymes of acrosomal origin cause dispersal of the cells of the corona, thus opening the route to the zona. Though some form of

chemotaxis, as exists in the syngamy of plant gametes, has been claimed for some animals, no clear evidence for this has been recorded (Tyler & Bishop 1963). The mechanism of union of the ovum and spermatozoön has been studied extensively in all its stages. The primary reaction between the gametes appears to be of an immunological nature, which would account for the exclusive specificity of fertilization. Metchnikoff (1900) and contemporaries first reported the antigenicity of spermatozoa and a species recognition system, dependent upon an agent in the ovum, a 'fertilizin', was identified surprisingly early (Lillie 1913). The sequence of the reactions of this with spermatozoan antifertilizins (associated with the plasma membrane) have attracted much attention (Metz & Monroy 1967, Bedford 1977). Such antibody–antigen interaction appears not only to be essential to contact between the gametes but also to initiate the subsequent entry of the spermatozoön by the lytic action of enzymes derived from the acrosome (see p. 119, Austin & Bishop 1958, Srivastava et al 1965). This *zona-lysin* enables the spermatozoön to pass through the zona pellucida into the circumvitelline space and to come into direct contact with the oöcyte. Penetration is followed immediately by permeability changes in the zona which effectively block the subsequent entry of other spermatozoa (Austin & Braden 1956). The *zona reaction*, as this phenomenon is called, is however not a complete block to polyspermy; two or more spermatozoa may pass *simultaneously* through the zona, a not uncommon event in the case of some rodents, seemingly also a possibility in man. The result is one of the types of *triploid* zygotes that may arise. Further, there is evidence of a second line of defence, the *vitelline block*, associated with the plasma membrane of the ovum. Both blocking mechanisms may depend upon discharge of the contents of *cortical granules*—electron-dense particles subjacent to the plasma membrane—into the circumvitelline space (Szollosi & Ris 1961, Szollosi 1967). However, recent evidence derived from in vitro fertilization of *human* ova suggests that the zona pellucida is, under these conditions, a complete block to polyspermy (Soupart & Strong 1975). Electron microscope studies suggest that the actual entry of the spermatozoön into the ovum is effected by fusion of their plasma membranes, that of the former being left on the surface of the ovum (Szollosi & Ris 1961, Szollosi 1967). Once within the ovum, the head and neck of the spermatozoön become detached from the middle part and tail which soon disappear, their significance in fertilization, if any, and their ultimate disposal being obscure. For a review of the uncertainties and problems in regard to the mechanisms of fertilization consult Bedford (1977) and for ultrastructural details see Austin (1968). The occurrence of auto- and iso-immune anti-spermatozoal antibodies has been exhaustively surveyed.

The second maturation division of the ovum is now completed, with the extrusion of a second polar cell into the circumvitelline space, which has become opened up by shrinkage of the oöplasm. Failure of extrusion of the second polar cell is another mechanism of formation of a *triploid* zygote. Meanwhile, the head of the spermatozoön swells to become the *male pronucleus*, being at this juncture morphologically indistinguishable from the *female pronucleus* (2.16). Both nuclei move to a central position in the ovum and each duplicates its DNA content. Meanwhile, two centrioles appear, probably derived from the anterior centriole of the spermatozoön. The chromosomes become organized from each pronucleus and arranged on the spindle between the centrioles and, since 23 are contributed from each, the typical diploid human number is now re-established. The degree of fusion of the two pronuclei before the appearance of the chromosomes varies in different species but usually the chromosome groups remain separate during prophase. They now split longitudinally and the resultant halves segregate as in an ordinary mitosis. The two sets, each consisting of the diploid number of chromosomes with the normal amount of DNA, retreat to opposite poles of the cell, on whose surface a deepening groove develops as the zygote enters the next phase in its development, *cleavage* or *segmentation* (p. 100 and below).

The chronological elements in the events of the human fertilization are still only inexactly known.

2.16 The process of fertilization in a mammalian ovum. Diagrammatic (After Sobotta). The female pronucleus and second polar cell, shown in A, are only formed after fertilization.

PARTHENOGENESIS

It is generally agreed that a mature ovum contains within itself all the material potentiality to form a new being. Apart from the *natural parthenogenesis* which occurs in some invertebrates, this potentiality of the ovum to develop further without fertilization can be released experimentally by a variety of mechanical, chemical and physico-chemical means, such as pricking, exposure to alteration of tonicity and reaction in the surrounding medium, treatment with various kinds of radiation, etc (Beatty 1957, 1967). Such *artificial parthenogenesis* has been studied in a wide range of invertebrate and vertebrate animals, including mammals. Such offspring rarely survive beyond the embryonic stage but viable young have occasionally been obtained, e.g. in the case of rabbits. The particular interest of these parthenogenetic phenomena in vertebrates is that they illustrate the fact that, apart from its normal necessary chromosomal contribution, the spermatozoön plays little part in embryogenesis. However, there is some evidence that the plane of bilateral symmetry is determined in some animals by the direction and place of entry of the spermatozoön. Nevertheless, both in this determination and the early polarization of the zygote, there must be a considerable flexibility, because the blastomeres resulting from its early segmentation are 'totipotent', in the sense that they may separate to form complete embryos, as in the formation of uniovular twins (but see p. 158).

EARLY DEVELOPMENT OF THE HUMAN EMBRYO

CLEAVAGE

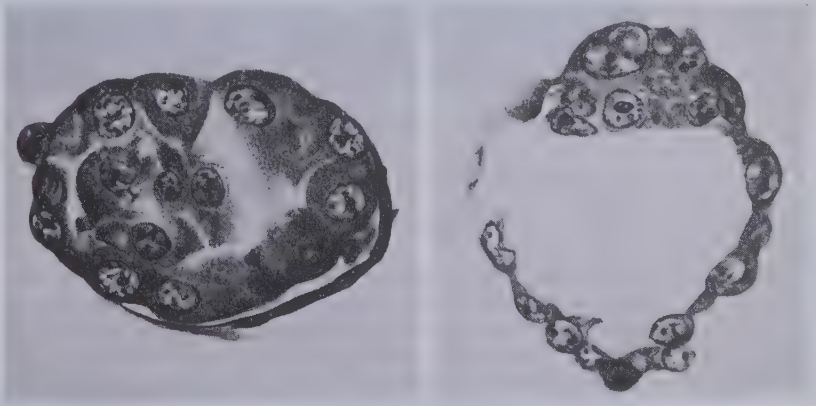
As we have seen (p. 100), cleavage is the process whereby a *unicellular* fertilized ovum with an exceptionally large ratio of cytoplasm to nucleus is transformed into a *multicellular* mass of *blastomeres*, each of which approximates to the ratio found in general somatic cells. For example, in the sea urchin, volumetric ratios are 550:1 at the onset of cleavage, reducing to 6:1 in individual blastomeres at its termination (Brachet 1960, 1965, 1967, et seq.). Comparative studies show that cleavage is essentially a series of mitotic divisions with little overall cytoplasmic growth but with a dramatic synthesis of nuclear DNA; also cytoplasmic

factors important in subsequent development are differentially parcelled in the cytoplasm of the resultant blastomeres (p. 109).

As each generation divides, the nuclear population is, of course, doubled, preceded by replication of chromosomal DNA as in any other mitotic division (p. 42). The precursors for this replication are dispersed in the oöplasm of the zygote which is rich in various RNAs (p. 39); *cytoplasmic* DNA is contained in both mitochondria and yolk platelets, whilst the oöplasm also contains abundant low molecular weight nucleic acid precursors. The relative contributions from these different sources to the processes of replication, transcription and translation remains uncertain. Similarly, the interesting question of whether cytoplasmic nucleic acids are wholly broken into unitary molecules before incorporation into nuclear DNA, or are utilized in more substantial segments bearing coded genetic information, remains unresolved. (For earlier comparative reviews on the synthesis and transformations of nucleic acids during embryogenesis, consult Brachet & Quertier 1963, Brown 1966, Tyler 1967a, Gurdon 1968, Brachet 1969.)

Synthesis of *new* ribosomal RNA is low during cleavage; but some protein synthesis continues, particularly that related to the formation of microtubular spindles of mitoses, the production of increasing areas of cell membrane and additional DNA polymerases. The foregoing analyses, until recently, applied mainly to observations on non-mammalia and, for technical reasons, mammalian data were less plentiful and lacked the same precision (see Jones-Seaton 1950, Dalcq 1954, Austin 1961, 1965, 1968). However, detailed analyses on mammalian oöcytes and during early embryogenesis are now accumulating (Herbert & Graham 1974, Church & Schultz 1974).

Relatively few specimens of the earliest stages of human development occurring in the normal environment of the female genital tract were recovered and studied (Hertig et al 1954, 1956) —including one 2-cell stage, a few, possibly abnormal, up to the 12-cell stage, and one presumed normal 12-cell stage (vide infra). More recently a 7-cell stage has been recovered and analysed (Avendano et al 1975).



Successful attempts at the in vitro fertilization of mature mammalian ova and their subsequent culture up to the blastocyst stage have been made since the early 1930s (Lewis & Hartman 1933, Mulnard 1964, 1965). Early development was recorded using time-lapse cinematography, and over the last 25 years, similar techniques have been applied to human ova (Shettles 1953, 1955, 1958). Techniques of *in vitro fertilization* (IVF) of human ova have been greatly improved (Edwards et al 1965, 1969). Preovulatory oöcytes, recovered by laparoscopy in women under the control of gonadotrophins (Steptoe & Edwards 1970), have often been fertilized and cultured to the 8- and 16-cell stages and beyond (**2.20**). Reintroduction of cultured morulae into the uterine cavities of women with pathological uterine tubes and in whom pregnancy would otherwise be impossible (Steptoe & Edwards 1976), although initially unsuccessful, resulted in the first full-term birth late in 1978. This clinical approach is now being pursued in a number of centres with limited (< 20%) success. (Nevertheless, such techniques often result in multiple potentially viable zygotes and their fate, whether alternative clinical action, scientific observation, experimentation, or rejection is still provoking much ethical, philosophical and theological debate, despite the obvious clinical advantages. Recently (Asch et al 1984, 1985, Lim-Howe et al 1987) success with a new complementary/alternative procedure to IVF has provoked widespread interest; namely *gamete intrafallopian transfer* (GIFT). Partner selection is critical; female—under 38 years, confirmed tubal patency, regular ovarian cycles; male—sperm > 20 million per ml, > 40% motile, < 40% abnormal; both —post-coital test + ve, no antisperm antibodies in either. After hormonally induced superovulation, oöcytes are recovered and suitably prepared; similarly a sperm sample. Two oöcytes followed by a measured volume and concentration of sperm are then passed via a cannula into the ampullary lumen of each tube. Fertilization occurs (success rate > 40%) in this natural environment. (Mr J Erian, personal communication)

Fertilization normally occurs in the ampullary uterine tube, probably within 24 hours of ovulation. After completion of the second maturation division the zygote divides into two blastomeres of approximately equal size (**2.17**). (Human cleavage may

2.17 Early human cleavage. Two-blastomere stage recovered from the uterine tube. A polar cell is seen at each end of the cleavage plane. Magnification × *c.*700. (Hertig et al 1954.)

be designated *total, equal* and *indeterminate*, see p. 100). The human 2-cell stage recorded was recovered from the middle of the uterine tube 60 hours after a fertile mating (**2.17**), the menstrual pattern, however, indicating an age of 36 hours. By repeated division and subdivision of the blastomeres a mulberry-shaped mass of cells, hence termed the *morula*, is formed (**2.20D–F, 21**). Intense activity of their cytoplasm is evidenced by the constant streaming of contained granules, and the individual blastomeres are not motionless, but restlessly alter their positions relative to one another and reorientate themselves within the zona pellucida. The human morula is believed to enter the uterus at about the 8- to 12-cell stage and about 72 hours after fertilization. The four human morulae of 5–12 blastomeres which are recorded, however (all believed to have been abnormal), were recovered from the uterus on the fourth day after presumed ovulation and fertilization. The 12-cell stage, assumed to be normal, consisted of 11 small peripheral cells which surrounded a larger centrally placed one, indicating that during the earlier cleavage divisions two different groups of cells emerge and the earliest visible signs of such differentiation has now been claimed even at the 7-blastomere stage (Avendano et al 1975). Of these diverging cell lines one will form the embryo and the other will form the nourishing and protective membranes by which it is surrounded. The former is composed of centrally sited larger cells, few in number, which divide more slowly and retain to a high degree the developmental potential of the fertilized ovum, termed the *formative cells*; the latter consists of smaller and more numerous superficially placed

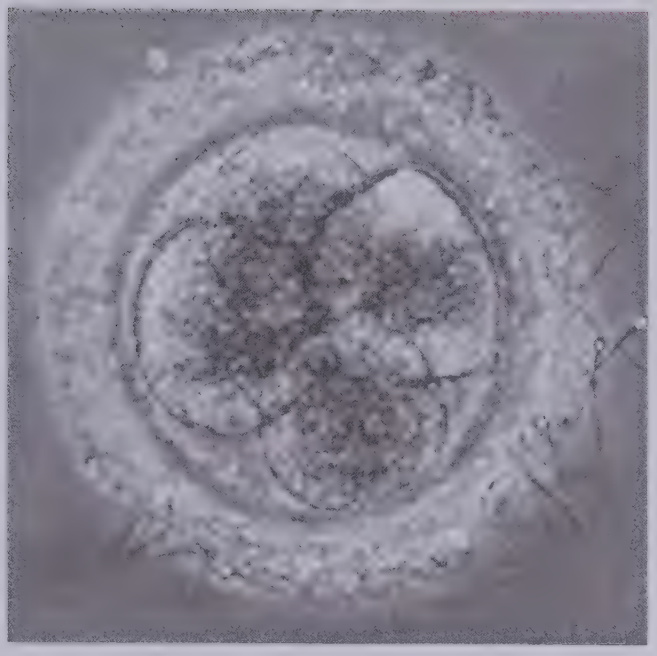
cells, which divide more rapidly as they differentiate into progenitor *trophoblastic cells*. (For possible *causal mechanisms* leading to emergence of distinctive *formative* and *trophoblastic cell lines*, see Herbert & Graham 1974.)



If the first two blastomeres are separated, each is potentially capable of continuing development into a complete embryo—it has been claimed that 25–30% of instances of monozygotic twinning in man follow separation at this stage. It has been demonstrated experimentally in the mouse (Tarkowski 1961, 1963, Mintz 1962, 1964, 1965, 1970) that if one of the first two blastomeres is killed, the remaining one can continue to develop into a small but complete embryo. However, blastomeres isolated at the 4- or 8-cell stages often fail to continue normal development and are limited to the formation of simple *trophoblastic vesicles* which contain no inner cell mass and are therefore devoid of formative cells (Tarkowski 1965). Conversely, from the 2-cell to the morula stage, two cleaving zygotes may be fused, development proceeding to the formation of a single 'giant' embryo (2.4).

THE BLASTOCYST

Before the zona pellucida disappears, fluid, either secreted by the trophoblastic cells or derived from the uterine lumen, begins to accumulate within the morula. (Cell death of a number of deeply

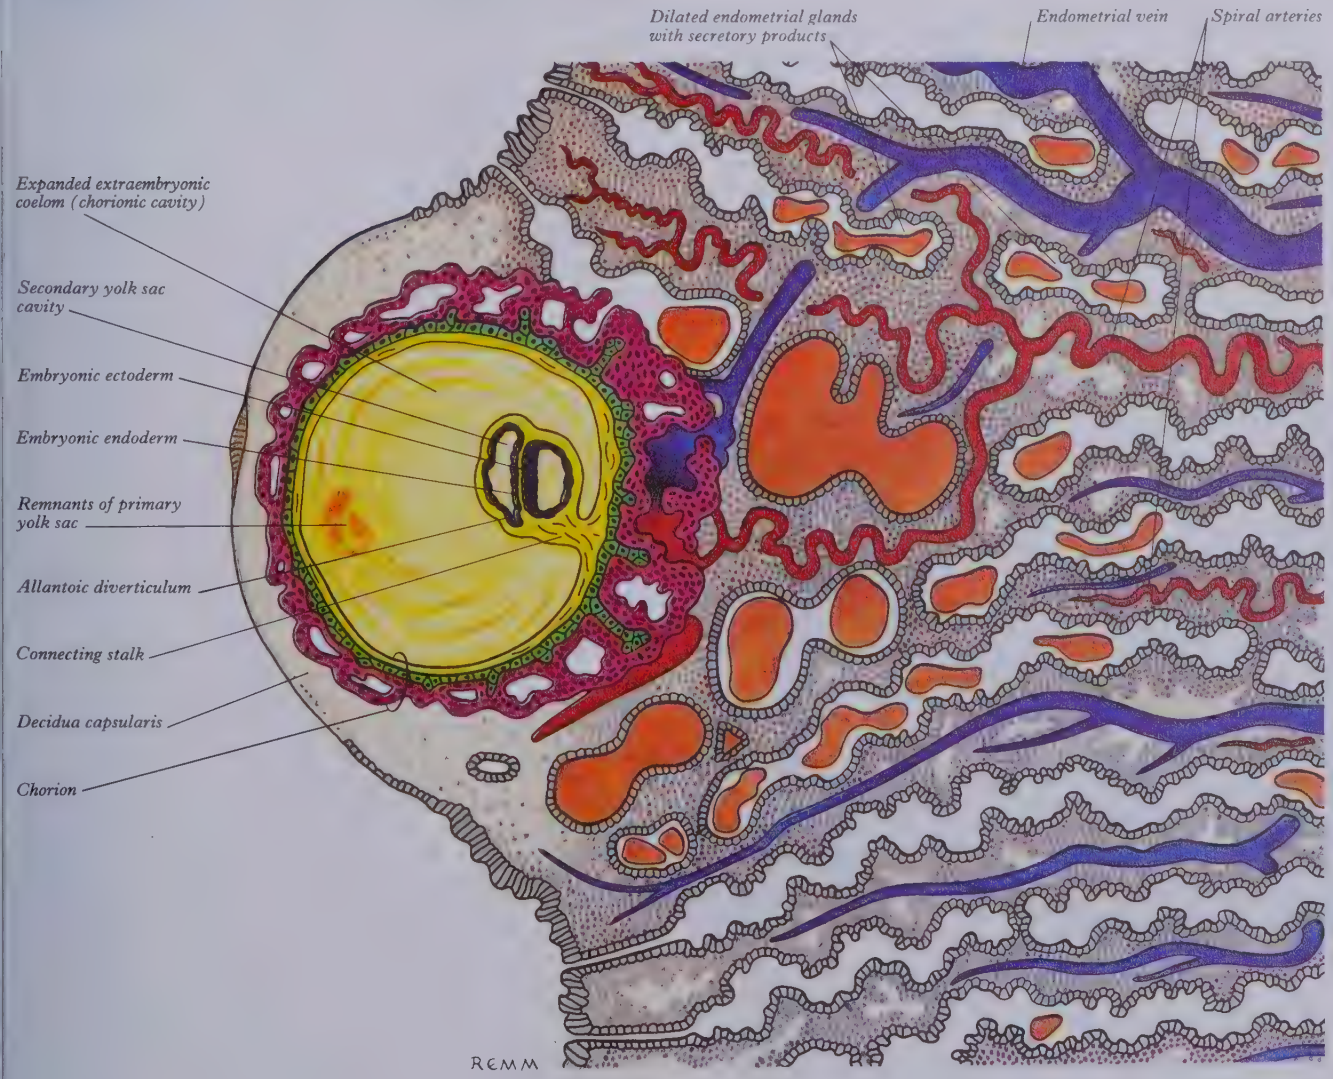
placed blastomeres has also been demonstrated in some mammals but, as yet, evidence for this phenomenon is lacking in man.) The intercellular spaces enlarge and coalesce to form a single fluid-filled *blastocyst cavity*. (It should be noted that the latter is not directly homologous with the *blastocoele* of primitive chordates, **2.1**, p. 100.) This cavity is largely bounded by *mural trophoblast cells*, except at one place where a clump of cells, termed the *inner cell mass (embryoblast* or *formative mass*) (**2.18,19,20,21**), projects into the cavity. This is widely considered to represent the residue of totipotential cells, some of which, the *embryogenic cells*, are destined to form the tissues of the embryo proper (see, however, p. 100). The segmenting zygote has now been converted into a *unilaminar blastocyst*. Of some 60 cells composing the blastocyst at this stage, only about 5 are formative cells; the remainder constitute the flattened (*mural*) trophoblastic epithelium forming the wall of the vesicle (Hertig et al 1954). This *unilaminar blastocyst* is formed by the end of the fourth or the beginning of the fifth day after ovulation and lies free in the uterine cavity (**2.21**).

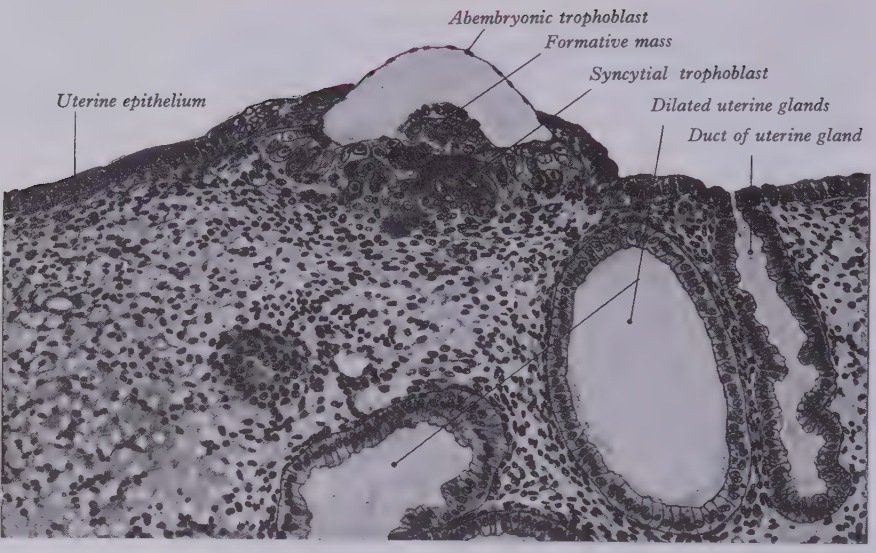
The zona pellucida disappears during the fifth day when the blastocyst is about 130–140 μm in diameter. The cells of the inner mass have multiplied and form an irregular clump insinuated into the wall of the blastocyst and flanked by trophoblast. One blastocyst described in detail at this stage (Hertig et al 1954) consists of 107 cells (**2.19**), of which 69 are *mural trophoblast cells*. Of the

Consult text and references for further details and alternative views of formation of amnion, yolk sac, and cytotrophoblast.



remainder, 8 are large *embryonic cells* constituting the *formative mass*, whilst the remaining 30 are future *polar trophoblast* cells and lie around its margins; they soon spread to cover the external aspect of the formative mass (at the *embryonic pole* of the blastocyst). At the same time, the inner aspect of the mass becomes lined by a single layer of polyhedral cells, the *embryonic endoderm* (*alternatively termed hypoblast* or *endoblast*).

Late in the sixth day after fertilization the polar trophoblast adheres to the uterine mucosa, exerting a histolytic action on its lining epithelium, then its underlying tissue. As they engulf the degenerating uterine tissue, the trophoblast cells in this situation divide with great rapidity and their individual progeny fuse with each other (Boyd & Hamilton 1966) so that all trace of cellular definition is lost. Accordingly the formative mass becomes covered with a multinucleated mass of cytoplasm, the *syncytial trophoblast* (*syntrophoblast*), which continues to burrow into the stratum compactum of the uterine mucosa. As the blastocyst embeds more deeply the remainder of its trophoblastic wall undergoes a similar change; but, at a slightly later stage, cell boundaries again appear on the inner or embryonic surface of the syncytial trophoblast. Thereafter the wall of the whole blastocyst consists of an inner germinative cellular layer, the *cellular trophoblast* (*cytotrophoblast*), covered on its outer surface with syncytial trophoblast, thickest over the formative mass, i.e. at the area of deepest penetration or *embryonic pole*, and thinnest over the area most recently embedded or *abembryonic pole*.

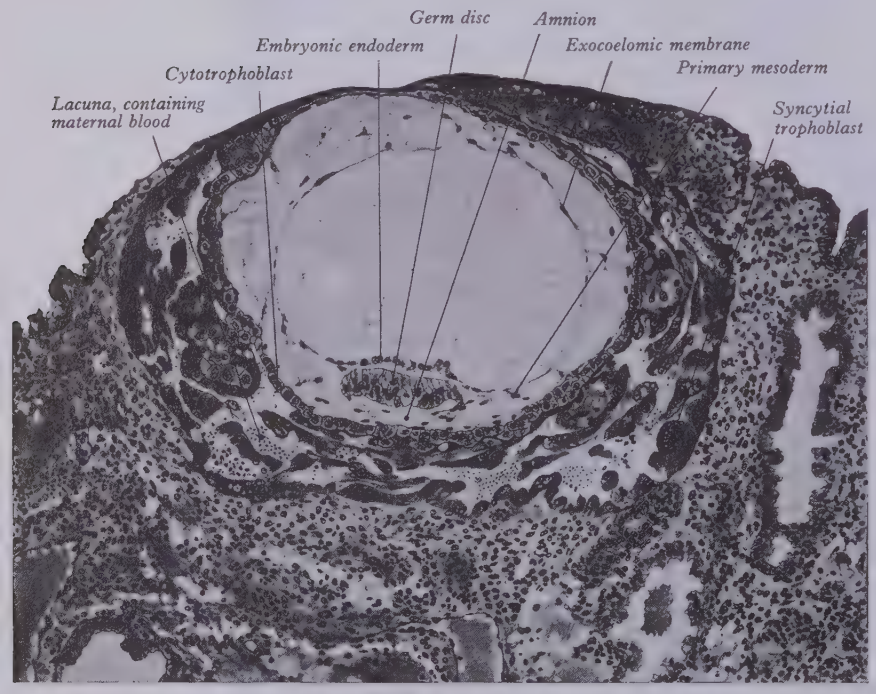


The *site of implantation* is normally on the posterior wall of the uterus, nearer to the fundus than to the cervix, and may be in the median plane or to one or other side (see, however, p. 131).

The youngest implanting human blastocyst hitherto recovered and described in detail (Hertig & Rock 1945) shows an early stage in the process. The polar trophoblast displays an extensive development of syncytium, which has destroyed a patch of uterine epithelium and underlying stroma (**2.22**). The blastocyst is not completely embedded and a portion of its wall at the abembryonic pole still projects into the uterine lumen. The fertilization age is believed to be $7\frac{1}{2}$ days (Hertig & Rock 1945).

In a slightly older specimen (Hertig & Rock 1945) ($9\frac{1}{2}$ days) the blastocyst is completely embedded. The syncytial trophoblast has undergone further proliferation and now covers the wall at the abembryonic pole as a thin layer. Irregular *lacunae* have developed in the syncytium which communicate with eroded maternal veins. The formative mass now consists externally of a thick plate of large, irregularly arranged cells, termed the *embryonic ectoderm* (*germ disc* or *embryonic epiblast*), and internally of a single-layered sheet of *embryonic endoderm*, which intervenes between the disc and the blastocyst cavity. On its external surface the germ disc is in process of separation from the trophoblast by the formation of a cavity, which will soon become the *cavity of the amnion* (**2.21,22,23,24**). Re-examination of early rhesus monkey and human embryos has led to a modification of this long held view of amniogenesis (Luckett 1975). A *primordial amniotic cavity* develops by cavitation within the inner cell mass and initially has no direct relation with the overlying trophoblast. This occurs in 7-day human blastocysts. Subsequently the epiblastic roof thins and disappears forming a slightly cup-shaped germ disc which is surmounted by a transitory *tropho-epiblastic cavity*. The definitive amniotic epithelium forms by upfolding and

2.21 (*contd*) Further expansion and differentiation of the blastocyst.

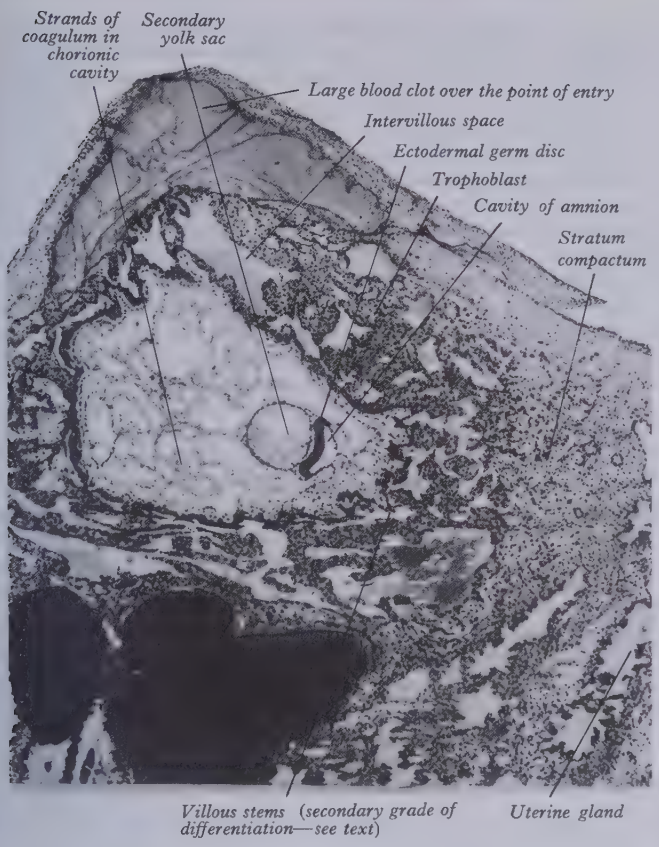


2.22 A human blastocyst (Carnegie 8020), fertilization age 7-7½ days, in process of embedding in the uterine mucosa. In the actual specimen the abembryonic trophoblast had collapsed on the formative mass but, for clarity, it has been shown projecting into the uterine cavity. (Rock & Hertig 1942, 1944). Magnification × *c.*150.

proliferation of the margins of the epiblastic disc, the process being completed by 9 days.

In the immediately succeeding stages the non-polar abembryonic walls of the blastocyst become *bilaminar* as its cavity becomes lined with a thin layer of flattened cells, which are in continuity with the embryonic endoderm around its margins and enclose a cavity now termed the *primary yolk sac*. It has been uncertain whether these are cells wholly derived from the cytotrophoblast, whether they are formed by an extension from the endoderm (as in the rabbit, dog and some other mammals) or have a mixed origin. In a relatively recent review and analysis, Luckett (1978) is firmly convinced that in the rhesus monkey, and man, their derivation is exclusively hypoblastic (i.e. endodermal). Whatever their origin, a variety of terms have been applied to this tissue layer—*extraembryonic hypoblast* and later *extraembryonic endoderm* or the *exocoelomic (Heuser's) membrane*. The primary yolk sac, formed in this way (**2.21, 23**), appears to meet a functional need in the selective transport of the fluid which the trophoblast absorbs carrying cytolytic nutritive products from the uterine mucosa, making them available for the nourishment of the germ disc at this stage.

The cells of the germ disc, hitherto arranged in an irregular manner, now dispose themselves as a plate of columnar cells. At the same time extraembryonic mesodermal cells of hypoblastic origin and delamination from the inner surface of the cytrotrophoblast intervene between the latter and the primary yolk sac. (The relative contributions to the mesenchymatous cells from these various sources remain controversial.) The wall of the sac becomes retracted from the wall of the blastocyst, although it often remains connected to it near the abembryonic pole by strands of mesoderm. Descriptions of several human blastocysts (Stieve 1936, Odgers 1937, Dible & West 1940, Hertig & Rock 1941, 1945, Davies 1944) which have reached this *trilaminar* stage and already are completely embedded in the uterine mucosa are now available e.g. see **2.21, 23, 24**. The trophoblast is thickest over the embryonic pole and diminishes over the sides of the blastocyst but is exceedingly thin over the abembryonic pole, the last part to be embedded. It is lined over most of its extent by a single layer of cytotrophoblast and the syncytial trophoblast contains numerous lacunae. Maternal blood from invaded vessels occupies the lacunae and serves as a new source of nourishment.



Within the trophoblastic vesicle, the cells of the germ disc are now a columnar epithelium, the *embryonic ectodermal plate* or *disc*. Externally it is separated from the cytotrophoblast by the amniotic wall, cavity and contained fluid and some extraembryonic mesoderm; internally it is in close contact with the embryonic endoderm, although a distinct basement membrane intervenes. The embryonic endoderm consists of a single layer of low cuboidal epithelial cells, lining the ventral surface of the germ disc and forming the roof of the primary yolk sac, which is lined elsewhere by the exocoelomic membrane and which contains fluid and some apparent coagulum (this appearance resulting from the effects of histological fixation). The intervals between the trophoblast, on the one hand, and the primary yolk sac and developing amnion, on the other, are again occupied by fluid in which are found extraembryonic mesodermal cells, noted above, and mesenchymatous in nature, together with a certain amount of coagulum (**2.24**). This extraembryonic mesoderm soon forms a loose net, the *magma reticulare*, in which a series of enlarging clefts develop and begin to coalesce. As this proceeds the trophoblastic wall of the bastocyst with its lining of mesoderm becomes a separate membrane, the *chorion*, and the general cavity of the blastocyst can therefore now be termed the *chorionic cavity* or *extraembryonic coelom* (**2.21, 24**).

2.23 A human blastocyst (Carnegie 7700), fertilization age 12-12½ days, embedded in the stratum compactum of the endometrium (Hertig & Rock 1941). Magnification × *c.*105. Compare with **2.22**. Note lacunae in the syncytial trophoblast, many containing maternal blood; also that the primary yolk sac, surrounded by the exocoelomic membrane, does not fill the blastocyst cavity. The cells of the germ disc are now columnar and form an ectodermal plate. (Drawn from a photomicrograph by Dr A T Hertig.)

The cavity of the amnion with its roof of epiblastic 'amniogenic' cells and extraembryonic mesoderm, and its floor of embryonic ectoderm, now constitutes the *amnio-embryonic vesicle*. At first mesoderm connects chorion to amnion over a wide area but, with continued development and coalescence of clefts in the mesoderm extending the extraembryonic coelem, this attachment soon becomes increasingly circumscribed (**2.21**) and condenses to form a *connecting stalk* (body stalk), a permanent connection between (initially) the caudal rim of the embryonic disc and chorion, a pathway along which blood vessels of the embryo later establish communication with those of the chorion. Subsequently it becomes converted into part of the *umbilical cord* (vide infra); its embryonic attachment becoming transposed, later, to the ventral abdominal wall (p. 143).

While the connecting stalk is being defined, the primary yolk sac suffers a reduction in size, the mechanism of which is obscure, although it seems probable that part of its wall becomes drawn out by the mesodermal strands which anchor it to the abembryonic chorion, and which then loses its connection with the rest of the

2.24 An advanced human blastocyst, embedded in the stratum compactum. Estimated age, 13.5 days (Rock & Hertig 1942).

sac. The resultant smaller cavity is the *definitive* (or *secondary*) yolk sac (2.21, 24) but is often referred to simply as *the yolk sac*. Some investigators (Heuser & Streeter 1941), however, maintain that the secondary yolk sac is a new formation by a rearrangement of the embryonic endodermal cells on the deep surface of the germ disc. (Consult Luckett 1978.)

At slightly older stages, of which many examples are available, the chorionic cavity contains two hollow vesicles (the amnion and the yolk sac), each covered with extraembryonic mesoderm, by which they are connected to the chorionic wall (2.21, 24, 29). Only the cells where the two vesicles are in contact with each other contribute to the formation of the body of the embryo and it is therefore this region which is termed the *bilaminar embryonic disc (embryonic shield* or *area*).

It is noteworthy that, of the multitude of cells derived from the fertilized ovum *at this stage*, only a relatively small number take part in the formation of the embryo, while the vast majority form its covering and nourishing membranes and certain other extraembryonic structures to be noted later. Hypotheses concerning the causal mechanisms of this early differentiation have been critically examined in relation to development in the mouse (Herbert & Graham 1974). The ectodermal cells of the germ disc are columnar and separated from the endoderm by a basement membrane. By the third week the ectoderm takes the form of three or four interlocking rows of cells continuous round its margins with the cells of the amnion which are flatter and more elongated and form only a single stratum, which is covered externally with a layer of extraembryonic mesoderm. The endodermal cells of the disc are flattened, but those lining the rest of the yolk sac vary in shape and patches of cubical or low columnar cells are found, especially on its caudal wall. Except in some localized situations, to be noted later (p. 135, 139), the endoderm seldom forms more than a single layer of cells.

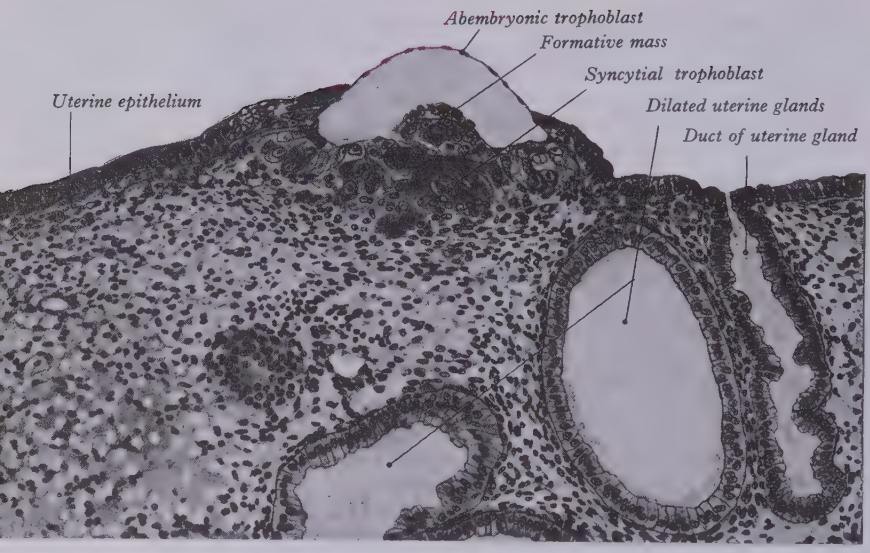
An inconstant feature of the embryo is sometimes observed at this stage within the mesodermal connecting stalk between the amnion and disc to the trophoblast; this may contain an *amniotic duct*, extending from the amniotic cavity to end blindly near the trophoblast. In reptiles, and in many mammals, the amnion arises by a process of folding around the periphery of the embryonic disc. The amniotic duct of the human embryo has been interpreted as the homologue of the point of closure of these folds (but it has also been suggested that its presence depends on the chance occurrence of a trophoblastic lacuna which breaks through into the amniotic cavity). See Luckett (1975), who describes human amniogenesis as a modified form of folding.

Concomitant with the changes which transform the zygote into a morula, the latter is slowly carried along the uterine tube by the action of the cilia of its lining epithelium and probably by gentle waves of muscular contraction which perhaps also generate currents in the tubal fluid. Passage along the tube covers a period of about 3 days, and the morula is then transformed into a blastocyst which remains *free* in the uterine cavity for a further 3 days before implantation. During this interval the uterine mucosa is preparing for the reception of the blastocyst (p. 146). The disappearance of the zona pellucida, after the formation of the blastocyst, allows the syncytial trophoblast to come into direct contact with the uterine mucosa and initiate implantation.

ECTOPIC IMPLANTATION

Implantation of the blastocyst normally occurs in the endometrium of the uterine body, more frequently on the posterior wall somewhere near the fundus, but may occur elsewhere in the uterus or in an *extrauterine* or *ectopic* site. Implantation near the internal os results in the condition of *placenta praevia* with its attendant risk of severe antepartum haemorrhage (p. 156).

Alternatively, the zygote or segmenting morula may be arrested at any point during its migration through the uterine tube and implant in its wall. Previous tubal inflammatory episodes may predispose to such tubal arrest and it has also been suggested that congenital abnormalities of the tube, tubal tumours, transperitoneal migration of an ovum from one ovary to the opposite tube, delayed ovulation and psychological stress, which may cause tubal spasm, are additional predisposing factors (Woodruff & Pauerstein 1969).

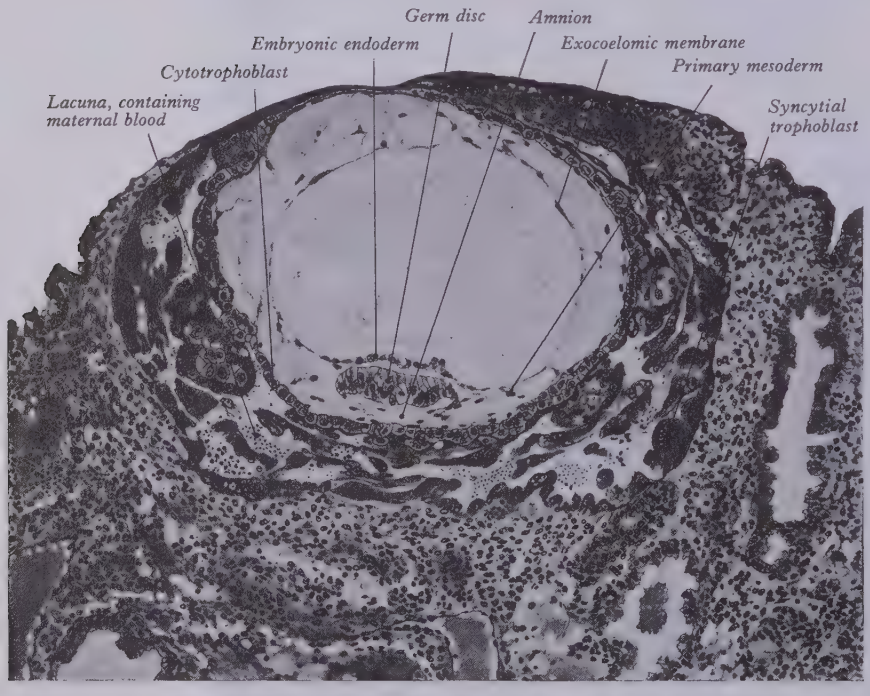


Nidation in the intramural part of the tube often results in early abortion of the conceptus whereas, if it occurs elsewhere in the tube, development often proceeds for about 2 months and is then usually followed by tubal rupture with death of the embryo and severe intraperitoneal haemorrhage—a grave surgical emergency. However, slow rupture of the tube may occur, accompanied by a further implantation of the conceptus into any adjacent peritonealized surface (*secondary abdominal pregnancy*), which again ultimately leads to rupture of the surface with similar consequences.

Primary ovarian or *abdominal* pregnancies have also been described, in which it has been presumed that the fertilization occurred in the vicinity of the ovary; most cases, however, are probably of the secondary type following a slow tubal rupture or a slow extrusion of the conceptus through the abdominal ostium of the tube.

Apart from their important clinical implications, such conditions emphasize the interesting fact that the conceptus can implant successfully into tissues other than a normal progestational endometrium. Further, prolonged development can occur in such sites and is usually terminated by a mechanical or vascular accident and not by a fundamental nutritive or endocrine insufficiency or by an immune maternal response.

Differentiation of the Embryonic Area

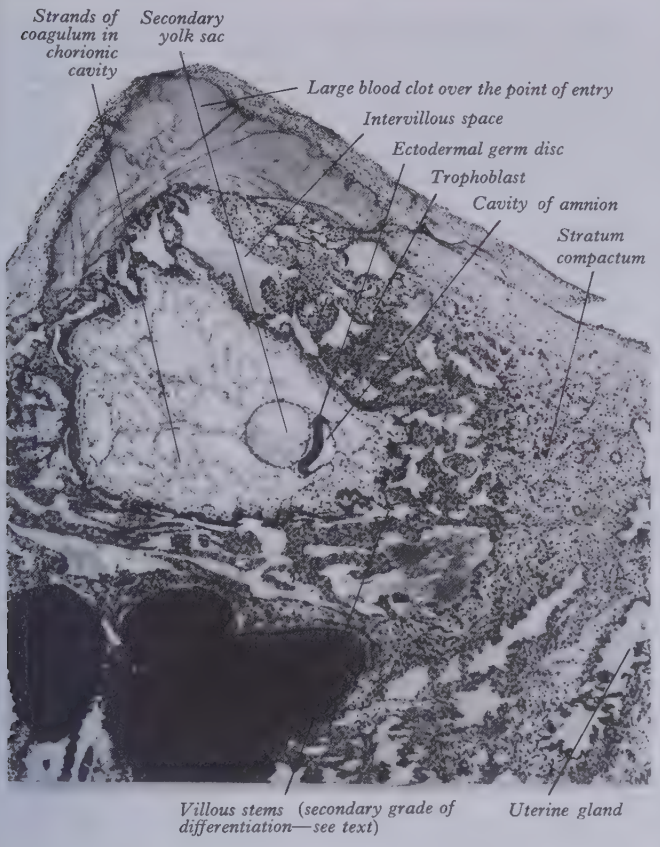


Near the end of the second week, the embryonic area thus consists of an almost *circular, bilaminar disc* which separates the cavity of the amnion from that of the secondary yolk sac. As we have seen, the amniotic aspect of the area consists of a thick plate of columnar embryonic ectodermal (epiblastic) cells, 2–4 cells thick, which is continuous around its margins with the flattened cells lining the amniotic cavity. A single layer of rather flattened polyhedral endodermal (hypoblastic) cells forms the roof of the secondary yolk sac; this roof is quite closely applied to the superjacent ectodermal

2.22 A human blastocyst (Carnegie 8020), fertilization age 7-7½ days, in process of embedding in the uterine mucosa. In the actual specimen the abembryonic trophoblast had collapsed on the formative mass but, for clarity, it has been shown projecting into the uterine cavity. (Rock & Hertig 1942, 1944). Magnification × *c.*150.

proliferation of the margins of the epiblastic disc, the process being completed by 9 days.

In the immediately succeeding stages the non-polar abembryonic walls of the blastocyst become *bilaminar* as its cavity becomes lined with a thin layer of flattened cells, which are in continuity with the embryonic endoderm around its margins and enclose a cavity now termed the *primary yolk sac*. It has been uncertain whether these are cells wholly derived from the cytotrophoblast, whether they are formed by an extension from the endoderm (as in the rabbit, dog and some other mammals) or have a mixed origin. In a relatively recent review and analysis, Luckett (1978) is firmly convinced that in the rhesus monkey, and man, their derivation is exclusively hypoblastic (i.e. endodermal). Whatever their origin, a variety of terms have been applied to this tissue layer—*extraembryonic hypoblast* and later *extraembryonic endoderm* or the *exocoelomic (Heuser's) membrane*. The primary yolk sac, formed in this way (**2**.21, 23), appears to meet a functional need in the selective transport of the fluid which the trophoblast absorbs carrying cytolytic nutritive products from the uterine mucosa, making them available for the nourishment of the germ disc at this stage.



2.23 A human blastocyst (Carnegie 7700), fertilization age 12-12½ days, embedded in the stratum compactum of the endometrium (Hertig & Rock 1941). Magnification × *c.*105. Compare with **2**.22. Note lacunae in the syncytial trophoblast, many containing maternal blood; also that the primary yolk sac, surrounded by the exocoelomic membrane, does not fill the blastocyst cavity. The cells of the germ disc are now columnar and form an ectodermal plate. (Drawn from a photomicrograph by Dr A T Hertig.)

The cells of the germ disc, hitherto arranged in an irregular manner, now dispose themselves as a plate of columnar cells. At the same time extraembryonic mesodermal cells of hypoblastic origin and delamination from the inner surface of the cytrotrophoblast intervene between the latter and the primary yolk sac. (The relative contributions to the mesenchymatous cells from these various sources remain controversial.) The wall of the sac becomes retracted from the wall of the blastocyst, although it often remains connected to it near the abembryonic pole by strands of mesoderm. Descriptions of several human blastocysts (Stieve 1936, Odgers 1937, Dible & West 1940, Hertig & Rock 1941, 1945, Davies 1944) which have reached this *trilaminar* stage and already are completely embedded in the uterine mucosa are now available e.g. see **2**.21, 23, 24. The trophoblast is thickest over the embryonic pole and diminishes over the sides of the blastocyst but is exceedingly thin over the abembryonic pole, the last part to be embedded. It is lined over most of its extent by a single layer of cytotrophoblast and the syncytial trophoblast contains numerous lacunae. Maternal blood from invaded vessels occupies the lacunae and serves as a new source of nourishment.

Within the trophoblastic vesicle, the cells of the germ disc are now a columnar epithelium, the *embryonic ectodermal plate* or *disc*. Externally it is separated from the cytotrophoblast by the amniotic wall, cavity and contained fluid and some extraembryonic mesoderm; internally it is in close contact with the embryonic endoderm, although a distinct basement membrane intervenes. The embryonic endoderm consists of a single layer of low cuboidal epithelial cells, lining the ventral surface of the germ disc and forming the roof of the primary yolk sac, which is lined elsewhere by the exocoelomic membrane and which contains fluid and some apparent coagulum (this appearance resulting from the effects of histological fixation). The intervals between the trophoblast, on the one hand, and the primary yolk sac and developing amnion, on the other, are again occupied by fluid in which are found extraembryonic mesodermal cells, noted above, and mesenchymatous in nature, together with a certain amount of coagulum (**2**.24). This extraembryonic mesoderm soon forms a loose net, the *magma reticulare*, in which a series of enlarging clefts develop and begin to coalesce. As this proceeds the trophoblastic wall of the bastocyst with its lining of mesoderm becomes a separate membrane, the *chorion*, and the general cavity of the blastocyst can therefore now be termed the *chorionic cavity* or *extraembryonic coelom* (**2**.21, 24).

The cavity of the amnion with its roof of epiblastic 'amniogenic' cells and extraembryonic mesoderm, and its floor of embryonic ectoderm, now constitutes the *amnio-embryonic vesicle*. At first mesoderm connects chorion to amnion over a wide area but, with continued development and coalescence of clefts in the mesoderm extending the extraembryonic coelem, this attachment soon becomes increasingly circumscribed (**2**.21) and condenses to form a *connecting stalk* (body stalk), a permanent connection between (initially) the caudal rim of the embryonic disc and chorion, a pathway along which blood vessels of the embryo later establish communication with those of the chorion. Subsequently it becomes converted into part of the *umbilical cord* (vide infra); its embryonic attachment becoming transposed, later, to the ventral abdominal wall (p. 143).

While the connecting stalk is being defined, the primary yolk sac suffers a reduction in size, the mechanism of which is obscure, although it seems probable that part of its wall becomes drawn out by the mesodermal strands which anchor it to the abembryonic chorion, and which then loses its connection with the rest of the

2.24 An advanced human blastocyst, embedded in the stratum compactum. Estimated age, 13.5 days (Rock & Hertig 1942).

sac. The resultant smaller cavity is the *definitive* (or *secondary*) yolk sac (2.21, 24) but is often referred to simply as *the yolk sac*. Some investigators (Heuser & Streeter 1941), however, maintain that the secondary yolk sac is a new formation by a rearrangement of the embryonic endodermal cells on the deep surface of the germ disc. (Consult Luckett 1978.)

At slightly older stages, of which many examples are available, the chorionic cavity contains two hollow vesicles (the amnion and the yolk sac), each covered with extraembryonic mesoderm, by which they are connected to the chorionic wall (2.21, 24, 29). Only the cells where the two vesicles are in contact with each other contribute to the formation of the body of the embryo and it is therefore this region which is termed the *bilaminar embryonic disc (embryonic shield* or *area*).

It is noteworthy that, of the multitude of cells derived from the fertilized ovum *at this stage*, only a relatively small number take part in the formation of the embryo, while the vast majority form its covering and nourishing membranes and certain other extraembryonic structures to be noted later. Hypotheses concerning the causal mechanisms of this early differentiation have been critically examined in relation to development in the mouse (Herbert & Graham 1974). The ectodermal cells of the germ disc are columnar and separated from the endoderm by a basement membrane. By the third week the ectoderm takes the form of three or four interlocking rows of cells continuous round its margins with the cells of the amnion which are flatter and more elongated and form only a single stratum, which is covered externally with a layer of extraembryonic mesoderm. The endodermal cells of the disc are flattened, but those lining the rest of the yolk sac vary in shape and patches of cubical or low columnar cells are found, especially on its caudal wall. Except in some localized situations, to be noted later (p. 135, 139), the endoderm seldom forms more than a single layer of cells.

An inconstant feature of the embryo is sometimes observed at this stage within the mesodermal connecting stalk between the amnion and disc to the trophoblast; this may contain an *amniotic duct*, extending from the amniotic cavity to end blindly near the trophoblast. In reptiles, and in many mammals, the amnion arises by a process of folding around the periphery of the embryonic disc. The amniotic duct of the human embryo has been interpreted as the homologue of the point of closure of these folds (but it has also been suggested that its presence depends on the chance occurrence of a trophoblastic lacuna which breaks through into the amniotic cavity). See Luckett (1975), who describes human amniogenesis as a modified form of folding.

Concomitant with the changes which transform the zygote into a morula, the latter is slowly carried along the uterine tube by the action of the cilia of its lining epithelium and probably by gentle waves of muscular contraction which perhaps also generate currents in the tubal fluid. Passage along the tube covers a period of about 3 days, and the morula is then transformed into a blastocyst which remains *free* in the uterine cavity for a further 3 days before implantation. During this interval the uterine mucosa is preparing for the reception of the blastocyst (p. 146). The disappearance of the zona pellucida, after the formation of the blastocyst, allows the syncytial trophoblast to come into direct contact with the uterine mucosa and initiate implantation.

ECTOPIC IMPLANTATION

Implantation of the blastocyst normally occurs in the endometrium of the uterine body, more frequently on the posterior wall somewhere near the fundus, but may occur elsewhere in the uterus or in an *extrauterine* or *ectopic* site. Implantation near the internal os results in the condition of *placenta praevia* with its attendant risk of severe antepartum haemorrhage (p. 156).

Alternatively, the zygote or segmenting morula may be arrested at any point during its migration through the uterine tube and implant in its wall. Previous tubal inflammatory episodes may predispose to such tubal arrest and it has also been suggested that congenital abnormalities of the tube, tubal tumours, transperitoneal migration of an ovum from one ovary to the opposite tube, delayed ovulation and psychological stress, which may cause tubal spasm, are additional predisposing factors (Woodruff & Pauerstein 1969).

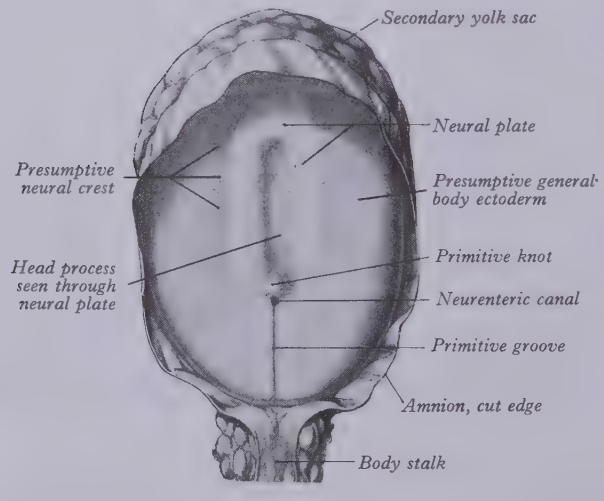
Nidation in the intramural part of the tube often results in early abortion of the conceptus whereas, if it occurs elsewhere in the tube, development often proceeds for about 2 months and is then usually followed by tubal rupture with death of the embryo and severe intraperitoneal haemorrhage—a grave surgical emergency. However, slow rupture of the tube may occur, accompanied by a further implantation of the conceptus into any adjacent peritonealized surface (*secondary abdominal pregnancy*), which again ultimately leads to rupture of the surface with similar consequences.

Primary ovarian or *abdominal* pregnancies have also been described, in which it has been presumed that the fertilization occurred in the vicinity of the ovary; most cases, however, are probably of the secondary type following a slow tubal rupture or a slow extrusion of the conceptus through the abdominal ostium of the tube.

Apart from their important clinical implications, such conditions emphasize the interesting fact that the conceptus can implant successfully into tissues other than a normal progestational endometrium. Further, prolonged development can occur in such sites and is usually terminated by a mechanical or vascular accident and not by a fundamental nutritive or endocrine insufficiency or by an immune maternal response.

Differentiation of the Embryonic Area

Near the end of the second week, the embryonic area thus consists of an almost *circular, bilaminar disc* which separates the cavity of the amnion from that of the secondary yolk sac. As we have seen, the amniotic aspect of the area consists of a thick plate of columnar embryonic ectodermal (epiblastic) cells, 2–4 cells thick, which is continuous around its margins with the flattened cells lining the amniotic cavity. A single layer of rather flattened polyhedral endodermal (hypoblastic) cells forms the roof of the secondary yolk sac; this roof is quite closely applied to the superjacent ectodermal



plate, a basement membrane intervening, and it is continuous peripherally with the cuboidal or columnar cells lining the secondary yolk sac. At this stage few mesodermal cells are found between the ectoderm and endoderm of the embryonic area but thin strata of extraembryonic mesoderm clothe the outer surfaces of the amnion and secondary yolk sac and line the chorion (p. 145) —the space bounded by these various mesodermal layers constituting the *chorionic cavity* or *extra-embryonic coelom.*

The walls of the amnion on the one hand, and that of the yolk sac on the other, may now be defined as extraembryonic *somatopleure* and *splanchnopleure* respectively. The former consisting of an epithelial layer (trophoblast or amniotic lining) associated with a layer of *somatopleuric extraembryonic mesoderm*, whilst the latter comprises the endodermal epithelial lining of the yolk sac together with *splanchnopleuric extraembryonic mesoderm.* At a *junctional zone* surrounding the margins of the embryonic area, where the walls of the amnion and yolk sac converge, the somatopleuric and splanchnopleuric layers of mesoderm are continuous.

At an early stage the embryonic area is radially symmetrical, with no specialized features distinguishing its future cephalic, caudal and lateral borders; but with the extensions of the extra-embryonic coelom noted above and the increasing separation of the amnion from the overlying chorion, the mesodermal connecting stalk becomes increasingly defined and its embryonic attachment is soon limited to a zone which marks the future *caudal edge* of the embryonic area.

The first change within the embryonic area itself occurs near the opposite (*cephalic*) edge, where, in a localized region, the endoderm in the yolk sac roof thickens, forming an oval plate of large vesicular cells, the *prechordal plate*, which at a later stage contributes cells to the general head mesenchyme (p. 136) and which, together with the closely applied superjacent ectoderm, forms the transient *oropharyngeal membrane.* The attachment of the body stalk and the position of the prechordal plate have now defined the *plane of bilateral symmetry* of the embryonic area.

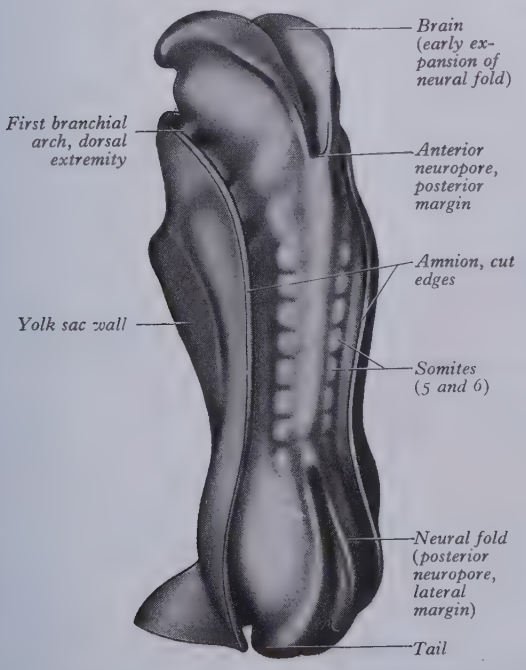
During immediately succeeding stages the embryonic area changes from a circular *bilaminar* disc to first an oval, and then a pear-shaped *trilaminar* one as a third *mesodermal layer* becomes interposed between the embryonic ectoderm and endoderm. The long axis of the oval and pear lie in the future cephalo–caudal axis of the developing embryo, whilst the pear-shaped outline is narrow caudally and expanded at the cephalic end. These shape changes accompany the emergence of proliferative and cell migratory zones in the caudal midline of the primitive ectoderm of the embryonic area—a linear *primitive streak* with, at its cephalic end, a *primitive node* or *knot.* From the former generations of *intraembryonic mesodermal cells* and from the latter an axial *head process* (ultimately forming the notochord) pass between the ectoderm and endoderm. (For long these were considered the principal, if not the sole, derivatives of streak and node; however, vide infra.)

2.25 A human embryo, 1.16 mm long. The amnio-embryonic vesicle has been laid open widely, most of the amnion having been removed. The embryonic area is exposed in almost its whole extent and shows an early stage of differentiation. Estimated age 19 days. (W C Gerge 1942.)

Presumably (based on the evidence of comparative studies, p. 107), under the primary inductive influences of the chorda-mesoderm, the central regions of the ectoderm which overlies it commences the formation of a *neural plate*, the primordium of the central nervous system (**2.25**, 27). The margins of the plate are surrounded by a strip of presumptive *neural crest* tissue (p. 137) which, again, is surrounded peripherally by the layer which will form the general body ectoderm. These various regions will now be considered further.

As noted elsewhere (p. 107) many experimental embryologists consider that the totipotency of the fertilized mammalian oöcyte and initial blastomeres suffers a stepwise reduction, as the determination and differentiation of the various embryonic regions proceeds. Alternative views have also been advanced (see p. 108). Despite the relative paucity of experimental analyses, because of technical difficulties on mammalia, it is widely held that by the blastocyst stage the vast majority of the cells have already suffered a severe restriction in their developmental potency, being destined to form extraembryonic structures (p. 98), whilst the pluripotent cells are restricted to the embryonic area. It was proposed (Streeter 1942) that, as the changes outlined above occur, these pluripotent cells become progressively circumscribed, first in the caudal part of the oval embryonic area and then as a narrowing midline strip in the caudal end of the increasingly pear-shaped area, i.e. the site of formation of the *primitive streak* which, as development proceeds, becomes more obvious as a linear opacity when viewed from the amniotic aspect. (For more recent *experimental* data on mammalia see Herbert & Graham 1974.)

In the early stages of development the living tissues are greyish and translucent, but any localized thickening due to cellular proliferation and patterns of cell migration naturally interferes with the translucency and causes a localized opacity as in the case of the primitive streak, indicating that rapid multiplicative growth is occurring throughout its length. Such growth also affects neighbouring epiblastic areas and both these and the streak are involved in complex cell migrations. Thus some cell progeny diverge from the streak and contribute to the neural plate, neural crest and general body ectoderm. Others converge on and enter the streak, these diverging dorsocaudally to form *extraembryonic mesenchyme*, including the body stalk. Further streams radiate in most directions as *intraembryonic mesenchyme* (vide infra). Finally, additions are made to the midline endodermal roof of the secondary yolk sac. At the headward end of the streak another area of exceptionally active growth and cell migration forms a knob-like thickening termed the *primitive knot* or *Hensen's node* (**2.25**) and here the ectoderm is fused with the endoderm.



From the primitive knot a rod-like column of cells grows headwards in the midline separating the presumptive neural plate from the subjacent roof of the yolk sac until its cranial tip reaches the caudal margin of the prechordal plate. This is termed the *head process (notochordal process)*—the forerunner of the skeletal axis of the body. This, initially a cylindrical solid rod of cells, now becomes canalized and caudally the canal breaks through on to the ectodermal surface at the posterior end of the primitive knot. More cranially the endodermal cells lying ventral to the canalized head process disappear and the head process then becomes, briefly, a constituent part of the roof of the yolk sac in the median plane. The cells forming the floor of the canal of the head process also break down so that the canal communicates freely with the yolk sac and, at its caudal end, a temporary communication is established between the yolk sac and the amniotic cavity. This connection, which pierces the embryonic area at the primitive knot (i.e. the caudal end of the neural groove), is the *neurenteric canal.* At this stage a transverse section across the embryonic area cranial to the primitive knot shows that, in the median plane, the roof of the yolk sac is, for a time, formed by the cells of the head process (**2.27A**), and this intercalation, which forms the *chordal or notochordal plate*, extends forwards to include the region which will subsequently form the roof, or dorsal wall, of the pharynx.

Later, these cells of the head process become separated from the endoderm and form the *notochord*, the roof of the yolk sac being repaired by the fusion of the adjoining endodermal cells. Subsequently the notochordal cells are encased by a homogeneous sheath and continued proliferation of cells within the sheath results in a solid but flexible rod, later surrounded by mesoderm to form the primitive or *blastemal vertebral column* (p. 159).

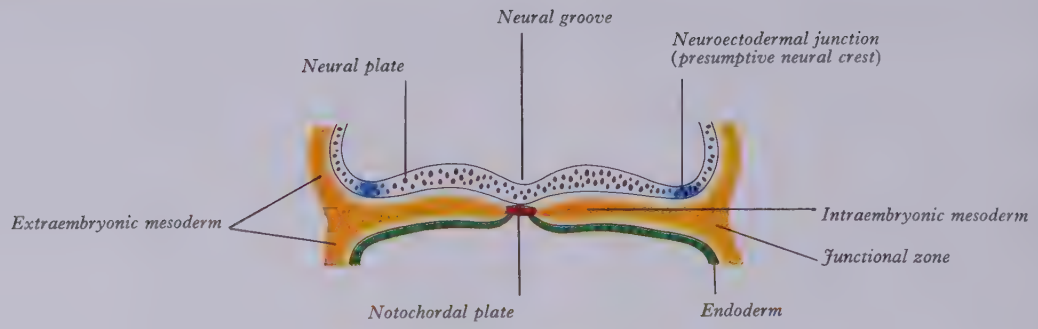
During the earlier part of this period another prominent change affects most of the embryonic area. From the sides and surroundings of the primitive streak occurs an intensely active multiplicative cell growth. The cellular progeny, having converged on the streak, sink into the substance of the germ disc and then spread laterally forwards and backwards until they extend over the whole embryonic area (*with the exception of most of the median plane*). They insinuate themselves between the ectoderm and the underlying endoderm and produce a third layer, the *intraembryonic mesoderm*. (**2**.27,28). For a review of experimental data of these stages of development in higher vertebrates consult Bellairs (1971).

The primitive streak is the principal but not the only source of intraembryonic mesoderm; the latter also receives accessions from the margins of the notochord and from the neural crest (p. 137), particularly in the head and branchial arches (Hörstadius 1950), and the latter also receive contributions from ectodermal placodes and from the thickened endoderm of the prechordal plate. As mentioned above, this plate forms an integral part of the future oropharyngeal membrane and it is probably involved in inductive processes of cranial structures (termed a *head organizer region* by earlier workers). Similarly, in the midline at the opposite end of the embryonic area, a patch of endoderm thickens and becomes closely applied to the overlying ectoderm, between the caudal tip of the primitive streak and the attachment of the body stalk, to form the future *cloacal membrane*.

As the streams of intraembryonic mesodermal cells radiate from the lateral margins of the primitive streak (**2**.27,28), they separate the ectoderm and endoderm of the embryonic area, then soon approach and become confluent with extraembryonic mesoderm around the margins of the area, i.e. at the *junctional zone* where the splanchnic and somatic strata of extraembryonic mesoderm merge. The streams passing in a *cephalic* direction flank the differentiating head process (later the notochord), skirt the margins of the prechordal plate and then converge medially to fuse in the midline beyond its cephalic border. This transmedian mass is the *cardiogenic mesoderm* in which the heart and pericardium are to develop. Around the extreme *cephalic* margin of the embryonic area, the cardiogenic mesoderm fuses with the junctional zone of extraembryonic mesoderm mentioned above and this confluent mesodermal region will eventually form the *septum transversum* and *primitive ventral mesentery* of the foregut (p. 232).

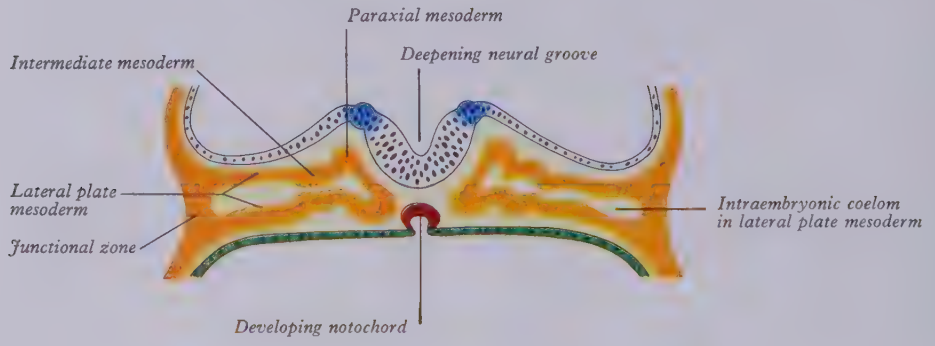
2.26 A human embryo, 2.1 mm long, with nine somites. Viewed from the left lateral and dorsal aspects. (From a model by Eternod.) Nearly all the yolk sac, and the caudal amnion have been excised to show the tail region.

The intraembryonic mesoderm which streams *caudally* from the primitive streak skirts the margins of the cloacal membrane and then converges towards the caudal midline extremity of the embryonic disc to become continuous with the extraembryonic mesoderm of the connecting stalk.



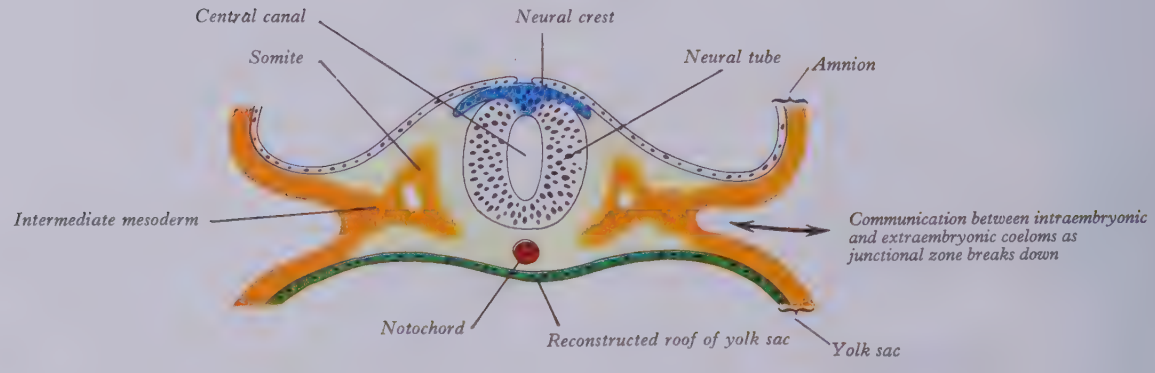
The ectodermal thickening of the *neural plate*, from which most of the central nervous system develops, initially corresponds precisely in length to the underlying notochord. Thus it extends from the cranial border of the primitive knot to the caudal border of the future oropharyngeal membrane but it also extends laterally beyond the notochord, to cover the medial strips of intraembryonic mesoderm. As the plate grows, its margins become raised (**2**.26,27,28) as the *neural folds*, with a longitudinal, midline *neural groove* between them.

The neural folds become particularly prominent at the anterior end of the area and the walls of the groove become expanded (**2**.26), the first sign of brain formation. It is not a continuous enlargement; two slight transverse constrictions indicate a division into three *parts* or *regions*, named craniocaudally: the *prosencephalon* or *forebrain*, the *mesencephalon* or *midbrain* and the *rhombencephalon* or *hindbrain* (see p. 185). As we have seen, between the cephalic margin of the forebrain and the cardiogenic mesoderm the ectoderm and the endoderm are in contact over a small area forming the *oropharyngeal membrane* (**2**.28,29). As the neural groove deepens, its dorsal edges come into contact with each other and fuse to convert the groove into a sagittal slit-like canal (**2**.27A–E). It should be noted that as the edges of the groove approximate they carry with them the adjoining general body ectoderm and, when the process of fusion occurs, like fuses with like, i.e. ectoderm with ectoderm and neural tissue with neural tissue to form a submerged *neural tube*. The process is effected first in the hindbrain or upper cervical region (**2**.26) in the latter part of the third week and extends both headwards and tailwards, until only a small opening is left at each end. These are the rostral and caudal *neuropores*; the former closes in the middle and the latter towards the end of the fourth week. The cells which lie in the line of fusion of the dorsal edges of the neural plate constitute the *neural crest* (**2**.27)—its fate is considered later (p. 137).



From initiation, the walls of the neural groove and tube are bathed by fluid in the amniotic cavity (*liquor amnii*) and are, in part, dependent on it for their nourishment whilst the neuropores remain open. It may be noted that closure of the neuropores coincides with the establishment of a blood vascular circulation for the neural tube; also the formation of choroid plexuses and the production of embryonic cerebrospinal fluid.

The fusion of the dorsal lips of the neural plate in the region of the brain results in the completion of the three zones mentioned above, and termed, somewhat inappropriately, the *primary cerebral vesicles* (see p. 185). Much of the walls of these 'vesicles' becomes thickened and develops into the nervous tissues including neuroglia of the brain and their cavities are modified to form the ventricles of the brain. In some important sites, however, the walls of the forebrain and hindbrain vesicles do not develop nervous tissue but, as mentioned, remain thin and modified into *choroid plexuses* (p. 192). At three loci in the roof of the hindbrain the thin tissue degenerates forming ventriculo-subarachnoid foramina (p. 186). The remainder of the tube forms the spinal cord, its cavity persisting as the central canal.



Meanwhile, throughout the extent of the notochord the intraembryonic mesoderm becomes arranged into three zones: (1) a thickened medial portion which lies immediately lateral to the grooved neural plate (later tube) and notochord, the *paraxial mesoderm*; (2) a narrower *intermediate mesoderm*, situated lateral but directly continuous with the paraxial mesoderm; and (3) a flattened *lateral plate* which extends from the intermediate mesoderm to the periphery of the embryonic area where it is continuous with the extraembryonic mesoderm on the outer

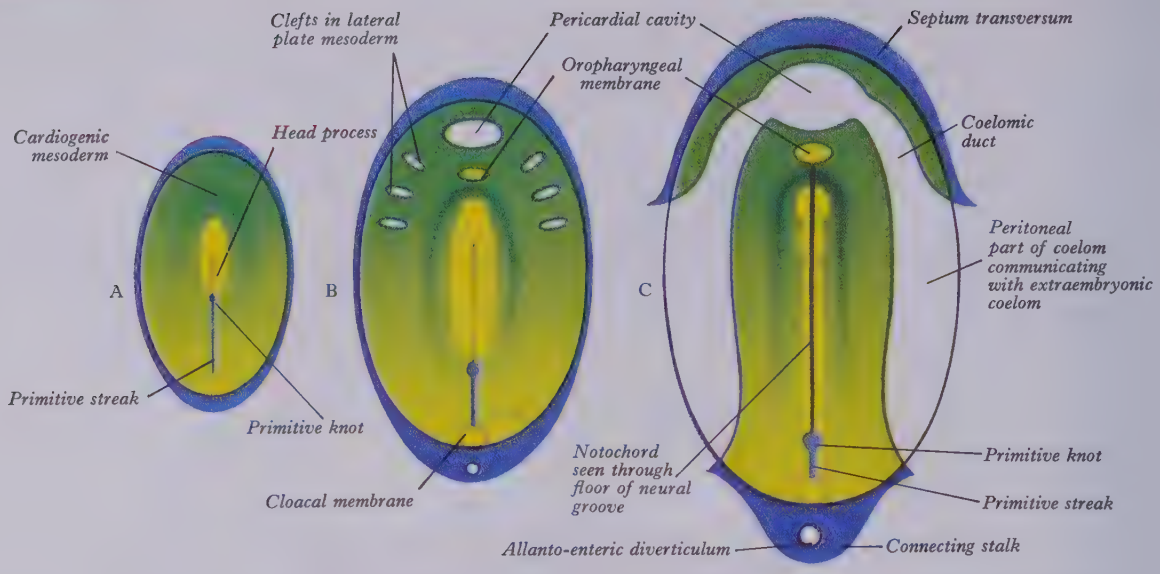
surfaces of the amnion and the yolk sac, i.e. at the *junctional zone* of mesoderm.

THE EMBRYONIC LAYERS

The appearance of the intraembryonic mesoderm and its three major medio-lateral divisions on each side completes the first stage of differentiation of the embryonic area. The embryo now consists of an outer protective and neural layer, the ectoderm, an inner nutritive layer, the endoderm, and an intermediate layer, the intraembryonic mesoderm, which is available primarily as a muscle-forming layer. It is clear from their history and their early differentiation that these layers are of considerable phylogenetic and ontogenetic significance but too much stress must not be laid on their independence from one another. The differentiation at this stage does not leave the constituent cells of the three layers with potencies so limited that complete divergence occurs in subsequent development. The developmental potential of the individual cell layers is reduced from the pluripotent condition found at an earlier period, but not to such an extent that the potencies of the cells of one layer are entirely different from those of the two remaining layers. Further, during subsequent development of the various organ systems, derivatives of the different layers are often closely interlocked and interdependent in terms of fundamental *morphogenetic mechanisms* (pp. 104–115).

However, the contributions of the three layers in the human embryo to the formation of the different systems and organs may, for convenience, be summarized:

The primitive embryonic ectoderm consists of columnar cells, which become cubical towards the periphery of the embryonic area. It gives origin to: (1) the epidermis and the lining cells of the glands which open on it, and the appendages of the skin, the hair and nails; (2) practically the whole of the nervous system, including the cranial and spinal ganglia, the sympathetic ganglia, the posterior lobe of the hypophysis cerebri and the pineal gland; (3) the chromaffin organs; (4) the anterior lobe of the hypophysis cerebri; (5) the epithelium of the cornea, conjunctiva and lacrimal gland, canaliculi, nasolacrimal sac and duct; (6) the lens; (7) the plain muscle of the iris; (8) the neuro-epithelium of the sense organs; (9) the epithelium lining the nose and paranasal sinuses, the roof of the mouth, the gums and the cheeks, the external acoustic meatus and external stratum of the tympanic membrane; (10) some salivary glands and the enamel of the teeth; (11) the epithelium lining the lower part of the anal canal and that of the terminal male urethra, scrotal and penile epidermis, also that of the female vulval (pudendal) cleft as far as and including the labia minora.



The primitive embryonic endoderm consists at first of flattened cells, which subsequently become columnar. It gives origin to: (1) the epithelial lining of the whole of the alimentary canal, with the exception of those portions already ascribed to the ectoderm; (2) the lining cells of the glands which open into the alimentary canal, including the liver and the pancreas and their ducts, but excluding the parotid salivary glands; (3) the epithelium lining the auditory tube and tympanic cavity; (4) the epithelium of the thyroid and parathyroid glands and the thymus; (5) the lining epithelium of the larynx, trachea and the smaller air passages, including the alveoli and the air saccules; (6) the epithelium of most of the urinary bladder and much of the urethra; (7) the epithelium of the prostate and many other paraurethral glands.

The intraembryonic mesoderm gives origin to the remaining organs and tissues of the body. These include: (1) all the connective and sclerous tissues and their arthroses; (2) the teeth with the exception of the enamel; (3) the whole musculature of the body, both striated and unstriated, with the exception of the musculature of the iris; (4) the blood and the blood vascular, and lymph and the lymphatic systems; (5) the urogenital system, except most of the lining of the urinary bladder, prostate and urethra—derivation of the vaginal lining is controversial; (6) the cortex of the suprarenal glands and the mesothelial linings of the pericardial, pleural and peritoneal cavities.

THE EMBRYONIC TISSUES

The cells of the embryo become arranged at this early stage into two fundamental types of tissue, *epithelial* and *mesenchymatous* and, despite regional modifications introduced as the various tissues develop, these types persist in large measure throughout life.

Epithelial tissues are those in which the cells are closely packed, with narrow intercellular clefts containing minimal extracellular material; subsequently the cells usually show inter-cell surface specializations such as desmosomes, tight junctions, gap junctions, etc (pp. 22–25). Characteristically, they clothe internal and external surfaces as simple or compound cellular sheets which separate phases of differing composition (e.g. the external environment and the subepithelial tissue fluids, intravascular and extravascular fluids, etc). Traffic of materials in the intercellular clefts between cells is limited and passage occurs across the cells and their limiting membranes, which function as energy-dependent selective barriers, enhancing the passage of some materials and impeding the passage of others.

2.28 Diagrams to illustrate the formation of the intraembryonic coelom —the embryonic area is viewed from the dorsal aspect: structures are seen developing in, or through, the epiblast. Tissues dorsal to the coelom have been removed. Fold formation not shown.

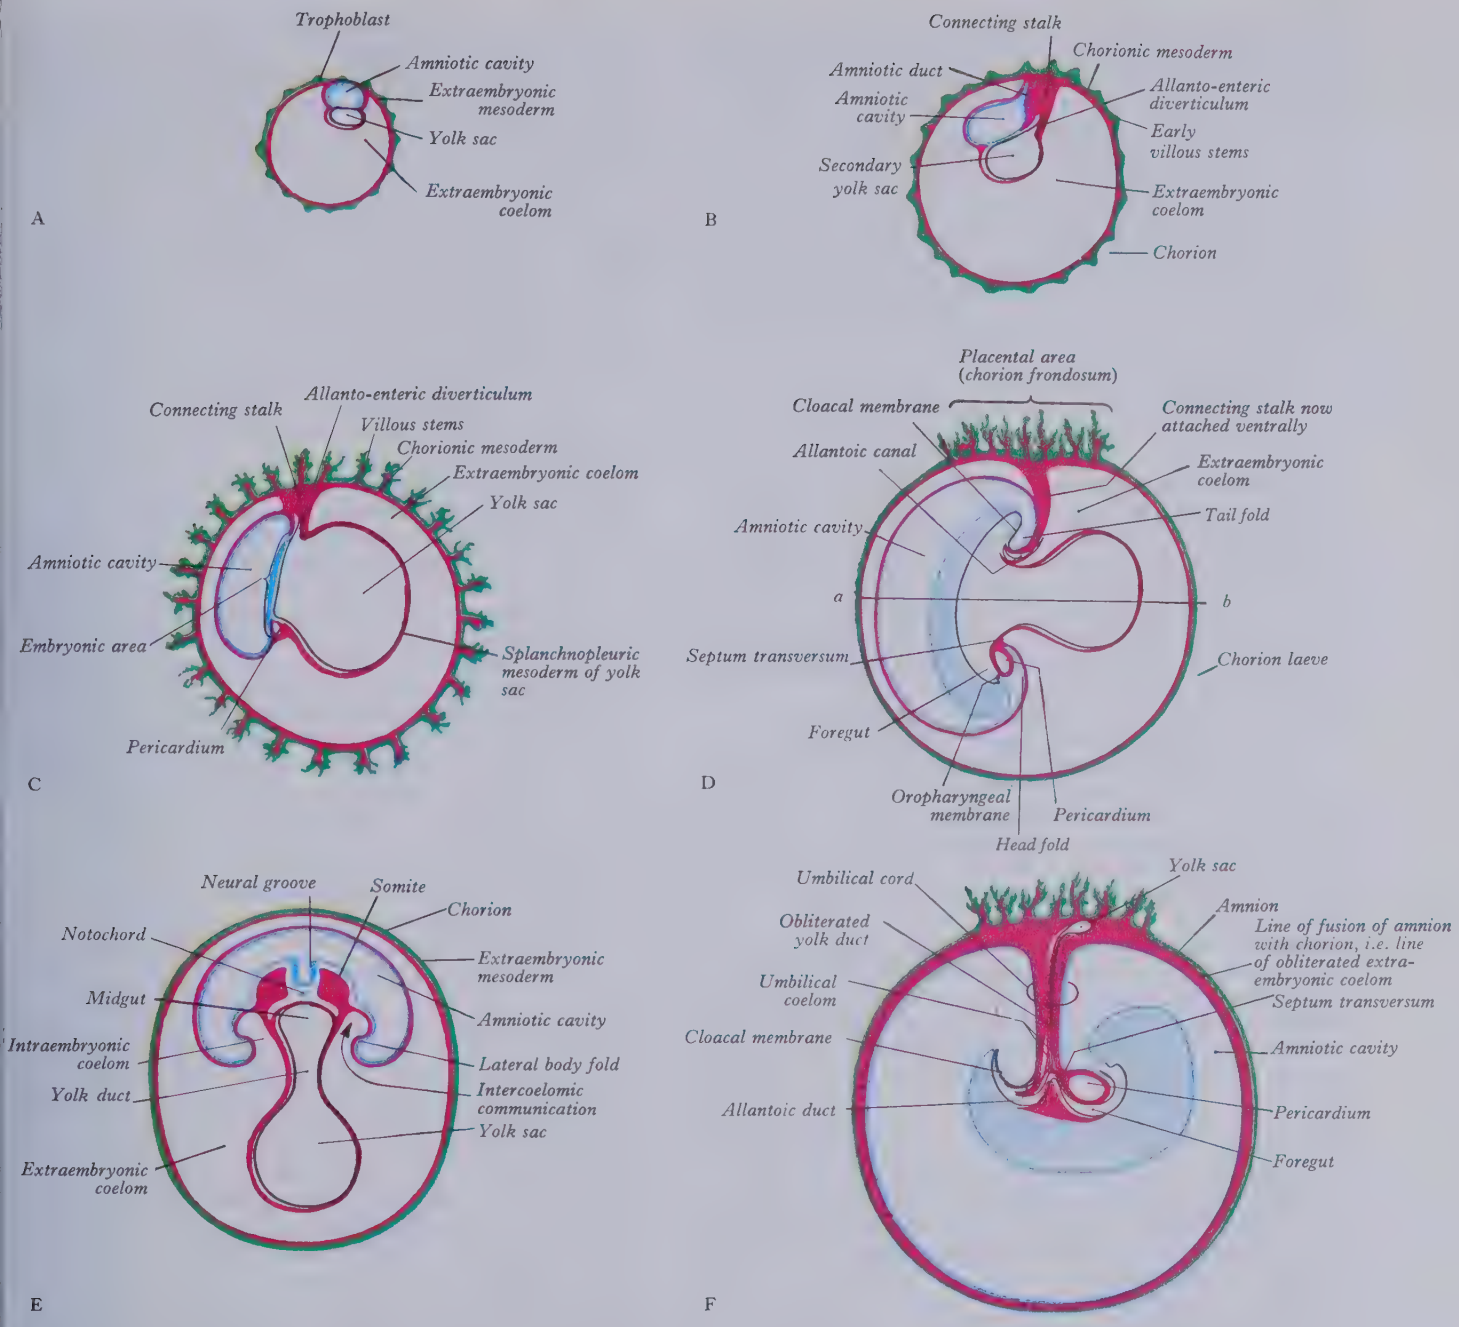
The majority of the derivatives of the embryonic ectoderm and endoderm listed above retain their epithelial character throughout life. The third germ layer, mesoderm, also contributes many tissues of an epithelial type (although they may also be termed endothelia or mesothelia depending upon their topographic site). These include the visceral and parietal mesothelia of the coelomic cavities, many of the derivatives of the intermediate mesoderm such as the pro-, meso- and metanephroi and their ducts, the paramesonephric (Mullerian) duct system and the cortex of the suprarenal gland. Further, after first passing through a mesenchymatous stage (vide infra) many mesodermal cells contribute to the formation of the widespread endothelial cell layers which line the blood and lymphatic vascular systems. Still other mesothelia develop to line the various synovial cavities of the many joints, bursae and tendon sheaths, the anterior chamber of the eye and the periotic perilymphatic space of the internal ear. The myotome of mesodermal somite origin (p. 139) also maintains an epithelial arrangement throughout its early stages.

Mesenchyme, a name first introduced over a century ago (Hertwig 1881), forms the remaining tissue of the early embryo, occupying all the regions between the various epithelial layers described above. In contrast it consists of a loosely arranged tissue with wide spaces containing copious extracellular fluid which carries a variety of hydrated mucosubstances (p. 67), suspended in which are scattered amoeboid, primitive *mesenchymal cells*. The latter usually appear stellate in fixed and stained preparations, they often show some degree of phagocytic ability and they retain a potentiality for developing into a wide array of cell types. Many mesenchymal cells are derived from various regions of the early intraembryonic mesoderm, e.g. from the lateral plate where they form the core between the limiting epithelia of the splanchnopleure and somatopleure and from the dermotome and sclerotome of the mesodermal somites (p. 140).

Mesenchymal cells are, however, not exclusively of mesodermal origin; it is probable that the extraembryonic mesenchyme of the yolk sac and chorion receive contributions from the neighbouring endoderm and cytotrophoblast respectively. Within the embryonic body considerable accessions are also received, particularly in the head region from the neural crest, placodes and the endodermal prechordal plate.

In subsequent development mesenchymal cells differentiate into many different tissues including: the general and specialized connective tissues (cartilage, bone, dentine) and their many types of attendant cell (p. 300); smooth visceral, cardiac and, in some sites, striated muscle; the endothelium of the blood and lymphatic vascular systems and any attendant musculo-adventitial walls; the various blood-forming sites, lymphoid tissue, bone marrow, spleen and the remaining elements of the reticulo-endothelial and macrophage systems; the tissues of joints including their synovial cells and those of bursae and tendon sheaths; finally the sheaths of nerves, muscles and the periostea of bones.

Subregions of the Embryonic Layers



In addition to the general summaries of the derivatives of the primitive embryonic layers given above, it may also prove convenient here to indicate the principal *subregions* of these layers and their main contributions to the developing embryo.

THE EMBRYONIC ECTODERM

This may be divided into (a) general body ectoderm; (b) neural plate; (*c*) neural crest; (*d*) ectodermal placodes.

General body ectoderm gives rise to: (1) most of the cutaneous epidermal cells; the secretory, duct-lining and myoepithelial cells of sweat, sebaceous and mammary glands; the hairs and nails; (2) the epithelia of the cornea and conjunctiva and the secretory and duct-lining cells of the lacrimal gland; (3) the respiratory nasal epithelium, the epithelia lining the paranasal sinuses, lips, cheeks, gums and palate, the secretory and duct-lining cells of the nasal, labial, palatine, general oral and salivary glands; (4) the embryonic enamel organ and dental enamel; (5) the epithelial lining of the external acoustic meatus and external epithelium of the tympanic membrane; (6) the epithelial lining of the lacrimal canaliculi, sac and nasolacrimal duct; (7) the epithelium of the lower anal canal and terminal male urethra.

Neural plate cells give rise to: (1) all the neurons of the *central* nervous system; these include not only those neurons wholly confined to the central nervous system but also those somatic motor and preganglionic efferent neurons with somata within the central system and axons which pass out into the peripheral nervous system; (2) the macroglial cells, i.e. varieties of astrocyte and oligodendrocyte; (3) generalized ependymal cells lining the ventricles, aqueduct and central canal of brain and spinal cord; (4) specialized ependymal cells, including tanycytes, those covering the choroid plexuses and distinctive regions of the third ventricle such as the subcommissural organ; (5) cells belonging to the APUD series. (The term is an acronym for cells showing characteristic amine handling properties—Amine Precursor Uptake and Decarboxylation. The evolution and modification of the concept is discussed more fully elsewhere, p. 1376 and at other appropriate points throughout the volume.) These include pinealocytes, magnocellular and parvocellular peptide-secreting neurons of the hypothalamus and reticular formation and certain

2.29A Diagram showing an early stage in development of the human blastocyst. B Diagram illustrating the early formation of the allanto-enteric diverticulum and the definition of the connecting stalk. C A later stage of the development. Observe that the heart occupies the most anterior part of the embryonic area and is separated from the prosencephalon by the oral membrane. D The formation of the head and tail folds, the expansion of the amnion, and the delimitation of the umbilicus. E A transverse section along the line *ab* in D. Observe that the intraembryonic coelom communicates freely with the extraembryonic coelom. F A later stage in the development of the umbilical cord.

It should be noted that whilst these diagrams, from an earlier edition, are useful for the general changes in disposition of the embryo and extraembryonic membranes, the modern view of development of the villous stems has been revised—consult text.

adenohypophyseal cells; (6) all retinal cells and the epithelia of the iris, ciliary body and processes.

It has been proposed, relating to (1) above, that neurons may be classified as either *central neurons* or *peripheral neurons* (Lieberman 1974); this highlights a particular mammalian distinction, but as yet has limited general usefulness.

Neural crest cells, first forming a strip of tissue flanking the neural plate then *migrating* widely, often in well-defined streams, and subsequently forming local aggregations or invading other tissues, give rise to: (1) the sensory neurons of the dorsal root ganglia of the spinal nerves; (2) many of the sensory neurons of the ganglia of the trigeminal, facial, vestibulocochlear, glossopharyngeal and vagal cranial nerves (other cranial nerves may have transient populations, see p. 200); (3) the principal postganglionic autonomic neurons of both sympathetic and parasympathetic moieties, including the enteric plexuses, ganglionated sympathetic chains, and other ganglionic aggregates associated with, e.g. the cardiac, coeliac, mesenteric, renal and vesical plexuses; (4) many specialized peripheral sensory receptor cells (see also placodes below); Schwann cells, the perisomatic satellite cells of sensory ganglia, the 'glial' elements of autonomic ganglia and peripheral receptors; (5) the basal regions of the neurocranium and viscerocranium (p. 164), in particular the trabeculae cranii and cartilages of the branchial arches and possibly the osteogenic elements that become associated with these cartilages; (6) dentine production by odontoblasts of the tooth germs; probably admixed with mesenchyme from other sources, crest cells may contribute to the special visceral striated muscles derived from

the branchial arches, and to the smooth muscle of the branchial vessels; (7) some, at least, of the meningeal pia-arachnoid; (8) cells belonging to the APUD series (vide supra and p. 1376). These include: thyroid parafollicular (C) cells derived from ultimobranchial tissue, classic chromaffin tissue (phaeochromocytes of the adrenal medulla, paraganglia and para-aortic bodies and other outlying masses, see 8.235), varieties of small intensely fluorescent (SIF) cells associated with sympathetic ganglionic neurons, the glomus (type I) cells of the carotid body (and probably many other functionally similar sites throughout the body) and finally both dermal and epidermal melanoblasts and other epidermal, non-melanoblastic dendritic cells; (9) contributions to connective tissues throughout the body. For a review of neural crest see Leikola (1976).

Ectodermal placodes are specialized patches of ectodermal cells (the named placodes being the olfactory, otic, dorsolateral, epibranchial, suprabranchial and lental) which invaginate, sometimes coming into close association with cells from other sources. They all have some characteristics in common with the neural crest and give rise to: (1) the receptor and probably sustentacular cells of the olfactory part of the nasal mucosa; (2) the epithelial walls of the membranous labyrinth and the specialized receptor cells of its utricular and saccular maculae, the ampullary crests of its semicircular ducts, and the cochlear organ of Corti; (3) *some* of the primary sensory neurons of the trigeminal, facial, vestibulocochlear, glossopharyngeal and vagal cranial nerves (although their precise contribution to these in the *human* embryo needs further clarification); (4) the crystalline lens of the eye; (5) some members of the APUD series, in particular the parathyroid chief cells. Certain authors prefer to regard the cells of the adenohypophysis as having a placodal origin through the medium of the ectodermal anlage of Rathke's pouch and similar considerations may apply to the parafollicular cells of the thyroid through the anlage of the ultimobranchial body. (The lattermay therefore imply the existence of *endodermal* 'placodes'.)

It may be noted here that, despite cautious suggestions made about two decades ago (Pearse 1966), less than 10 of the over 40 cell varieties now accepted as belonging to the APUD series have definitely been shown to stem from the neural crest. Thus the large number of varieties of enterochromaffin cells present in the mucosae of the stomach and intestines, in the pancreatic islets and other varieties found in the bronchial mucosa, the lining epithelium of the urethra and prostatic parenchyma, have an uncertain origin. Their progenitors have been hypothecated as 'neuoendocrine-programmed ectoblastic cells' and a foregut endodermal origin has been postulated for the gastrointestinal/pancreatic varieties (Pearse 1977). For a further discussion of this topic and the introduction of the term 'paraneuron' see p. 1376 and refer to Fujita 1976.

THE EMBRYONIC MESODERM

This may be divided, as noted above, into *paraxial* mesoderm, *intermediate* mesoderm and the *lateral* plate. The paraxial mesoderm, as detailed below, segments into a longitudinal series of mesodermal somites and each somite is subdivided into a sclerotome, dermotome and myotome. The intermediate mesoderm forming a longitudinal, cord-like, cylindrical mass, which is continuous medially with the somites and laterally with the lateral plate, may best be considered as a cranio-caudal series of subregions—cervical, thoracic, lumbar and sacrococcygeal. Clefts appearing in the cardiogenic mesoderm and lateral plate coalesce to form the intraembryonic coelom (vide infra). The latter separates the lateral plate into somatopleuric (body wall) and splanchnopleuric (enteric) layers, which line or cover the ectoderm and endoderm and their derivatives respectively. As it enlarges the intermediate mesoderm projects into and also forms a partial boundary for the coelom, whilst the *zones of continuity* between the somatopleuric and splanchnopleuric mesoderm, after much differential growth, excavation, repositioning and in some places adhesion, become sculpted to form the definitive gastric, enteric, hepatic and splenic mesenteries. The epithelial or mesenchymatous nature of these various zones are discussed further below and in subsequent pages.

The paraxial mesoderm, through the medium of the somites, forms: (1) the vertebrae and their associated joints and ligaments, including much of the intervertebral discs; the ribs, costal cartilages, sternal plates (ultimately manubrium, sternebrae and xiphoid process), by migrations from the sclerotomes: cells from the latter probably contribute to the dura mater; (2) the dermotomic cells migrate ventrolaterally, admixing with neural crest cells and somatopleuric lateral plate mesoderm and, together with the costal elements, form the bulk of the tissues of the body wall (vide infra); (3) the cells of the myotomes, by migration, subdivision, rearrangement and sometimes fusion of cell masses from neighbouring myotomes, ultimately differentiate into the striated musculature of the trunk. (It appears that the limb muscles and lingual muscles, although segmentally innervated, develop in situ, with little obvious migration from the myotomes.) (4) perineural mesenchyme of uncertain, but possibly myotomic origin provides the microglia of the central nervous system.

The intermediate mesoderm through its principal longitudinal subdivisions, the nephrogenic cord, genital ridge and overlying medial and lateral coelomic mesothelia, forms: (1) the rudimentary pronephric and fully functional meso- and meta-nephric renal corpuscles and nephric tubules; (2) the mesonephric (Wolffian) duct and its derivatives—the vesical trigone, ureter and renal calices and collecting tubules in both sexes; male testicular fibrocellular framework and duct complexes, the epididymis, ductus deferens, seminal vesicle, ejaculatory duct and a small area of prostatic urethra; in the female merely rudimentary but homologous vesicular, tubular and duct systems are formed (p. 260); (3) the paramesonephric (Mullerian) duct and its derivatives—the female uterine tube and uterus, the development of the vagina being more conjectural; vestigial testicular structures and prostatic utricle in the male; (4) in both sexes, the whole of the gonadal tissues with the exception of the sex cells (gonocytes) themselves; (5) from the medial coelomic bay and encroaching on to the mesonephric ridge, the cortex of the adrenal gland; (6) the connective tissue framework, capsule, mesothelial covering and, where appropriate, the mesenteries of all the foregoing.

The lateral plate mesoderm becomes split, as noted, by the intraembryonic coelom, into somatic and splanchnic layers (p. 140), the somatic mesothelial lining of the coelom forming the serous parietal pericardium, pleura and peritoneum, whilst the splanchnic mesothelial lining forms the serous epicardium, pulmonary pleura and the visceral peritoneum that wholly or partly clothes the various abdominal and pelvic organs. The *somatopleuric mesenchyme*, as mentioned above and elsewhere, receives accessions from the neighbouring neural crest, and is also admixed with invading cells from adjacent dermotomes, myotomes and (in the thoracic region) sclerotomes. Thereafter mesenchymatous condensations of heterogeneous origins appear and growth and differentiation transform them into the osseous, cartilaginous, muscular, vascular, lymphatic and connective tissues of the body wall. As the appropriate spatio-temporal patterning of these tissues occurs, they gradually receive the terminals of ingrowing bundles of axonal processes (and accompanying Schwann cells) from the neuroblasts of the ventrolateral lamina of the neural tube and from the neuroblasts of the primordial spinal and autonomic ganglia. Similar tissues and transformations are involved in the formation of the limbs, the early limb buds consisting of an external covering of ectoderm and a mesenchymatous core of mixed origin.

The splanchnopleuric mesenchyme clothes the endodermal gut tube, including the endodermal cloaca, allanto-enteric diverticulum and their various subdivisions and glandular derivatives. Its cells grow and differentiate into the non-striated muscle, connective, vascular, lymphatic and adipose tissues of the walls of the stomach, small and large intestines, urinary bladder (excluding perhaps the trigone) and also the walls of (all but the finest terminal) biliary and pancreatic duct systems. Similar tissues are provided by splanchnopleuric mesenchymal cells in the walls of the tracheo-bronchial tree down to its finest pre-alveolar passages, but with the addition of cartilage as far as the commencement of the bronchiolar system. Most of these tissues

receive the ingrowing terminals of post-ganglionic sympathetic axons and preganglionic parasympathetic terminals from the vagus (foregut and midgut and their derivatives) and the pelvic parasympathetic nerves (hindgut). Corresponding regions are invaded by postganglionic parasympathetic neuroblasts derived, it is presumed, from the vagal and sacral neural crest respectively.

It should be noted that vascular venous differentiation in the splanchnopleuric mesenchyme caudal to the developing diaphragm leads to numerous radicles draining virtually the whole of the subdiaphragmatic gut, liver, pancreas and spleen and these gradually combine to form the hepatic portal vein. In the primitive pericardial region, similar mesenchyme, including its covering mesothelium, forms all the non-nervous tissues of the heart. The spleen differentiates in the mesenchyme of the dorsal mesentery of the stomach (dorsal mesogastrium).

It should also be stressed that in the ventrolateral walls of the embryonic pharynx *no coelomic cavity* develops so that in the branchial arches there is *unsplit* lateral plate mesenchyme that has received substantial additions from the cranial neural crest and possibly also from adjacent sclerotomes and dermotomes. Thus, whilst it has become customary to loosely classify many branchial structures as 'visceral' or 'special visceral', it is by no means clear in mammals in general, and particularly in mankind, which of these sources of mesenchyme predominates in the anlage of any specific derivative.

Finally it may be mentioned that the splanchnopleuric mesenchyme of the yolk sac, liver and spleen are the earliest loci of red blood cell formation, preceding the appearance of progenitor cells in the red bone marrow.

THE EMBRYONIC ENDODERM

The main derivatives of the embryonic endoderm have already been listed above and will be further detailed in subsequent sections: to avoid excessive repetition, therefore, only some additional points or as yet unresolved questions will be mentioned here.

(1) Whilst in general it is usually stated that the endoderm forms the epithelium of the whole alimentary tract and its associated glands, from stomatodeum to proctodeum, its precise extent is less certain cranially and the origin of some of the epithelial cell types cannot be regarded as proven. The epithelia of the lips, gums, parotid glands, cheeks, dental enamel and anterior part of the hard palate are accepted as definitely of *ectodermal* origin; similarly, most authorities accept that the lingual epithelium and that of the lingual glands are endodermal; the exact site of the transition line between the two is not yet established. It must be stressed that the line does not necessarily correspond to any particular outstanding topographic landmark, such as the oropharyngeal isthmus or linguogingival sulcus, and authorities differ concerning the ectodermal or endodermal status they ascribe to the submandibular and sublingual salivary glands. In contrast, the generally accepted caudal limit of the hindgut endoderm is at the level of the anal 'valves'.

(2) The endoderm of the remainder of the post-oral foregut forms the great variety of epithelia that characterize the various zones, recesses, diverticula and glands of the pharynx and the general, glandular and duct-lining epithelia of the oesophagus, stomach and proximal duodenum. Some parts of the embryonic pharyngeal lining form endocrine glands that lose all connection with the gut, whilst other regions become associated with specialized localizations of lymphoid tissue.

(3) The origin of the hair cells of the lingual, palatal, pharyngeal and laryngeal taste buds (neural crest or 'neurally- programmed' foregut endoderm) is uncertain but, in addition to their sensory receptor function, they have been classified as members of the APUD neuroendocrine series and dubbed paraneurons (Fujita 1976).

(4) The lymphoid-associated endodermal derivatives constitute *Waldeyer's ring*: characteristically their epithelial surfaces are uneven (showing undulations, folds, crypts, fossulae, clefts or sinuses); they include the nasopharyngeal tonsil (adenoid), the (auditory) tubal tonsils, the palatine tonsils and the lingual tonsil.

(5) The pharyngeal epithelia range from respiratory, mucus-secreting, ciliated, columnar epithelium which lines the upper nasopharynx, the environs of the opening of the auditory tube and the superior part of the dorsal surface of the soft palate, together with the laryngeal vestibule, to the non-keratinized stratified squamous epithelium which lines the rest of the pharynx and palate.

(6) The epithelial lining of the auditory tube, tympanic cavity with its mesentery-like mucosal folds and internal lamina of the tympanic membrane, and of the tympanic antrum is derived from endoderm (p. 1228) and ranges from tall columnar and ciliated, through cuboidal to simple squamous in different locations.

(7) Other pharyngeal, endodermal derivatives include the general mucous glandular and duct-lining cells; the main follicular and parafollicular cells of the thyroid (from different locations); parathyroid secretory cells (debate persists concerning their origin—Fujita 1976, Pearse 1977); and the cytoreticulum and concentric corpuscles of the thymus.

(8) Little is to be added to the widely held view that the great majority of the epithelial cells, glandular and duct-lining cells of the oesophagus, stomach, jejunum, ileum, colon, rectum and upper anal canal are of endodermal origin: similar considerations applying to the hepatocytes and duct-lining epithelia of the biliary duct system and to the pancreatic acinar and duct-lining cells: again the majority of epithelial cells—ranging from tall columnar ciliated and mucus-producing to an extremely attenuated simple squamous type—that line the whole of the tracheobronchial-alveolar respiratory tree are endodermal in origin. A similar derivation is also accepted for most of the transitional epithelium lining the urinary bladder and urethra and for the parenchymal secretory cells of the prostate and lesser urethral glands. In almost all these locations, however, as intimated above, are numerous cell types loosely termed *enterochromaffin cells*: characteristically these show properties of *receptor mechanisms* on their surfaces and the production of *neuroendocrine secretions* and *neurotransmitter-like* substances. (Not all the cells postulated as enterochromaffin have, as yet, fulfilled all these criteria.) Particular interest has been focused upon the pancreatic islet cells and the so-called neuro-insular complex (p. 1384).

(9) Finally, reference must be made to the possible relationship between endodermal cells and the haemopoietic stem cells (p. 675) and to the origin of the primordial sex cells (p. 254).

SEGMENTATION OF THE MESODERM

In all vertebrate embryos the intraembryonic mesoderm becomes incompletely divided by a longitudinal groove into a *paraxial part* and a *lateral plate*, on each side of the midline (**2**.27). The mesoderm in the floor of the groove which connects these two parts is the *intermediate mesoderm*, most of which subsequently forms the *nephrogenic cord*. The latter progressively expands into the coelomic cavity and further longitudinal grooves develop delineating its medial and lateral limits and principal subdivisions. Soon after the appearance of the initial longitudinal groove the paraxial mesoderm becomes subdivided into prismatic blocks by a series of transverse grooves (**2**.26, 27). This is termed *segmentation of the mesoderm* and the blocks of paraxial mesoderm so formed are the *mesodermal somites (primitive segments* or *metameres*). Commencing at the end of the third or the beginning of the fourth week in the region of the hindbrain, the process extends in a *cranio-caudal direction*, additional somites being added as the embryo grows in length until 42–45 pairs are present (**2**.125). The most cranial four or possibly five lying alongside the hindbrain participate in the formation of the skull and are named the *occipital somites*. However, other workers (de Beer 1937, Sensenig 1957) have suggested that originally nine somites were involved in the elaboration of part of the skull. The remainder flank the spinal cord and usually number: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 8–10 coccygeal. Variations in this sequence may occur, usually involving either an additional or a missing segment in either the thoracic, lumbar or sacral regions, a variation in one region often being accompanied by a compensatory variation in a neighbouring region. The first occipital pair are often asymmetrical in their degree of development and one or

both may be partly or completely suppressed. Some hold that mesodermal masses, serially homologous with the segmented paraxial mesoderm, arise beside the cranial tip of the notochord, the anlagen of the extrinsic ocular muscles (**2**.54). (For experimental data concerning mesodermal segmentation in higher vertebrates consult Bellairs 1971; for more recent analyses, hypotheses and related bibliographies see Burgess 1981, 1983.)

In the *human embryo* it is only the *paraxial* mesoderm alongside the notochord which is physically segmented but, in view of the obviously segmental arrangement of the nerves of the spinal cord and their areas of distribution to all the various embryonic layers, it is reasonable to suppose that forms of segmentation of other structures are present although more difficult to display.

This basic *metameric segmentation* is a characteristic feature of the whole phylum Chordata and is particularly well seen in the primitive miolecithal forms in which, after gastrulation (p. 102 and **2**.3), the mesoderm arises as a series of evaginations from the archenteron, which form independent, paired, segmental, coelomic, mesodermal pouches. These expand, separating the ectoderm from the endoderm until they meet dorsal and ventral to the gut as permanent dorsal and (often temporary) ventral mesenteries. It is quite evident that in these forms the metameric segmentation involves not only paraxial structures but the intermediate mesoderm and both somatopleure and splanchnopleure (and the coelom itself).

THE SOMITE

A typical human *mesodermal somite* consists of tightly packed (epithelioid) cells and at first contains a transient central cavity which is, however, soon obliterated by cells proliferated from its walls. The ventromedial cells, the *sclerotome*, become mesenchymatous and migrate medially to provide the tissue from which the axial skeleton is ultimately derived (p. 159). The dorsolateral somite cells form a *dermomyotome*. Spindle-shaped cells proliferate from its margins to form a tightly packed cellular mass on its medial aspect, the *muscle plate* or *myotome* (p. 175). The remaining epithelially arranged cells constitute the *skin plate* or *dermotome* (**2**.27D). The myotome is the forerunner of much of the striated musculature of the body (p. 175) and, after it has commenced differentiation, the cells of the dermotome lose their epithelioid character and become mesenchymatous. They spread to mix with the somatopleuric mesenchyme and, probably with accessions from the neighbouring neural crest, lay down the foundation of the dermis.

THE EARLY INTRAEMBRYONIC COELOM

During early somite formation a midline cavity appears in the *cardiogenic mesoderm*, the first indication of the *intraembryonic coelom*. As segmentation of the mesoderm proceeds, a number of clefts are also formed on each side in the lateral plate mesoderm. The clefts expand, gradually coalesce and the lateral plate becomes divided into a *somatic* and a *splanchnic* layer (**2**.27, 20). The somatic layer, with its covering of ectoderm, constitutes the *intraembryonic somatopleure* whilst the splanchnic layer, with the underlying endoderm, constitutes the *intraembryonic splanchnopleure*.

The lateral extremities of the cavity in the cardiogenic mesoderm curve to extend caudally and link up with the coalescing clefts in the lateral plate and as a result the intraembryonic coelom is formed as an inverted U-shaped tube, from which the pericardial, pleural and peritoneal cavities are subsequently developed. Around the periphery of the embryonic area the somatopleuric and splanchnopleuric mesoderms are continuous, at first both with each other and with the similar extraembryonic layers, at the *junctional zone* mentioned previously. Soon, however, the process of cavitation in the lateral plate extends beyond the embryonic area and the continuity between these layers is broken; the intraembryonic coelom is now thrown into free communication with the extraembryonic coelom (**2**.27C, 28C, 29C). This process, however, is limited to the lateral regions; it does not affect the rostral rim of the pericardial area or the regions immediately adjoining it on either side, where the median *primitive pericardial cavity* now opens into bilateral *pericardioperitoneal canals (coelomic ducts)* (**2**.28C). Accordingly, the junctional mesoderm around the rostrolateral border of the embryo which will form the *septum transversum* and *primitive ventral mesentery* of the foregut (p. 232) remains intact, as does the caudal junctional mesoderm which continues into the connecting stalk (**2**.28C).

The early formation of the intraembryonic coelom and its free communication with the extraembryonic coelom allows the fluid which fills the latter to gain access to the interior of the embryo. It thus provides a path for the passage of nutrients during the period which still has to elapse before the establishment of a blood vascular circulation (Streeter 1942). The walls of the coelom are formed of undifferentiated mesodermal cells (*mesoblasts*) which rapidly proliferate. From the mesoblasts of the somatopleure, together with those derived from the dermatome and some neural crest, the corium and subcutaneous tissues and numerous other mural connective tissues are formed. Splanchopleuric mesenchymal cells, on the other hand, later differentiate into the muscles, blood vessels, lymphatics, adipose and connective tissues of the walls of the heart and gastrointestinal tract.

It is not until later that the mesoblasts which directly line the coelom itself become differentiated into the mesothelia which characterize the various serous membranes (pp. 51, 135).

The Formation of the Embryo

Hitherto, the embryonic area, initially bilaminar and later trilaminar, has been essentially a *flattened* disc which changes to an oval and then a piriform outline. Towards the end of the third week, however, the embryo begins to assume its definitive shape. The immediate cause is the difference in the rate at which adjoining areas grow. The periphery fails to keep pace with that within the embryonic area and, as the embryo is increasing more rapidly in its long axis, especially at its cranial end where the walls of the neural groove are expanding to form the forebrain, both extremities tend to project beyond the original limits of the area (**2**.29). In this way a *head fold* is developed cranially and a *tail fold* caudally. Similtaneously, and for similar reasons, less prominent right and left *lateral body folds* develop and the extension of these four folds (**2**.29) gradually constricts off the embryo from the yolk sac and imparts its characteristic shape. The latter has been described as 'comma-like', increasingly convex dorsally, expanded cranially and tapering to a curved cauda (tail) concave ventrally; the whole progressively projects into the ballooning amniotic cavity.

Resulting from head fold formation, the prosencephalon, which was hitherto separated from the cranial extremity of the embryonic area by the oropharyngeal membrane (p. 132) and pericardium, comes to lie at the extreme cranial tip of the embryo. This alteration in position of the forebrain is accompanied by a corresponding alteration in the relative positions of the membrane and pericardium (**2**.29 C–F). The former now lies on the *ventral surface* and forms the floor of a depression, the primitive mouth or *stomatodeum*. Cranially the stomatodeum is bounded by the projecting forebrain, and caudally by the pericardium. The latter has not only altered its position relative to the cephalic extremity of the embryo but has also undergone a reversal of its surfaces and cranio-caudal limits, as will be examined below.

In addition to these positional alterations and reversals, head folding results in the inclusion within the embryo of a portion of the yolk sac, now termed the *foregut (proenteron)*. The latter is thus placed with the oropharyngeal membrane and pericardium on its ventral aspect and with the hindbrain placed dorsally. It communicates at its caudal end with the *midgut (mesenteron)* through an opening, the *anterior intestinal portal*.

The ventral bend of the head fold is associated with a correspondingly pronounced *midbrain flexure* which is concave ventrally and which underlies a projecting dorsal convexity (*midbrain prominence*) of the overlying ectoderm, seen to best advantage when the embryo is viewed from the side (e.g. **2**.55).

Before tail fold formation, the *caudal* end of the embryonic area is anchored to the trophoblast by the connecting stalk, which is covered on one aspect by the amnion (**2**.29C). The formation of

the tail fold carries the attachment of the connecting stalk round on to the *ventral* aspect of the embryo so that it now assumes the permanent attachment site of the umbilical cord. It will be remembered that the stalk was originally connected to the embryo at the caudal end of the primitive streak (but separated from it by the cloacal membrane (vide infra) and in consequence the primitive streak also extends around and reverses towards the ventral aspect of the embryo to the region which later lies immediately adjacent to the anal orifice. Some, however, hold the view that the primitive streak is continued into the rudimentary tail and does not appear in the perineum or on the ventral surface of the embryo.

Just as a recess of the yolk sac is included within the head fold to form the foregut, so a corresponding part is included within the tail fold to form the *hindgut (metenteron)*. But the similarity between these two included recesses goes further. A portion of the endoderm (earlier the prechordal plate, p. 132) in the floor or ventral wall of the foregut is in direct contact with the ectoderm over an area termed the *oropharyngeal membrane*. This membrane soon disappears and the communication of the gut with the exterior through the mouth is thus established. In part of the hindgut a similar relationship exists. As we have seen, even before the tail fold is defined, the ectoderm and endoderm are in contact with each other at the caudal end of the embryonic area, forming the *cloacal membrane*. As will be described later, this membrane subsequently breaks down in two places to form the *urogenital* and *anal orifices*.

Before tail fold formation an endodermal diverticulum arises from the dorsocaudal wall of the yolk sac and grows into the mesoderm of the connecting stalk (**2**.21). This outgrowth is the *allanto-enteric diverticulum* (**2**.29B). As the tail fold is defined, the proximal part of the diverticulum becomes incorporated in the hindgut and its distal part persists as the *endodermal allantoic duct* (p. 143), which then communicates directly with the *ventral* surface of the hindgut. The region of hindgut caudal to this communication expands to form the *endodermal cloaca* (p. 233). As tail fold formation continues, the cloacal membrane itself also progressively becomes intercalated in the ventral wall of the hindgut, even extending on to the adjoining caudal aspect of the connecting stalk, where it is associated with the allantoic part of the allanto-enteric diverticulum. Even before the latter is incorporated in the hindgut, the cloacal membrane becomes interrupted and shortened by the interposition of mesoderm between the endoderm of the diverticulum and the covering epithelium of the body stalk (Florian 1930).

Between the head fold and the tail fold the embryo, as noted, additionally becomes constricted off by right and left *lateral body folds*. The intervening dorsal portion of the yolk sac, which these folds gradually include within the embryo, constitutes the *midgut (mesenteron)*. At first the midgut communicates freely on its ventral surface with the rest of the yolk sac but the continued growth of all the folds results in a narrowing of the connection, which becomes drawn out as the *splanchnopleuric yolk stalk* (vitello-intestinal duct) which contains the *endodermal yolk duct* (**2**.29E, F). The remainder (distal part) of the yolk sac remains extraembryonic (paraplacental) and is often termed the *umbilical vesicle*. The subsequent history of the duct and the vesicle will be dealt with later.

THE NUTRITION OF THE EMBRYO

In early development the blastomeres derive their nourishment in part from the store laid up within the cell body of the primary oöcyte. Such stores are possibly maintained at a high concentration and are subsequently liberated in a more dilute form for absorption from the cavity of the blastocyst and later from the primary and secondary yolk sac cavities (p. 130). In addition, it is assumed that the blastocyst derives nourishment from tubal and uterine secretions, subsequently, during the process of embedding, from products stemming from the lysed uterine tissues. Then follows a period of about 2 weeks during which the embryonic disc is dependent on the nutriment it can obtain from the fluids which fill the cavities of the amnion, the coelom and the yolk sac. These fluids contain material absorbed by the trophoblast from the lysed uterine tissues and extravasated maternal blood, selectively modified perhaps, as they pass through the cellular walls of these various cavities. However, at an early stage in development these sources of supply are much diminished. The lumen of the neural tube is isolated by closure of the neuropores, the extraembryonic coelom becomes greatly reduced (**2**.29D,F) and is later shut off from the intraembryonic coelom, and the obliteration of the yolk duct separates the yolk sac from the gut. It therefore becomes imperative that some other source should be available at an early stage. This involves the maternal circulation coming into close, although indirect, *apposition* with the developing embryonic circulation.

The differentiating mesenchyme in which the embryonic vessels and erythrocytes develop, *angioblastic tissue*, is probably first formed from the deepest layer of mesenchyme which clothes the endoderm of the yolk sac early in the third week (p. 206).

Slightly later, angioblastic tissue can also be recognized in the connecting stalk and mesenchyme of the chorion, and it then appears also within the embryonic area. Tissue spaces form in the angioblastic tissue and the cells which line them differentiate into typical, flattened endothelial cells whilst adjoining spaces join to form capillary plexuses. While the yolk sac spaces are forming, small, localized groups of mesodermal cells project into them and become cut off to form *blood islets*, their cells differentiating into embryonic erythrocytes (pp. 206, 675).

The vessels formed in the chorion soon establish an intimate relationship with maternal circulation (**2**.32, p. 145). Vessels develop in the embryo as two longitudinal channels which, at their headward ends, invade the wall of the pericardium; the position and direction of the invasion changes with the progress of head fold formation. They are the rudimentary right and left dorsal aortae and, after folding their cranial ends, curve ventrally in the lateral wall of the pharynx to reach the cranial end of the pericardium, where they fuse, becoming continuous with the developing primitive tubular heart. Caudally the aortae traverse the connecting stalk as the rudimentary umbilical arteries and break up into capillaries in the chorion. The venules from the chorion converge on the stalk where they form the right and left umbilical veins, which run headwards in the somatopleure, close to the margin of the embryonic area, to reach the caudal end of the tubular heart.

The pericardial cavity never communicates directly with the extraembryonic coelom, and (before head folding) at its craniolateral limits the somatopleure and splanchnopleure are continuous (**2**.81A). With formation of the head fold the mesodermal masses extending from surfaces of the pericardium are altered in disposition or even reversed and the original cranial mass comes into intimate relation with the *ventral* wall of the foregut as far as the cranial rim of the anterior intestinal portal (**2**.29C). After reversal the caudal wall of the pericardium deepens dorsoventrally; the mesenchyme between it, the gut and proximal yolk stalk forms a sheet, which is the *septum transversum*. (It has been noted that prior to reversal this mesoderm formed a U-shaped mass intervening between the pericardium and the extraembryonic coelom, p. 140). The post-reversal septum transversum plays an important part in the later development of the diaphragm (p. 239). At this stage it is bounded on its headward surface by the pericardium and on its caudodorsal surface by the foregut; on its dorsolateral surface it is limited by the bilateral coelomic ducts, which connect the pericardium with the peritoneal cavity, and on its caudolateral surface by the single crescentic opening of the peritoneal cavity into the extraembryonic coelom. The umbilical and body wall veins, which run in the somatopleure, and the

vitelline veins, which run in the splanchopleure, meet in the junctional mesoderm of the septum transversum and so gain the venous end of the heart. Through these various channels the early embryonic circulation is established (p. 213, et seq.).

The Fetal Membranes and Placenta

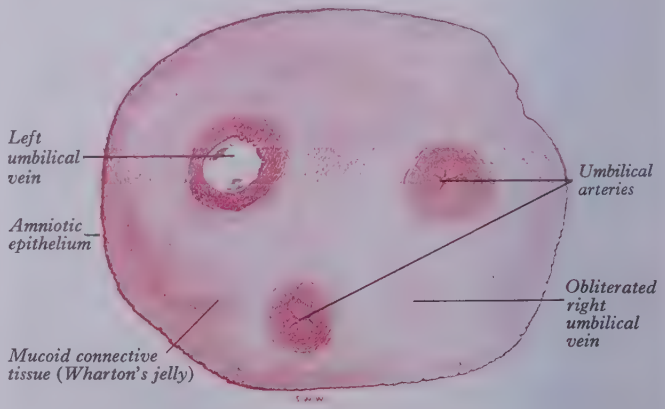
THE ALLANTOIS

The allanto-enteric diverticulum (2.29B, C) arises early in the third week as a solid, endodermal outgrowth from the dorsocaudal part of the yolk sac into the mesoderm of the connecting stalk. It soon becomes canalized and, when the hindgut is developed, the proximal (enteric) part of the diverticulum is incorporated in its ventral wall and the distal (allantoic) part remains as the allantoic duct and is carried ventrally to open into the ventral aspect of the cloaca or terminal part of the hindgut (2.29A–F). The diverticulum, lined with endoderm, is surrounded by mesoderm of the connecting stalk, in which the umbilical vessels develop at a slightly later stage.

In reptiles, birds and many mammals the allantoic diverticulum develops into a stalked vesicle which continues expanding into the extraembryonic coelom and forms a vascular organ to which the term *allantois* should perhaps be restricted. In birds it projects to the right side of the embryo and gradually spreads over the dorsal surface of the embryo as a flattened sac between the amnion and the chorion (serosa), and ultimately also spreads to surround the yolk sac. Its outer wall becomes applied to, and fuses with, the chorion (forming an *allantochorion*) which lies immediately inside the shell membrane. Blood is carried to the allantoic sac by two *allantoic* (or *umbilical*) *arteries*, which are continuous with the primitive aortae, and, after circulating through the allantoic capillaries, is returned to the heart by (initially) two *umbilical veins*. In this way the chorio-allantoic circulation, which is of the utmost importance in connection with the respiration and nutrition of the chick, is established. Oxygen is taken from, and carbon dioxide is given up to, the atmosphere through the porous egg-shell. Simultaneously nutritive materials are absorbed from the yolk by the network of blood capillaries in the splanchnopleuric wall of the yolk sac. This net is fed and drained to the embryonic body via *vitelline arteries* and *veins*, constituents of the yolk stalk. With the formation of the amnion the embryo is, in most mammals, separated entirely from the chorion and is not united to the chorion again until the allantoic mesenchyme spreads to become applied to its inner surface. The human embryo, however, is never wholly separated from the chorion, its caudal end being from the first connected with the chorion by a thick band of mesoderm, the *connecting stalk*, which accordingly is regarded as precociously formed *allantoic mesoderm*.

THE AMNION

This is a membranous sac which surrounds the embryo; it is developed in reptiles, birds and mammals (Amniota), but not in amphibia or fishes (Anamniota).



In the human embryo the amnion appears as a cavity within the inner cell mass adjacent to the overlying trophoblast. (For details see p. 129 and Luckett 1975.) This cavity is roofed by a stratum of epithelial cells, and its floor is formed by the cells of the embryonic germ disc—continuity between the roof and floor being at the margin of the disc. In the first half of pregnancy the epithelial cells are flattened and contain abundant glycogen; in later stages they become cuboidal or columnar over the placenta, the glycogen diminishes in amount and lipid globules appear in the cytoplasm (Goto 1959). Ultrastructurally, two types of amniotic epithelial cell have been described (Thomas 1965): the 'Golgi type' and the 'fibrillar type'. The former has a pronounced Golgi apparatus and a considerable content of rough endoplasmic reticulum and membrane-bound vesicles; the fibrillar cytoplasm of the latter contains few organelles. Possibly they are physiological variants of the same cell. Their free surfaces are beset with irregular microvilli embedded in a surface coat, whilst their deep surfaces rest on a basement membrane. The intercellular clefts present scattered desmosomes, but elsewhere the clefts widen and contain interlacing microvilli between which complex tubules penetrate the cell cytoplasm. These features suggest an active role in selective transport across the membrane (Lister 1968, Wynn & French 1968).

Externally the amnion is covered with a thin layer of somatopleuric extraembryonic mesoderm, which is continuous at the margins of the disc both with the splanchnopleuric extraembryonic mesoderm covering the yolk sac and with the intraembryonic mesoderm. Through the connecting stalk it is continuous also with the extraembryonic chorionic mesoderm.

Fluid, the *liquor amnii*, occupies the amniotic cavity and increases steadily in volume as the sac gradually expands in the extraembryonic coelom (2.29); this continues until the coelom is obliterated, except for a small volume which is enclosed within the proximal part of the umbilical cord (the *umbilical coelom*). The liquor amnii increases in quantity up to the sixth or seventh month and then diminishes somewhat; at the end of pregnancy it is usually about a litre. It provides a buoyant medium which supports the delicate tissues of the young embryo and allows free movement of the fetus during the later stages of pregnancy. It also diminishes the risk to the fetus of injury from without. It contains less than 2% of solids, including urea, inorganic salts, a small amount of protein and frequently a trace of sugar.

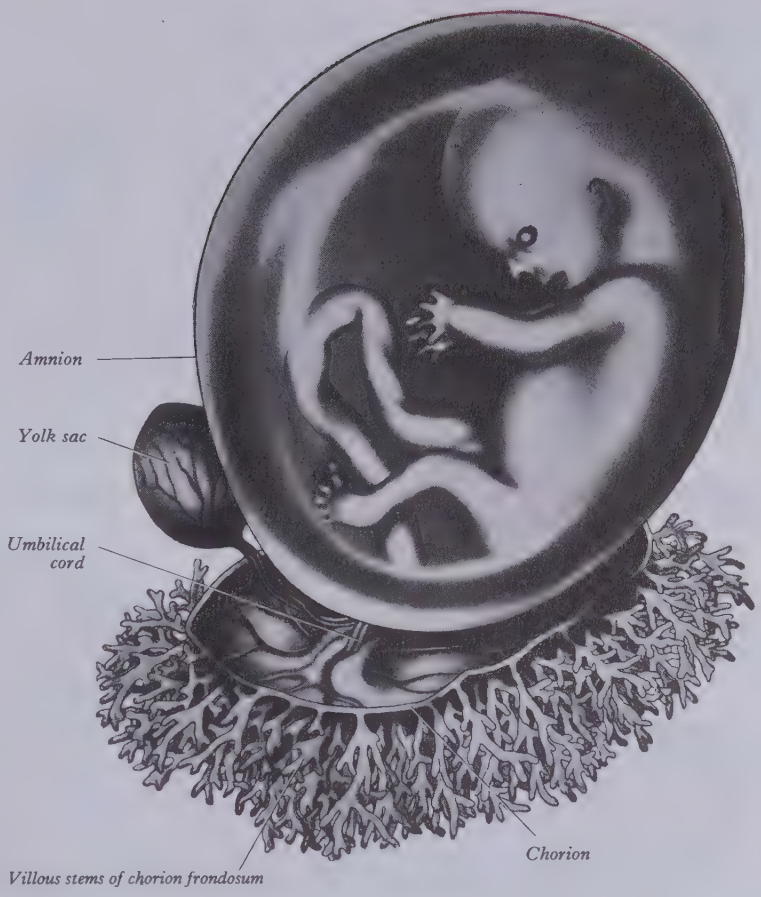
The source of the liquor, whether fetal, maternal or both, is not finally settled. Its volume is regulated by a multiplicity of factors, both fetal and maternal, but it is suggested that normally it is predominantly fetal in origin (Davies 1960). In the early stages it resembles blood plasma in composition and is probably formed largely by transport across the amniotic membrane but as pregnancy advances it becomes progressively more dilute, partly by the addition of fetal urine. It has been shown experimentally that there is a considerable and rapid flux of water across the amniotic membrane. There is rapid exchange between the amniotic fluid and maternal and fetal circulations, probably via the placenta and fetal kidneys. By the end of the third month the expanding amnion has extensive contact with the chorion and only these thin membranes separate the amniotic fluid from the decidua parietalis, the tissues and vessels of which may provide another route for the exchange of water and dissolved substances (Plentl 1958). A volume of amniotic fluid in excess of 2 litres is generally considered to be abnormal and constitutes *hydramnios*. A deficiency is termed *oligamnios*. Both conditions may be associated with fetal abnormalities, e.g. fetuses with agenesis of the kidneys or atresia of the lower urinary tract are often associated with oligamnios.

It has been suggested that fetal swallowing of amniotic fluid is a normal occurrence, and also that respiratory movements aspirate some fluid into the fetal lungs. In either case the fluid may be absorbed into the fetal circulation and then pass the placental barrier into the maternal circulation. Cases of oesophageal atresia or anencephaly, in which swallowing is impossible or impaired, and open spina bifida are often associated with hydramnios. With these neural defects, impaired swallowing is accompanied by direct discharge of cerebrospinal fluid into the amniotic liquor.

2.30 Transverse section through a human umbilical cord. Stained with haematoxylin and eosin. Magnification × *c*.8.

THE CONNECTING STALK AND UMBILICAL CORD

The connecting stalk (**2**.29) is, as described above, a mass of precociously formed allantoic mesoderm, which at first connects the caudal end of the embryonic area with the chorion. Proximally (its embryonic end) it surrounds the short allanto-enteric diverticulum but it is traversed throughout its length by the umbilical (allantoic) vessels. At first its dorsal surface is covered with the amnion and its ventral surface is bounded by the extraembryonic coelom. As a result of the folding of the embryo and distension of the amnion, the embryonic end of the connecting stalk comes to lie on the ventral surface of the embryo, and its mesoderm approaches that covering the yolk sac and its stalk. With continued expansion of the amnion, the extraembryonic coelom is largely obliterated (**2**.29) and its only remaining part surrounds the elongating yolk stalk; this part still communicates freely through the umbilicus with the intraembryonic coelom. The mesoderm-covered surfaces of the head, tail and folds of the expanding amnion now reach the chorion and converge on the connecting stalk and yolk stalk (and their vessels), and the umbilical cord is formed as they meet and their mesoderms fuse (**2**.29) thus almost completely closing off the intra-embryonic coelom. A limited exocoelomic recess persists in the embryonic end of the cord (umbilical coelom), retaining its communication with the intraembryonic coelom, and is involved in later enteric development (vide infra and p. 232).



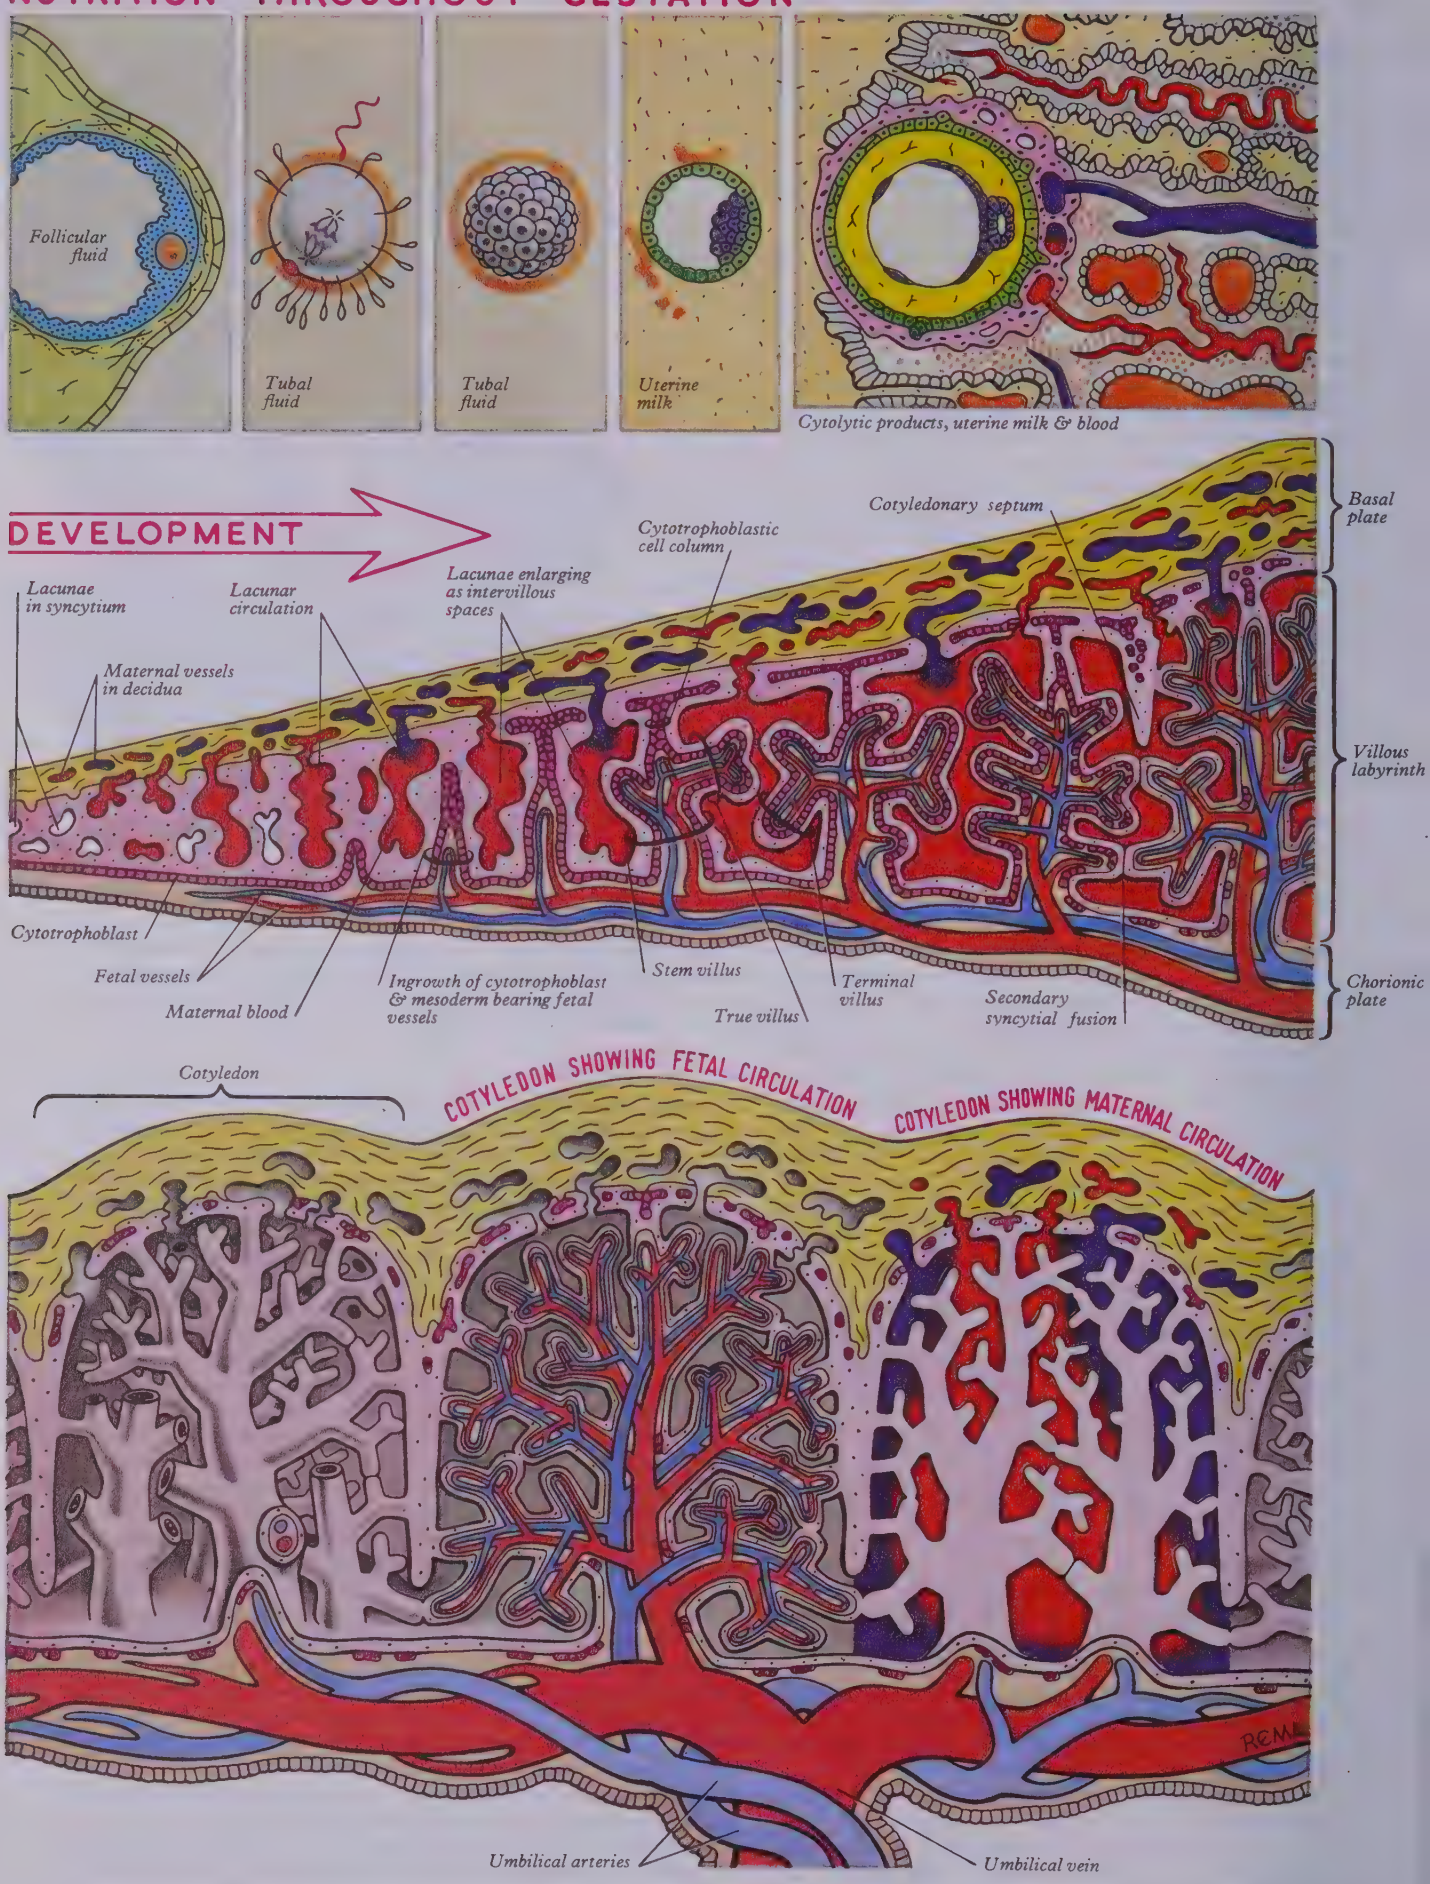
The umbilical cord (**2**.30) thus consists of an outer covering of flattened amniotic epithelial cells, containing an interior mass of mesoderm of diverse origins (vide infra). Embedded in the latter are two endodermal tubes—the yolk and allantoic ducts—their associated vitelline and allantoic (umbilical) blood vessels and, near its fetal end, the remains of the extraembryonic coelom mentioned above.

The *mesodermal core* is derived from the somatopleuric extraembryonic mesoderm covering the amniotic folds: the splanchnopleuric extraembryonic mesoderm of the yolk stalk which carries the vitelline vessels and clothes the endodermal yolk duct; and similar allantoic mesoderm of the connecting stalk which clothes the allantoic duct and carries initially two umbilical arteries and two umbilical veins. These various mesoderms fuse and are gradually transformed into the viscid, mucoid connective tissue (*Wharton's jelly*) which characterizes the more mature cord. The tissue consists of widely spaced fibroblasts separated by an extensive intercellular space filled with a copious matrix consisting of a delicate three-dimensional meshwork of fine collagen fibres surrounded by a dilute ground substance containing a variety of hydrated mucopolysaccharides. In specimens which have been excised *before* fixation and staining, the fibroblasts present stellate profiles, as they do in other areas of mucoid tissue when similarly prepared. However, it has been shown that if the tissue is fixed *before* any haemodynamic collapse and consequent modification of the jelly has occurred, the cells are long and strap-like and present a regular orientation (Parry 1970).

The part of the extraembryonic coelom (the *umbilical coelom*) included in the base of the umbilical cord acts as a sac which receives the normal *umbilical hernia* of the midgut, developing in the embryo between the sixth and tenth weeks (p. 232). After the disappearance of this hernia the extraembryonic coelomic sac is normally obliterated.

The yolk sac becomes located between the amnion and chorion as they fuse near the placental attachment of the cord (**2**.29, 31, 40)—it continues to grow slowly and is sometimes found at term in this site, as a small vesicle usually less than 5 mm in diameter. The yolk stalk and its contained endodermal duct and accompanying vessels gradually elongate with growth in length of the umbilical cord. The duct and vessels slowly degenerate and they have usually disappeared by mid-pregnancy.

The endodermal allantoic duct, which is confined to the proximal end of the growing cord, also elongates and thins but may persist as an interrupted series of epithelial strands until term. At the umbilicus the proximal strand is often continuous with the median intra-abdominal *urachus*, which in turn continues into the apex of the bladder (p. 258).



2.31 A fetus of about 8 weeks, enclosed in the amnion, magnified about $2\frac{1}{2}$ diameters. A part of the chorion frondosum with its branching villous stems is shown in the lower part of the figure. The villous stems have been detached from the basal plate, which is not shown here.

Usually, the embryonic right umbilical vein disappears in the early months of pregnancy (and exceptionally only one artery may persist). The vessels of the umbilical cord are rarely straight but usually show a twisted conformation which may exist as either a right- or left-handed cylindrical helix. The number of turns involved may be relatively few or, at the other extreme, may even exceed 300. Their causation has been variously ascribed to unequal growth of the vessels, or to torsional forces imposed by fetal movements; their functional significance is obscure; perhaps their pulsations and contractions (vide infra) assist the venous return to the fetus in the umbilical vein. When fully developed the umbilical vessels, particularly the arteries, are provided with a strong muscular coat which contracts readily in response to mechanical stimuli. The outermost muscle bundles pursue an interlacing spiral course so that, when they contract, they produce shortening of the vessel and thickening of the media, with folding of the interna and considerable narrowing of the lumen. This action may account for the periodic sharp constrictions of contour—the so-called *valves of Hoboken* which often characterize these vessels.

When fully developed, the umbilical cord is on average some 50 cm long and 1–2 cm in diameter, but the length is subject to great variation (20–120 cm). Obstetrical complications during labour may accompany an exceptionally short or long cord.

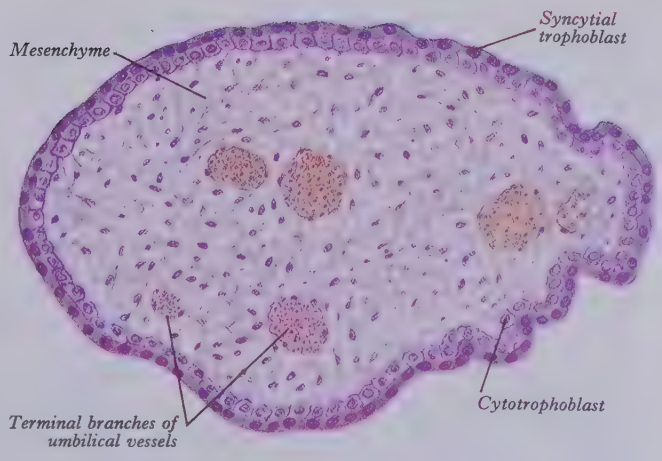
Cords may also exhibit *knots* which are 'true' or 'false'. True knots presumably follow some exceptional form of fetal movement in utero, and may embarrass the circulatory flow in the umbilical vessels. False knots are sharp variations in contour which may reflect abnormally pronounced looping of one of the umbilical vessels, or a local accumulation of a mass of Wharton's jelly. For variations in the placental attachment of the cord see p. 156, and for further details of its morphology and an extensive review of the relevant literature see Boyd & Hamilton (1970).

2.32 Nutrition of oöcyte, zygote, morula, free and embedded blastocyst, embryo and fetus, throughout gestation. Blastocystic and placental development proceed from left to right. Aspects of mature placental structure and circulation are shown below.

As noted (p. 125), fertilization occurs in the lateral or ampullary part of the uterine tube, and is immediately followed by cleavage. The segmenting zygote is conveyed along the tube to the uterine cavity by ciliary action of the tube aided by muscular tubal contractions, the journey occupying about 3 days. Approaching the uterine lumen the morula becomes a blastocyst still surrounded by the zona pellucida. The lysis of the zona and the formation of polar syncytial trophoblast over the formative mass are prerequisites for its implantation in the uterine mucosa (see pp. 127, 129). In the interval between ovulation and blastocyst arrival in the uterine cavity, preimplantation changes also occur in the uterine mucosa. These progestational changes are detailed later (p. 148) but, having occurred, the syncytial trophoblast adheres to the uterine mucous membrane, destroys the epithelium over the area of contact and excavates a cavity in the membrane in which the blastocyst implants. In a conceptus described by Bryce & Teacher (1908) the point of entrance was visible as a small gap closed by a mass of fibrin and leucocytes; in another (Peters 1899), the opening was covered with a mushroom-shaped mass of fibrin and blood clot, the narrow stalk of which plugged the aperture in the mucous membrane. It is held that this *operculum* represents in part some syncytial trophoblast cut off by the decidua capsularis (Böving 1963).

THE TROPHOBLAST AND CHORION

Actively excavating the uterine mucous membrane is the syncytial trophoblast which increases rapidly in thickness over the embryonic pole and then forms a progressively thinner layer over the rest of the wall towards the abembryonic pole. As the blastocyst implants, it invades and digests the uterine tissues, including the walls of the uterine (maternal) blood vessels (see **2**.22, 23 and Böving 1959, 1963). Lacunar spaces develop in the trophoblastic envelope and establish communications with each other. Early, many of them contain maternal blood (**2**.21, 23) derived from dilated uterine capillaries and veins, the walls of which have been partially destroyed. As the conceptus grows, the lacunar spaces enlarge, becoming confluent to form an initial blood-filled *intervillous space*; their trophoblastic walls are converted at first into an *irregular* spongework, or *labyrinth*. With further growth, however, the main strands of trophoblastic syncytium assume a *radial* arrangement. Thus, from early stages, the intervillous space is *completely spanned* by these radial strands which undergo an orderly sequence of three main histological changes (vide infra). Such strands extend from the syncytial layer of the chorion (on the embryonic aspect of which is a layer of cytotrophoblast, lined by vascularized fetal mesoderm) across the intervillous space to the layer of (peripheral) syncytium which is in close apposition to the excavated maternal tissues. Through spaces in the latter, extravasated maternal blood continues to enter the intervillous space.



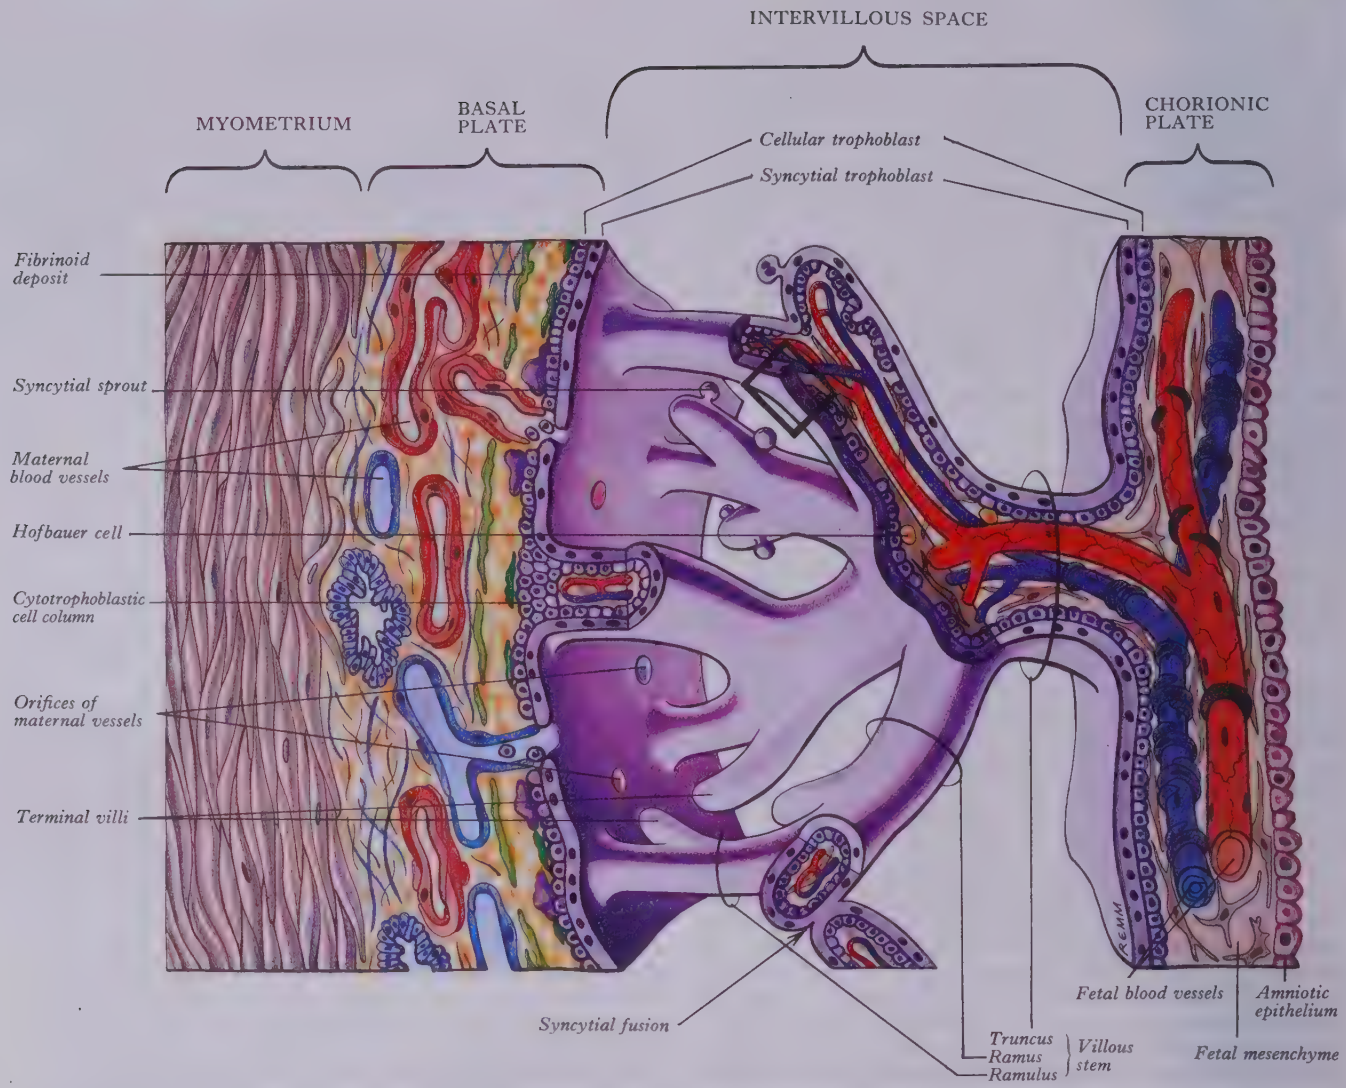
The central core of each syncytial strand is now invaded sequentially by the following:

(1) A growing *column* of proliferating cells extends from the chorionic cytotrophoblast and grows throughout the length of the strand until it reaches the syncytium on the maternal aspect of the intervillous space, *within which* it 'mushrooms' tangentially to meet and fuse with neighbouring outgrowths to form a spherical *cytotrophoblastic shell* around the conceptus (**2**.21, 23, 32).

(2) Each *cytotrophoblastic cell column* now develops, centrally and throughout much of its length, a *core* of extraembryonic mesoderm. This never completely reaches the trophoblastic shell, and it is uncertain how much of this mesoderm is derived by *inflexion* and *invasion* from the chorionic mesoderm, or whether it arises by differentiation of the central cytotrophoblastic cells.

(3) Capillaries now differentiate within the mesodermal core (**2**.32) and soon establish connections with the radicles of the umbilical vessels in the general mesoderm of the chorion.

The radial trabeculae undergoing these transformations are termed the *villous stems* and they, and their subsequent side branches, may be regarded as passing through the three grades of *histological differentiation* (primary, secondary and tertiary) just described (**2**.32). The term 'villous stem' is used here in preference to the traditional primary, secondary and tertiary chorionic *villi* because it is evident that, *initially*, there are no true villi (i.e. finger-like projections with a free tip which grow across the intervillous space to reach the maternal tissues).



2.33 A transverse section of a terminal villus stained with haematoxylin and eosin.

Each villous stem now consists, from its chorionic base and throughout much of its extent, of a vascularized mesodermal core, covered by a single (*Langhans*) layer of cytotrophoblast, which is again ensheathed by a layer of syncytium. Near the maternal end, however, it contains no mesodermal core but is formed of a solid *cytotrophoblastic cell column*, continuous peripherally with the trophoblastic shell and ensheathed by a layer of syncytium.

Two major changes now ensue (**2**.32); firstly, increasing complexity and subdivision of the maternal ends of the villous stems and, secondly, the development of free side branches. Expansion of the whole conceptus is accompanied by *radial growth* of the villous stems and, simultaneously, an integrated *tangential growth* with expansion of the trophoblastic shell. The attached maternal extremity of each villous stem undergoes a series of longitudinal divisions. Eventually each stem forms a complex consisting of a single *trunk (truncus)* attached by its base to the chorion, from which arise distally, second and third order branches (which have been named *rami* and *ramuli* respectively—Stieve 1926). Each of the latter remains attached at its maternal end to the trophoblastic shell.

Now, for the first time, *'true' villi* with free tips make their appearance as outgrowths from the sides of the villous stems, and particularly from the rami and ramuli rather than from the truncus. These have been variously termed *free, terminal, absorption* or *fringing* villi and it is predominantly across their walls that exchanges between the fetal and maternal circulations occur. Each terminal villus commences as a syncytial outgrowth which, as it continues to grow, is again invaded successively by cytotrophoblastic cells which then develop a core of fetal mesoderm; this is finally vascularized by fetal capillaries (i.e. each villus passes through primary, secondary and tertiary grades of histological differentiation). The terminal villi continue to form and branch, within the confines of the definitive placenta (vide infra) throughout gestation, projecting in all directions into the intervillous space, many of them making contact with those growing from adjacent villous stems. When this occurs some form of secondary adhesion or fusion may occur between their tips. Some earlier workers suggested that this may proceed to mesodermal or even vascular fusion between adjacent villi, but a recent survey of available evidence strongly suggests that this does not occur to any appreciable extent and that connection between villi is limited to fibrinoid adhesion between their surfaces or, at most, fusion between their syncytial tips. As these changes proceed, the intervillous space, at first spanned by the early villous stems and their branches, and then increasingly permeated by growing free villi, is finally, once again, transformed into an exceedingly complex *labyrinth* of fine intercommunicating maternal vascular spaces.

2.34 Schematic diagram to show the arrangement of the placental tissues. Note the chorionic and basal plates, and the intervillous space spanned by a villous stem and its divisions (truncus, rami and ramuli). The sectioned surfaces show the disposition of the fetal and maternal blood vessels, the amniotic epithelium, the cellular and syncytial layers of trophoblast and the complex junctional zone between the fetal and maternal tissues in the basal plate containing deposits of fibrinoid material and isolated masses of peripheral syncytium. Note also the presence of surface syncytial sprouts, a stromal trophoblastic bud and Hofbauer cells associated with a terminal villus, and syncytial fusion occurring between the tips of two terminal villi. See text for further details. The region enclosed in the rectangle is shown greatly enlarged in **2.35**.

The intervillous space, which contains the circulating maternal blood and is everywhere lined by syncytial trophoblast, is thus bounded:

(1) On its *fetal aspect* by a *chorionic plate*, consisting of syncytial, cytotrophoblastic and mesodermal layers of the chorion, the latter carrying radicles of the umbilical vessels, and soon to fuse with the mesoderm of the expanding amnion.

(2) On its *maternal aspect* by a *basal plate* consisting of the *peripheral syncytium* that has been divided by the growth of the cytotrophoblastic shell into an *inner layer* enclosing the intervillous space, and *external masses* which, together with the adjacent, modified and excavated uterine tissues, form a complex *junctional zone*.

(3) *Crossing it* from chorionic to basal plates, the main trunks of the *villous stems* dividing into their rami, ramuli and associated complex of free, or secondarily fused, terminal villi; the trunk and its branches may be regarded as the essential *structural, functional* and *growth unit* of the developing placenta.

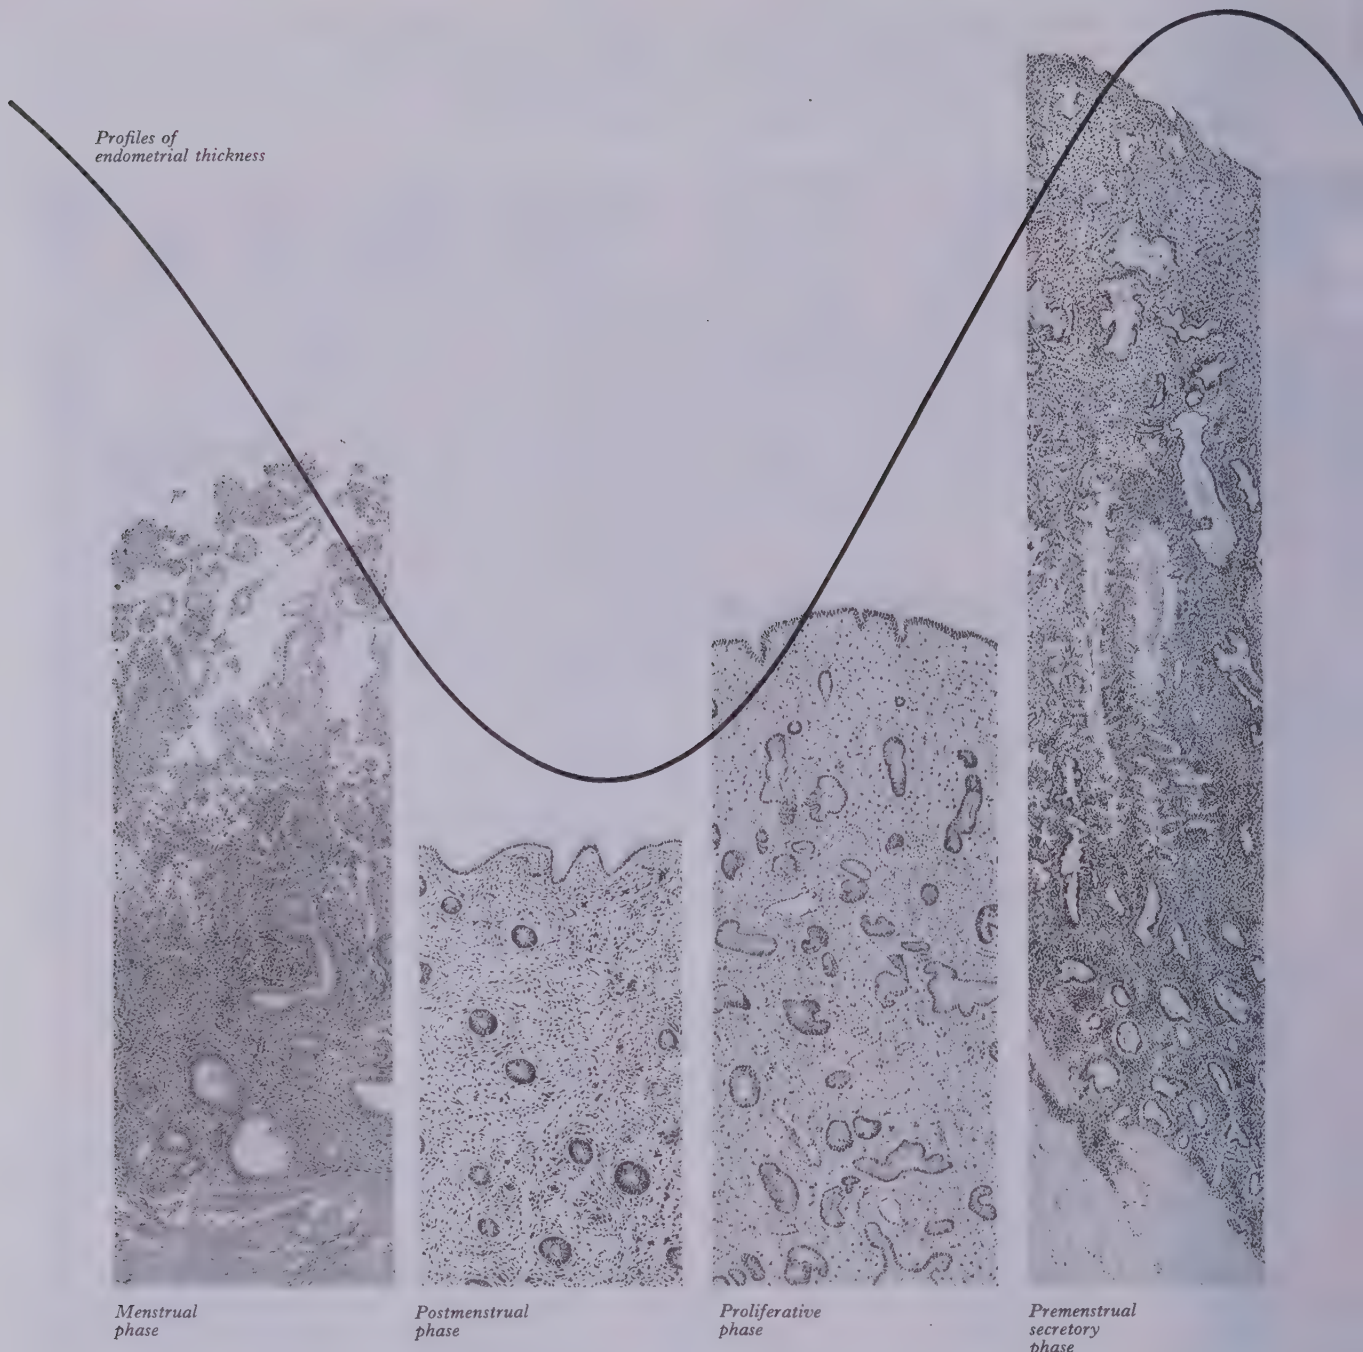
Further consideration of the placenta must now be deferred until the preparation of the uterine tissues for the implantation and development of the blastocyst has been briefly described.

CYCLICAL CHANGES IN THE UTERUS

Throughout the period of reproductive life (i.e. from about the fifteenth to the forty-fifth year), except during pregnancy and lactation, a series of closely interrelated cyclical changes occur in the ovary, uterus and vagina. Each cycle extends over a period of about 28 days. In the *ovarian cycle*, which is described more fully elsewhere (pp. 116, 1436), one follicle usually reaches full maturity, ruptures and releases its secondary oöcyte during this period. The wall of the follicle is then transformed into an important endocrine gland, the *corpus luteum* (p. 1437). About 10 days after ovulation the corpus luteum begins to regress, then ceases to function and is replaced by fibrous tissue.

The changes of the *uterine cycle (menstrual cycle)* chiefly involve the lining endometrium of the body and fundus of the uterus and may, for convenience, be divided into four phases: (1) menstrual; (2) postmenstrual; (3) interval or proliferative; and (4) premenstrual or luteal (but see also below).

In the *menstrual (haemorrhagic) phase* the superficial part of the endometrium, next to the free surface, is shed piecemeal, leaving only the basal zone, adjacent to the uterine muscle (**2.36A**). Outwardly this phase is marked by a discharge of blood with necrotic epithelial and stromal debris from the uterus through the vagina. This discharge, the *menstrual flow*, lasts some 3–6 days.



In the *postmenstrual (reparative) phase*, and even before the menstrual flow ceases, the epithelium from the persisting basal parts of the uterine glands grows luminally over the denuded surface of the endometrium. The latter is now only 1–2 mm thick and lined by low cuboidal epithelium. The glands are straight and

narrow. The stroma is dense and contains small numbers of lymphocytes amongst its more general population of rather ill-defined spindle-shaped cells (2.36B). This phase lasts about 4 days.

During the *proliferative (interval) phase* which lasts about 10–12 days, there is a growth of the endometrium associated with the presence in the bloodstream of oestrogenic hormones, internal secretions produced by the ovary (2.38A). The endometrium thickens to about 2–3 mm. Mitoses are present and the glands become distinctly tortuous. Their lining epithelium becomes tall columnar (2.36C). In the later part of the phase clear vacuoles

2.35 Schematic diagram showing the detailed ultrastructural features of the tissues (enclosed in a rectangle in 2.34) which intervene between the maternal and fetal blood streams. Note the contrasting architecture of the syncytial and the cellular trophoblasts, and the substantial basement membrane and delicate fetal mesenchyme which separate the trophoblast from the fetal vessels. Contrast the nucleate fetal, and anucleate maternal erythrocytes. For further description see text. (Based on data in Boyd & Hamilton 1970.)

2.36 Stages in the human menstrual cycle—the sections of the endometrium have all been reproduced at approximately the same magnification. The black line is a rough indication of the changes in endometrial thickness throughout the cycle. (Specimens kindly provided by the Shattock Museum, St Thomas's Hospital Medical School.)

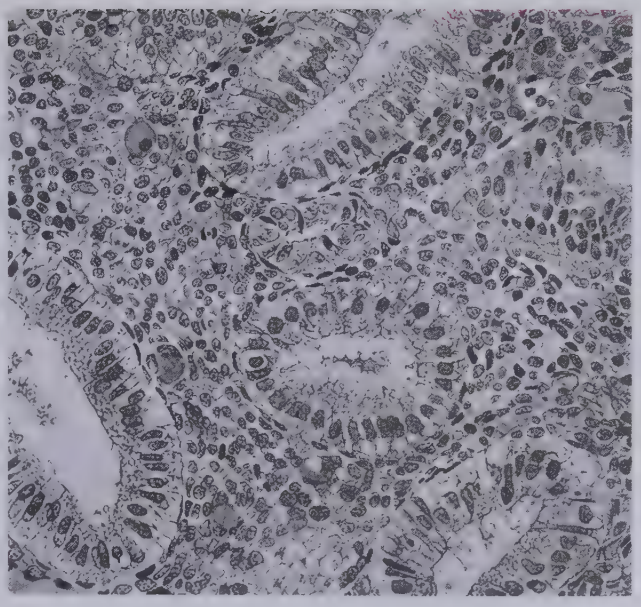
appear in the basal parts of the epithelial cells lining the glands. These vacuoles enlarge, occupy more of the cytoplasm and the nuclei are displaced from the basal regions of the cells towards the lumina of the glands (2.37). Secretion is exuded into the lumen, and for a while the glands may be distended with secretion containing mucin and glycogen which can be demonstrated both in the cells and in the gland lumina by appropriate histochemical methods. Mitoses decrease and finally cease, the end of the proliferative phase.

Ovulation occurs about *14 days before the onset* of the next menstrual flow. The changes occurring in the premenstrual phase depend upon the presence in the bloodstream of the hormones, *progesterone* and *oestrogens*, both secreted by the corpus luteum (2.38).

The *premenstrual phase* occurs during the 7 days preceding the next menstrual flow. The mucous membrane thickens and terminally may be 7–8 mm deep. In their middle regions, the glands become more voluminous and their walls folded upon themselves so that tuft-like processes project into the lumen. This gives the glandular wall a saw-toothed appearance in longitudinal section. Secretion is seen in the lumen of the active parts of the gland. The gland epithelial cells, which were tall and columnar at the commencement of the phase, become frayed and worn down on their luminal aspects and the nuclei resume their original basal position. The basal parts of the glands adjacent to the uterine muscle take little or no part in these changes. Later in the premenstrual phase characteristic changes appear in the interglandular stroma. These changes are most marked in the superficial part of the endometrium and around the blood vessels. Here the stromal cells, hitherto not clearly defined, become enlarged and swollen and for the first time definite cell outlines can be clearly seen. A few mitoses may be seen in the stroma at this stage. These changes constitute the *stromal premenstrual decidual reaction*. Three strata can now be clearly recognized in the endometrium (2.36D):

(1) *stratum compactum*, next to the free surface in which the necks of the gland are but slightly expanded and the stromal cells show a distinct decidual reaction, (2) *stratum spongiosum*, where the uterine glands are tortuous, dilated and ultimately only separated from one another by a small amount of interglandular tissue, (3) a thin *stratum basale*, next to the uterine muscle containing the tips of the uterine glands embedded in an unaltered stroma.

In the last days of the premenstrual phase lymphocytes appear in the endometrium in increasing numbers. They are found between and beneath the surface epithelial cells, amongst the stromal cells and around and between the gland cells. Towards the end of this period, as regression of the corpus luteum occurs, those parts of the stroma showing a decidual reaction and the glandular epithelium both undergo degenerative changes and the endometrium often diminishes in thickness. These degenerative changes precede the phase of bleeding.



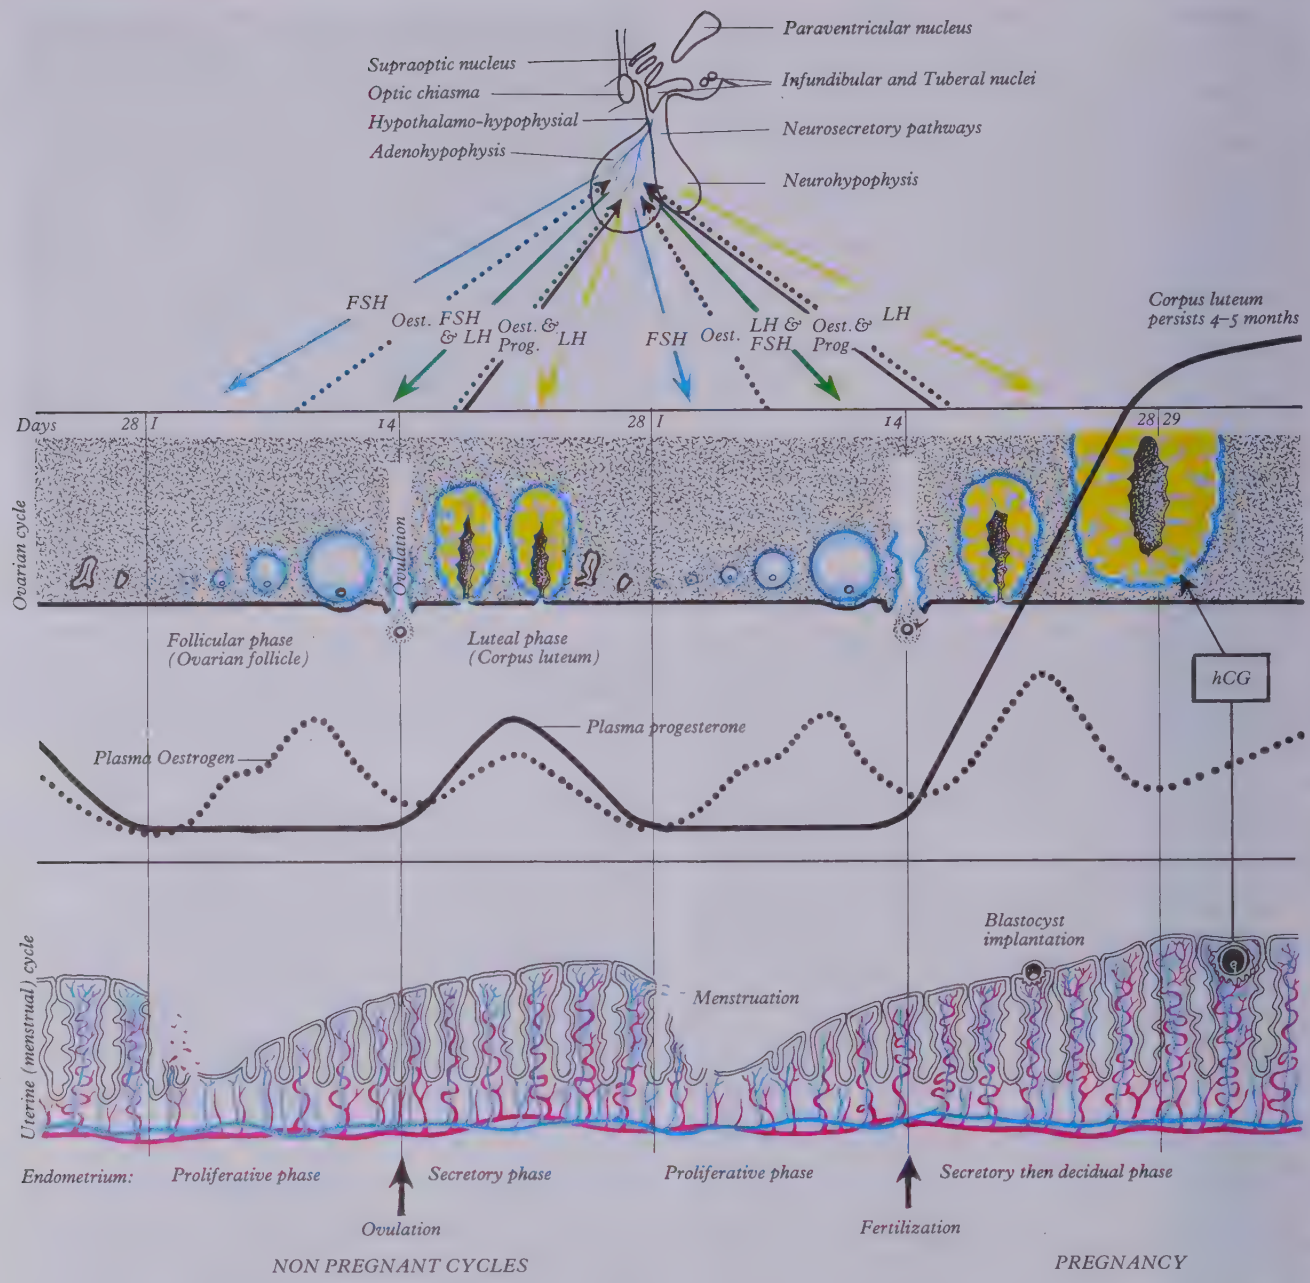
During *menstruation* blood escapes from the superficial vessels of the endometrium forming small haematomata beneath the surface epithelium which raise it. Blood and necrotic endometrium then begin to appear in the uterine lumen. The shedding of the endometrium starts at the surface and extends into the deeper layers. The amount of tissue lost is variable, but usually the stratum compactum and most of the spongiosum are desquamated.

The endometrium is regenerated from the stratum basale and that part of the spongy layer which remains, the surface epithelium being reformed with remarkable rapidity.

The *vascular bed* of the endometrium undergoes significant changes during the menstrual cycle. The arteries to the endometrium arise from a *myometrial plexus* and consist of *short straight* vessels to the basal portion of the endometrium and more muscular *spiral arteries* to its superficial two-thirds. The venous drainage consists of narrow perpendicular vessels which anastomose by cross branches and is common to both the superficial and basal layers of the endometrium. The arterial supply to the basal part of the endometrium remains unchanged during the menstrual cycle. The spiral arteries to the superficial strata, however, lengthen disproportionately, become increasingly coiled and their tips approach more closely the uterine epithelium during the late proliferative and, particularly, in the premenstrual phases of the menstrual cycle. This leads to a slowing of the circulation in the superficial strata with some vasodilation. Immediately before the menstrual flow these vessels begin to constrict intermittently causing stasis of the blood and anaemia of the superficial strata. During the periods of relaxation of the vessels, blood escapes from the devitalized capillaries and veins, thus causing the *menstrual haemorrhage*.

The endometrial changes leading to premenstrual hypertrophy are a preparation for reception of the blastocyst and result from the action of oestrogen and progesterone (**2.38**). If fertilization of the ovum does not occur, the corpus luteum undergoes degeneration. The breakdown of the endometrium follows this cessation of function and is due to the drop in progesterone and oestrogen levels (p. 1437).

The uterine cycle may thus, alternatively, be considered as consisting of a *pre-ovulatory (follicular)* phase, which includes the postmenstrual and proliferative stages and a *post-ovulatory (progestational* or *secretory)* phase, which includes the second half of the menstrual cycle, i.e. the premenstrual and menstrual stages. These two *phases* are of approximately equal duration, although the pre-ovulatory phase is more variable than the post-ovulatory phase. The former is largely under the control of oestrogens alone and the epithelial cells in this phase possess large microvilli, whilst their cytoplasm contains much rough endoplasmic reticulum, lipid globules and lysosomes which become more numerous as the phase progresses. Histochemically the epithelium can be shown to contain large amounts of ribonucleoprotein and alkaline phosphatase, signifying the production and utilization of protein. In the progestational phase, which is under the control of both oestrogens and progesterone, the above activity declines and the surfaces of the cells become irregular with smaller and shedding microvilli and cytoplasmic processes; large vesicles appear in the apical cytoplasm and more numerous lysosomes are present. Acid phosphatases, malic and succinic dehydrogenases, cytochrome oxidase and adenosine triphosphatase are present with large amounts of glycogen and mucopolysaccharide (McKay et al 1956, Nilsson 1962).



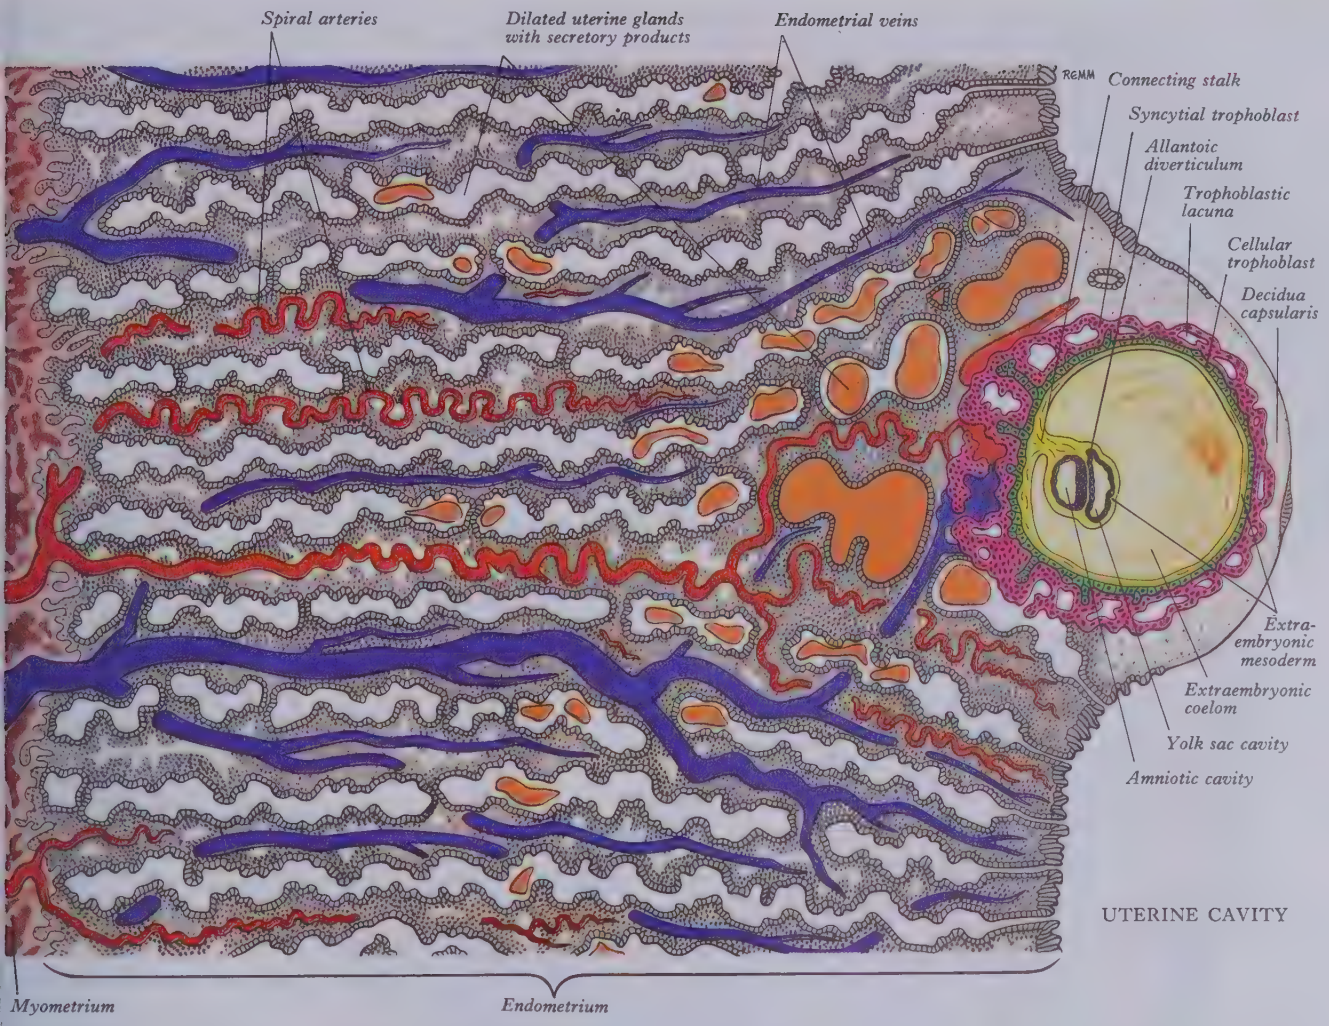
2.37 Section of human endometrium at about the seventeenth day of the menstrual cycle to show the accumulation of secretions in the basal parts of the epithelial cells lining the glands, resulting in displacement of the nuclei towards the lumen of the gland. Magnification × *c.*300. Stained with haematoxylin and eosin. (Kindly lent by the Shattock Museum, St Thomas's Hospital Medical School.)

A form of menstruation frequently occurs in the absence of ovulation (*anovulatory cycles*), particularly in post-pubertal girls and also in women approaching the menopause. Instead of liberating its ovum, the ripe follicle fails to rupture and undergoes degeneration. This is accompanied by a rapid reduction in oestrogen secretion with consequent breakdown of the uterine mucosa in the proliferative phase and in the absence of the changes evoked by the presence of progesterone in the bloodstream (an *oestrogen-withdrawal* bleeding—Corner 1938).

THE DECIDUA

If fertilization and successful implantation occur, a hormone secreted by the syncytiotrophoblast, *human chorionic gonadotrophin* (hCG), and controlled by cytotrophoblast secreted gonadotrophin-releasing hormone (GnRH), prolongs the life of the corpus luteum, which continues to secrete progesterone and oestrogens for the first trimester. (Thereafter these and other hormonal functions are the province of the definitive placenta, p. 156.) Menstruation does not occur and the vascular endometrium, now known as the *decidua of pregnancy*, thickens further to form a suitable nidus for the conceptus. (Chorionic gonadotrophin also appears early in the urine and its presence here is used as a basis for many of the tests for early pregnancy.) The interglandular tissue increases in quantity; it contains a number of leucocytes and is crowded with large round, oval or polygonal *decidual cells*. These are stromal cells which have accumulated glycogen and lipid in their distended cytoplasm. They continue to be conspicuous in the early stages of gestation but regress in the later months. Their precise significance is uncertain. They may offer a nutritive pabulum which is engulfed by the syncytial trophoblast but, on the other hand, they have been regarded as a defensive mechanism to protect the endometrium from excessive destruction. These changes are well advanced by the second month of pregnancy, when the three strata recognizable in the premenstrual phase, compactum, spongiosum and basale, are better differentiated and easily distinguished.

After the blastocyst is embedded, distinctive names are applied to different regions of the decidua: the part covering the



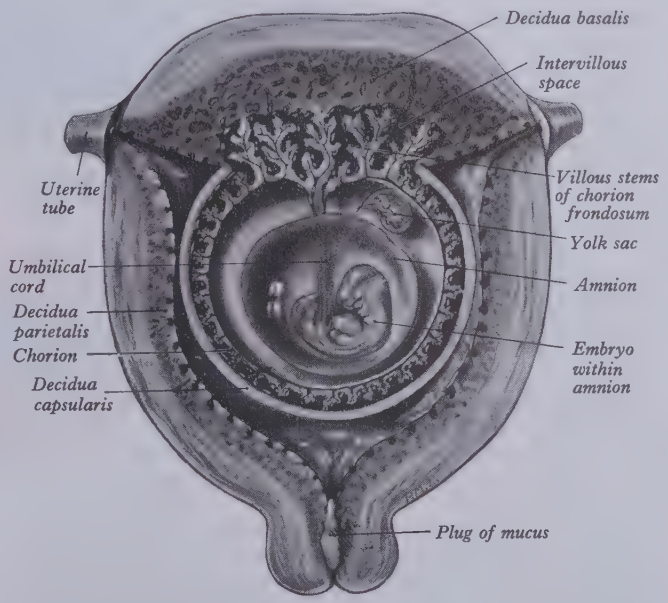
2.38 Composite diagram emphasizing some salient features of the female reproductive cycles. Note the (simplified) neuro- endocrine control loops, the periodic changes during the non-pregnant state of the ovarian cycle with concomitant endometrial changes of the menstrual (uterine) cycle, variations in circulating plasma hormone levels; finally, the dramatic sequelae when pregnancy supervenes. Neuro-endocrine controls are further detailed elsewhere (pp. 1436, 1453). FSH-follicle stimulating hormone; LH-luteinizing hormone; Oest.-oestrogens; Prog.-progesterone; hCG-human chorionic gonadotrophin. (Modified from Wendell-Smith et al 1984)

conceptus *decidua capsularis*; the part between the conceptus and the uterine muscular wall *decidua basalis*, and it is here that the placenta is subsequently developed; the part which lines the remainder of the body of the uterus *decidua parietalis* (**2**.40).

Coincidently with the growth of the embryo and the expansion of the amnion (p. 153), the decidua capsularis is thinned and distended (**2**.39, 40) and the space between it and the decidua parietalis gradually obliterated. By the beginning of the third month of pregnancy the capsularis and parietalis are in contact; by the fifth month the capsularis is greatly thinned, while during the succeeding months (**2**.41) it virtually disappears and the parietalis also largely atrophies, owing to the increased pressure. The glands of the compactum are obliterated and their epithelium is lost; in the spongiosum the glands are compressed, they appear as oblique slit-like fissures and their epithelium undergoes degeneration; in the limiting or boundary zone, however, the glandular epithelium remains cuboidal.

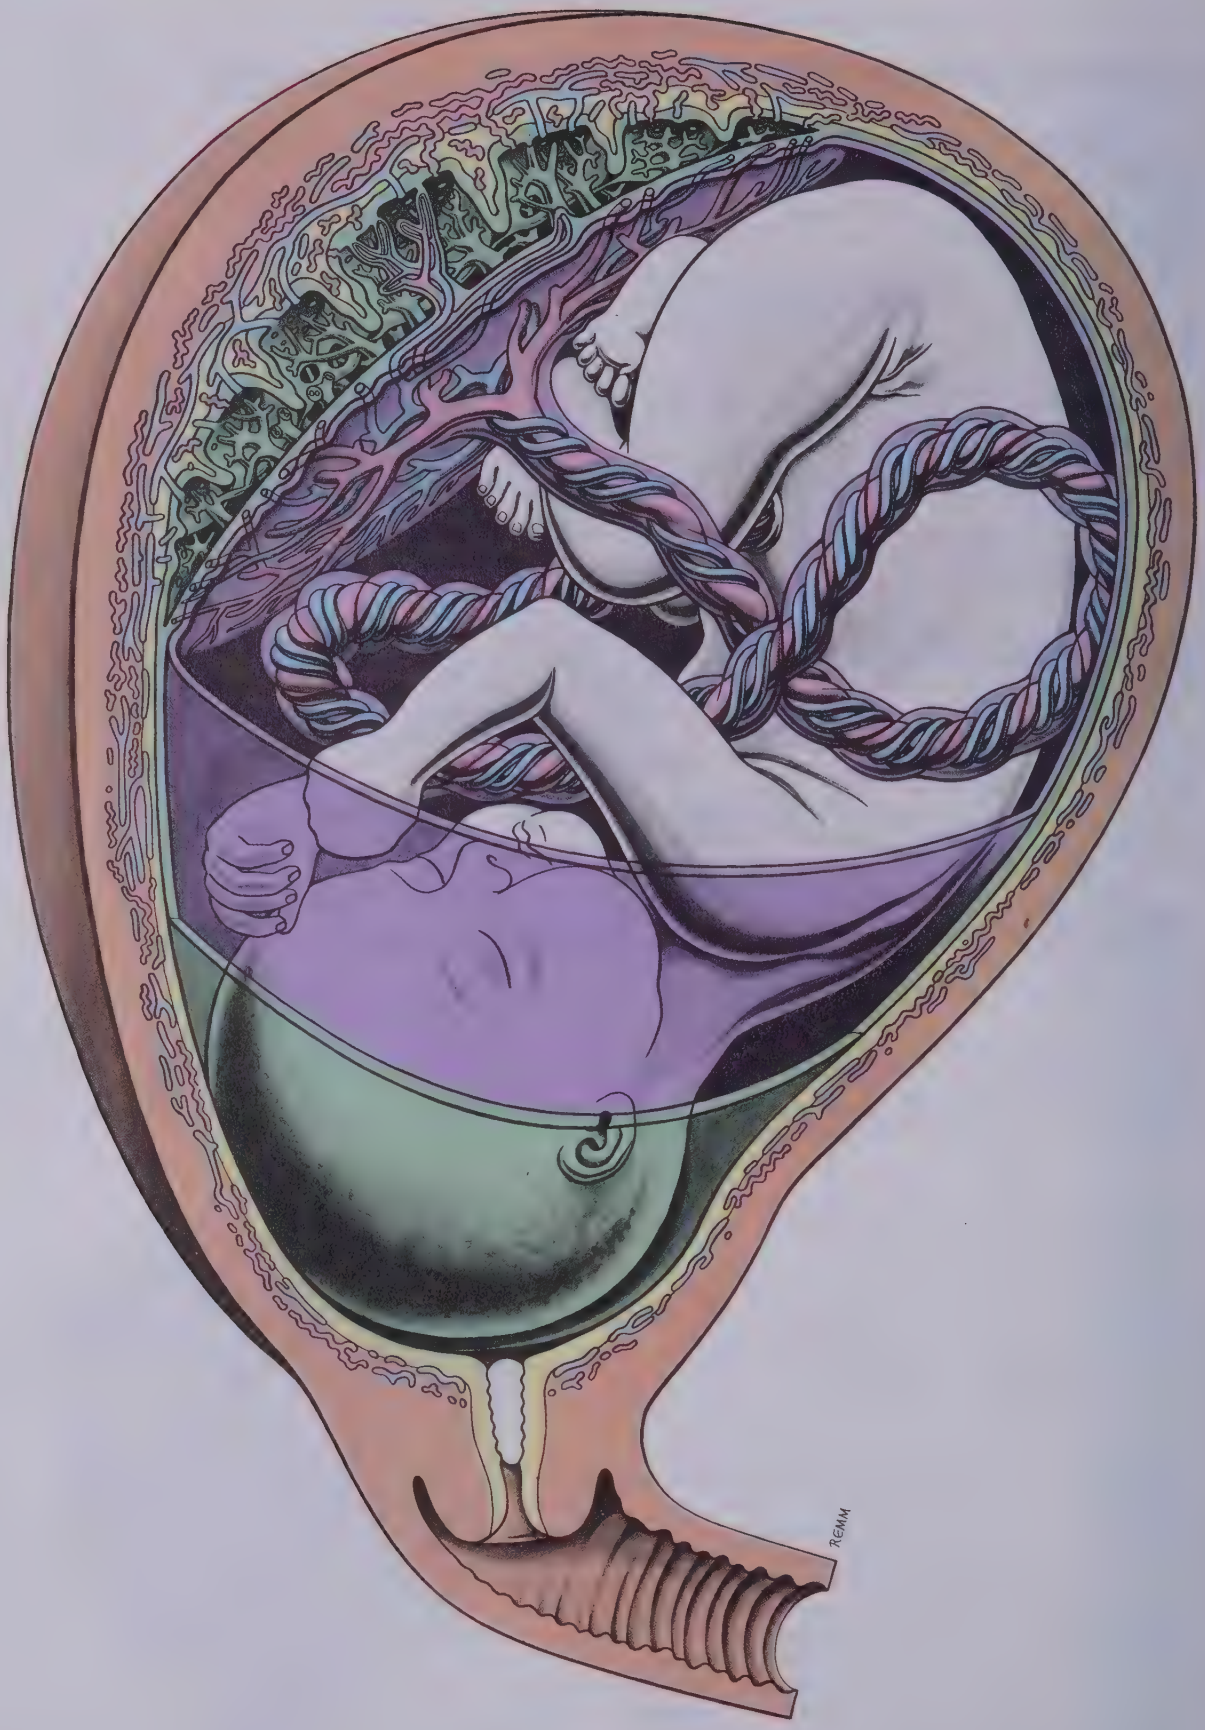
Implantation, the Chorion and Placenta

As we have seen (p. 125), during the early series of cleavage divisions of the zygote two distinctive groups of blastomeres emerge; one forms the *inner cell mass* including the *embryogenic cells*, the other consists of the outer, more numerous, smaller, rather flattened, polyhedral cells of the primitive *blastocystic trophoblast*. The latter spreads to cover the inner cell mass and consequently *polar* and *mural* regions of trophoblast may now be distinguished. Comparative studies have shown that such cells in the blastocysts of a number of different mammals possess many features in common. They are characterized by short, irregular microvilli on their external surfaces, numerous invaginations of the plasma membrane between the microvilli, with adjacent micropinocytotic vesicles in the cytoplasm, and junctional complexes between the cells at the outer end of the intercellular clefts (Enders & Schlafke 1965). Their cytoplasm carries many



2.39 A diagram showing the general structure of the implanting blastocyst and its relationship to the tissues of the endometrium on the 15th day after fertilization. Note the arrangement and gradation in thickness of the syncytial trophoblast which has eroded the maternal tissues. Some of the deeper trophoblastic lacunae already contain maternal blood. Note also the active dilated uterine glands, the endometrial venous plexus, spiral arteries, and the stage of development of the cellular trophoblast, amnion, yolk sac, allantoic diverticulum, connecting stalk and the extraembryonic mesodermal layers lining the extraembryonic coelom. For further details see text.

mitochondria, a variably developed Golgi complex, glycogen clusters, lipid inclusions, lysosomes, free ribosome rosettes, but scanty granular endoplasmic reticulum.



From the cells of this primitive layer some hold that all the elements of the chorion are derived, including the varieties of syncytium and also, at least in part, its mesodermal lining.

The origin of *syncytial trophoblast* was long debated, many workers holding that it arose by endomitosis of the primitive cells without cell division, but there is an increasing body of evidence (Boyd et al 1968) that it arises by proliferation of the cellular layer, with subsequent fusion of primarily independent cells on its external surface. During early implantation, and particularly in the polar trophoblast, it has been claimed that transiently nuclear division is so rapid that all traces of cellular definition are lost, a deep cellular layer only reappearing at a slightly later stage (Boyd & Hamilton 1966). The cellular layer itself persists, somewhat modified, as the germinal *cytotrophoblast* which, by multiplicative growth, can add additional cells which fuse with the overlying syncytium, may contribute cells to the underlying extraembryonic mesoderm and, by its continued growth, is an important factor in the expansion of the whole conceptus. It should be noted that proliferating and migrating epiblastic cells of the germ disc, converging on the primitive streak, entering the disc tissue and then diverging dorsocaudally, has been proposed as a prominent, if not exclusive, source of extraembryonic mesoderm (Luckett 1978).

6 or 7 days after ovulation the endometrium is well into the development of its secretory phase (p. 148) and, with the disappearance of the fibrillary zona pellucida and elaboration of polar

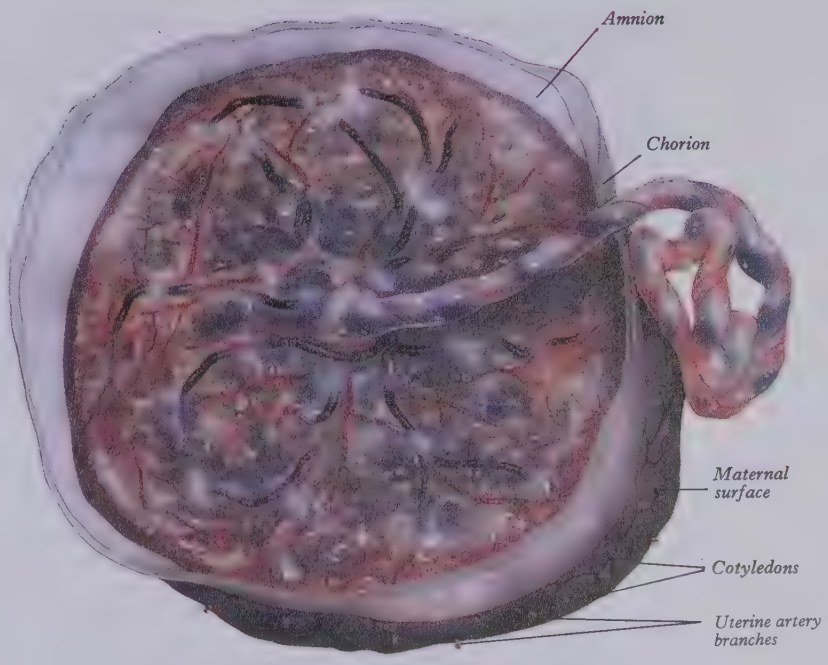
2.40 A plan of the gravid uterus in the second month. A placental site precisely in the uterine fundus as indicated in the plan is, however, rather unusual. (The dorsal, ventral or lateral wall of the corpus uteri is more usual.)

2.41 Diagram showing a full-term human fetus *in utero*, including a sectional view of the placenta, the amnion (mauve), chorion (green), uterine wall (orange), the umbilical cord and its contained vessels, the cervix with a plug of mucus in the cervical canal, and the rugose vaginal wall. Note the characteristic flexed posture of the fetus and its limbs, and the overall position within the uterus which the fetus commonly occupies. (Other positions, although less fequent, are, however, also quite common.) Note also the single umbilical vein carrying oxygenated blood, the two umbilical arteries carrying deoxygenated blood, the arborization of these vessels in the chorionic plate (seen through the overlying amnion) and their branches which pass into the villous stems. The latter span the intervillous space and their trunci, rami, ramuli and terminal villi may be seen; incomplete placental septa project from the basal plate towards the chorionic plate. See text for further details.

synctium, the stage is set for the implantation of the blastocyst. From comparative studies (Böving 1959) the mechanisms of implantation have been described as *muscular*, involving blastocyst transport (and spacing in polyovular species), *adhesive*, whereby the blastocyst becomes attached to the uterine mucosa, and *invasive*, being the means by which it enters the uterine tissues. Whilst the earliest stages of human blastocyst attachment and penetration have not been available for study, a number of mammals, including primates (Wislocki & Streeter 1938), have been subjected to close scrutiny using light and electron microscopy (Reinius 1967, Nilsson 1967, Tachi et al 1970).

Early implantation is initiated by a close approach of the trophoblastic plasma membrane to the tips of the microvilli and irregular surface protrusions of the uterine epithelial cells. At these points the trophoblast surface often presents patches of 'bristle-coated' membrane, with adjacent cytoplasmic plaques having a crystalline substructure, with numerous neighbouring lysosomes. The microvilli shorten and disappear and for a period there is a close mutual adaptation between the contours of the trophoblast and the uterine epithelial cell surfaces. The syncytium now sends finger-like projections between adjacent epithelial cells towards the underlying basement membrane, the two layers becoming closely interlocked by the formation of numerous tight junctions between them. The epithelial cells then degenerate and are engulfed by the trophoblast, resultant cellular debris becoming enclosed in phagosomes within the trophoblastic cytoplasm. The subepithelial basement membrane is soon penetrated, with the development of oedema, hyperaemia and cell degeneration in the neighbouring stroma.

Subsequent implantation of the human blastocyst continues with erosion, degeneration and phagocytosis of maternal vascular endothelium, glandular epithelium with secretory products and decidual cells, until the blastocyst sinks into and occupies a ragged *implantation cavity* in the decidua (*interstitial implantation*).



Later stages of development, which include the definition of the layers of the chorion, the elaboration of syncytial trophoblast, which is thick at the embryonic pole and thins towards the abembryonic pole and carries a lacunar circulation, and the principal stages in the development of the intervillous space, the villous stems and their branches and the trophoblastic shell have already been described.

From the third week until about the second month of pregnancy the *entire chorion* is covered with villous stems which are thus continuous peripherally with the trophoblastic shell in close apposition with *both* the decidua capsularis and the decidua basalis. The latter, however, are stouter, longer and show a greater profusion of terminal villi. As the conceptus continues to expand, the decidua capsularis is progressively compressed and thinned, the circulation through it is gradually reduced and, accordingly, its related villous stems and villi slowly atrophy and disappear. This process starts at the abembryonic pole and by the end of the third month the abembryonic hemisphere of the conceptus is largely denuded. This continues until the whole chorion which is related to the capsularis is smooth (the *chorion laeve*); in contrast, the villous stems of the disc-shaped region of chorion related to the decidua basalis increase greatly in size and complexity (the *chorion frondosum*), and together with the basalis constitute the *definitive placental site*.

An exhaustive account of the growth, dimensional changes, vasculature and haemodynamics, cell varieties, ultrastructure and histochemistry of the placenta, and the physiological aspects of placental transfer and its status as a metabolic store and endocrine gland, lies beyond the scope of the present volume. What follows is necessarily an abbreviated account of selected topics and the interested reader should consult the profusion of original papers devoted to these subjects. The exhaustive classical volume by Boyd & Hamilton (1970) provides an unrivalled source of information and an extensive bibliography. A provocative survey of placental transfer mechanisms is to be found in Longo (1972).

Definition of the Human Placenta

The human placenta (Wislocki 1929, Hill 1932, Grosser 1936, Mossman 1937, Amoroso 1952) is defined as *discoidal* (in contrast to other shapes, e.g. *zonary*, *bidiscoidal*, *diffuse*, etc seen in other forms). It is initially *labyrinthine* as the early villous stems are formed, but becomes secondarily *villous* with the development of generations of terminal villi and finally there is a partial return to a *labyrinthine* state as superficial adhesion or partial fusion occurs between the tips of a number of villi (vide supra). Maternal blood bathes the surfaces of the chorion which bound the intervillous space and it is thus defined as *haemochorial*, distinguishing it from the different grades of fusion between the maternal and fetal tissues which exist in many other forms (*epitheliochorial syndesmochorial*, *endotheliochorial* and even an approach to a *haemoendothelial* condition but with the vascular endothelial basement membrane and a fine layer of perivascular connective tissue persisting). The chorion is vascularized by the allantoic blood vessels of the body stalk and the human placenta is termed *chorioallantoic* (whereas in some forms a *choriovitelline* placenta either exists alone or supplements the chorioallantoic variety). Finally, the human placenta is said to be *deciduate* because maternal tissue is shed with the placenta and membranes at term as part of the afterbirth (vide infra).

2.42 The fetal surface of a recently delivered placenta, drawn from a coloured photograph kindly provided by Mr E F Gibberd. The spiral umbilical vessels in the umbilical cord, and their radiating branches shine through the transparent amnion. The maternal surface is exposed in the lower and right corner of the figure. Note the small branches of the uterine artery entering a series of grooves. Note also the fringes of amnion and chorion, the the majority of which have been cut away near the placental margin.

THE PLACENTA AT TERM

The expelled placenta (2.42) is a flattened discoidal mass with an approximately circular or oval outline, with an average volume of some 500 ml (range 200–950 ml), average weight about 500 g (range 200–800 g), average diameter 185 mm (range 150–200 mm), average thickness 23 mm (range 10–40 mm) and an average surface area of about 30 000 mm^2. Thickest at its centre (the original embryonic pole) it rapidly diminishes in thickness towards its periphery where it continues as the chorion laeve.

Macroscopically, its *fetal* or *inner surface*, covered by amnion, is smooth, shiny and transparent and the mottled appearance of the subjacent chorion, to which it is closely applied, can be seen through it. The umbilical cord, usually attached near the centre of the fetal surface, and branches of the umbilical vessels radiate out under the amnion from this point, the veins being deeper and larger than the arteries. Beneath the amnion and close to the attachment of the cord, the remains of the yolk sac can sometimes

be identified as a minute vesicle, up to 5 mm in diameter, with a fine thread—a vestige of the yolk stalk—attached to it.

The *maternal surface* is finely granular and mapped into some 15–30 lobes by a series of fissures or grooves. The lobes are often, somewhat loosely, termed *cotyledons* (but see also below) and the grooves themselves correspond to the bases of incomplete *placental septa* which become increasingly prominent from the third month onwards, and extend from the maternal aspect of the intervillous space (the basal plate) towards, but do not quite reach, the chorionic plate. The septa form initially as ingrowths of the cytotrophoblastic shell, with a covering of syncytium, but from the fourth month they develop a complex core derived from the maternal tissues which includes reticulin fibres and associated cells, decidual cells, remnants of glandular epithelium, occasional blood vessels and, deep to the cytotrophoblast, a stratum of fibrinoid material. Later, cytotrophoblastic cells often penetrate into the fibrinoid at various points with a resultant admixture of the fetal and maternal tissues and, in the later months of pregnancy, patches of central degeneration occur in many septa, which, incidentally, increases the difficulty of histological interpretation. The nature of the maternal surface of the expelled placenta is of course determined by the tissue plane of separation of the placenta at parturition.

Studies of the human placenta include morphometric analysis, surface architecture using scanning electron microscopy, ultrastructural studies of angioarchitecture and possible mechanisms whereby the maternal placental circulation is controlled. The ultrastructure of biopsies taken from placental uterine beds which were presumed to be normal has been reviewed. A detailed investigation into the connective tissue 'skeleton' of the placenta, with a helpful bibliography, has been provided by Ockleford & Wakely (1982).

SEPARATION OF THE PLACENTA

After delivery of the fetus the placenta becomes separated from the uterine wall and, together with the so-called 'membranes', is expelled as the *afterbirth*. Separation takes place along the plane of the stratum spongiosum and extends beyond the placental area, detaching (1) almost the whole remaining thickness of the largely degenerate, confluent, decidua parietalis and decidua capsularis, (2) the chorion laeve and (3) the amnion. These three layers are partially fused together and are continuous with the placenta at its margin; they constitute the *membranes* familiar in obstetrics. The process of separation requires rupture of many uterine vessels but their torn ends are closed by the firm contraction of the muscular wall of the uterus after delivery of the placenta and membranes and thus, under normal circumstances, postpartum haemorrhage is limited in amount. When the placenta and membranes have been expelled, a thin layer of stratum spongiosum is left as a lining for the uterus, but it soon undergoes degeneration and is cast off in the early part of the puerperium. A new epithelial lining for the uterus is then regenerated from the remaining stratum basale.

PLACENTAL LOBES AND LOBULES

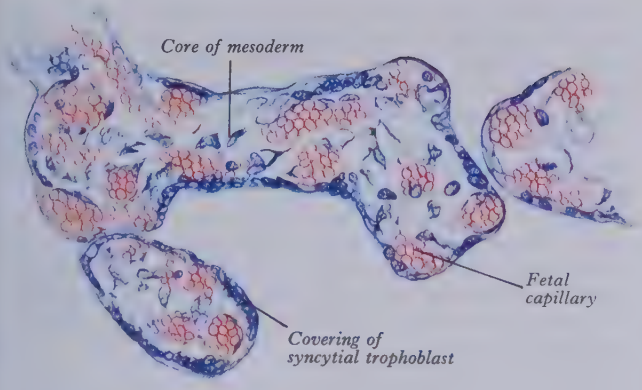
The placental *lobes* are demarcated by the grooves on its maternal surface, and they correspond in large measure to the major branches of distribution of umbilical vessels, particularly well seen in specimens X-rayed after intravascular injection of radio-opaque media. However, the application of the term cotyledon to these major lobes does not correspond directly to its usage in comparative placentology.

Particularly in those forms with a diffuse kind of placentation, the whole chorion does not bear villous structures evenly, for these are restricted to a large number of scattered discontinuous patches (*fetal cotyledons*) with non-villous chorion between them. These fetal cotyledons come into apposition with similarly distributed discrete areas of endometrium (the *maternal cotyledons* or *uterine caruncles*); the combination of one fetal unit with its associated maternal unit is termed a *placentome*.

The fetal cotyledon of the human placenta evidently corresponds to a major villous stem and its branches; early in pregnancy, the chorion bears some 800–1000 of such stems but as pregnancy advances, with the formation of the chorion laeve and possibly some fusion between adjacent stems, the number is progressively reduced until only about 60 persist in the placental area in the last months of pregnancy. However, this number is distributed between the 15–30 lobes, i.e. each lobe (or 'cotyledon' of obstetrics) contains 2–4 major villous stems and is to be regarded as compounded of this number of *placentomes* or *lobules*.

THE PLACENTAL TISSUES

These are arranged as a chorionic plate, a basal plate and, between the two, the villous stems, their branches and the intervillous space (2.32–41).



The chorionic plate is covered on its fetal aspect by the amniotic epithelium, its cells described elsewhere, followed by a connective tissue layer carrying the main branches of the umbilical vessels, then a diminishing layer of cytotrophoblast and finally the inner syncytial wall of the intervillous space. The connective tissue layer derives from fusion between mesoderm-covered surfaces of amnion and chorion and is more fibrous and less cellular than Wharton's jelly of the umbilical cord, except near the larger vessels. The latter radiate and branch from the cord attachment (with variations in the branching pattern), until they reach the bases of the trunks of the villous stems, which the branches enter and then arborize within their rami, ramuli and terminal villi. There is no anastomosis between vascular trees of adjacent stems but, in contrast, the two umbilical arteries are normally joined by some form of substantial transverse (Hyrtl's) anastomosis at, or just before they enter, the chorionic plate.

The basal plate consists, from fetal to maternal aspect, of: (1) the syncytium (and perhaps in patches, maternal tissue) which forms the outer wall of the intervillous space; (2) Rohr's stria of fibrinoid; (3) what remains of the cytotrophoblastic shell; (4) Nitabuch's stria of fibrinoid and; (5) the remains of the decidua.

The striae of fibrinoid are irregularly interconnected and strands pass from Nitabuch's stria into the adjacent decidua. The latter contains basal remnants of the endometrial glands, large and small decidual cells scattered in a connective tissue framework which also supports an extensive venous plexus. These deeper layers of the basal plate also contain a variety of *giant cells* which may possess either multilobate nuclei or are in fact multinucleate. Their origin has been disputed, but the majority probably have a fetal origin, arising either by the isolation of masses of peripheral syncytium or by growth from the cells of the cytotrophoblastic shell. For some, however, a maternal origin cannot be excluded. Their role is uncertain but they may be one source of placental hormones. In this regard, the possession by the cytotrophoblastic cells in this region of prominent nucleoli, a particularly basophilic cytoplasm rich in RNA and varieties of cytoplasmic inclusions (Dallenbach-Hellweg & Nette 1964), both acidophil and basophil, may also be related to an endocrine secretory role.

Throughout the second half of pregnancy the basal plate is thinned and progressively modified, with a relative diminution of the decidual elements, and an increasing deposition of fibrinoid and admixture of fetal and maternal derivatives. It is, as we have seen, through the deeper decidual layers of the plate that separation of the placenta occurs at parturition and through its various layers the maternal blood vessels approach and reach the intervillous space. The spiral arteries of the endometrium do not open directly into the intervillous space until the fifth or sixth week, after which they pass through the plate and open through gaps in the cytotrophoblastic shell and peripheral syncytium. The terminal parts of the vessels are dilated, lose their muscular walls by degeneration and present a hypertrophy of their lining endothelium. Proliferations of cytotrophoblast often grow back for some distance along their lumina (Hamilton & Boyd 1960).

The veins which drain the blood away from the intervillous space pierce the basal plate and join tributaries of the uterine veins. The presence of a marginal venous sinus, which has hitherto been described as a constant feature, occupying the peripheral margin of the placenta and communicating freely with the intervillous space, has not been confirmed.

2.43 Part of a section of a branching terminal villus in a mature placenta (ninth month). Note the close approach of many of the fetal capillaries to the subepithelial basement membrane; see text for details.

In the macaque monkey, radio-opaque material injected into the aorta passes in spurts or jets to the intervillous space and at sufficient pressure to drive it towards the chorion, thus preventing a short circuit of arterial blood into the venous openings. The openings of the coiled arteries show intermittent activity, probably due to alternating constriction and relaxation of the arteries themselves. Myometrial contractions alter the pressure in the intervillous space and promote placental venous drainage (Ramsey et al 1963, Martin 1965).

THE STRUCTURE OF A VILLUS

Terminal villi are the essential structures involved in exchanges between mother and fetus and, accordingly, the villous tissues separating fetal and maternal blood are of crucial functional importance; numerous investigations have been instigated.

Each villus has a core of connective tissue bearing fetal capillaries and separated by a basement membrane from the ensheathing cyto- and syncytial trophoblast which is bathed by the maternal blood in the intervillous space (2.32,34,35,43). Cohesion between the cells of the cytotrophoblast and also between this layer and the syncytium is provided by numerous desmosomes between their apposed plasma membranes.

In earlier stages, the cytotrophoblast forms an almost continuous layer on the basement membrane, but after the fourth month it gradually expends itself producing syncytium (Midgley et al 1963). As cytotrophoblast reduces, syncytium becomes directly related to the basement membrane over an increasingly large area and simultaneously itself becomes progressively thinner, but a few cytotrophoblastic cells, usually disposed singly, persist until term.

The cells of the *villous* cytotrophoblast (*Langhans cells*) are pale-staining with only a slight basophilia. Ultrastructurally, they show a rather electron-translucent cytoplasm, with few free polysomes, little granular endoplasmic reticulum but a number of large mitochondria, a fairly extensive Golgi apparatus, microfilaments particularly in association with the desmosomes and occasional vacuoles and dense inclusions. Between the desmosomes, the cell membranes of adjacent cells may be smooth and straight, or they may undulate, and are separated by a featureless gap of some 20 nm. Sometimes the intercellular gap widens to accommodate microvillous projections from the cell surfaces; the gap occasionally contains patches of fibrinoid.

In contrast, the syncytial cytoplasm is more strongly basophilic and possesses many ultrastructural features which distinguish it from the cytoplasm of the Langhans cells. Where the plasma membrane adjoins basement membrane it is often complexly infolded into the cytoplasm, whereas the surface bordering the intervillous space is beset with numerous long microvilli, the cores of which show linear densities. These microvilli are responsible for the brush border of light microscopy.

The syncytial cytoplasm is exceedingly complex and more electron-dense than that of Langhans cells. It contains a wealth of free ribosomes, cisternae of granular endoplasmic reticulum, scattered representations of the Golgi complex, a cytoskeleton of microfilaments and a profusion of vesicles and vacuoles, some smooth and some coated, of a wide size range, numerous lysosomes, phagosomes and other electron-dense inclusions. It evidently is not, as was earlier claimed, a simple homogeneous semipermeable membrane but an intensely active tissue layer across which all transplacental transport must occur.

Glycogen is held to be present in both layers of the trophoblast at all stages but it is not always possible to demonstrate it by histochemical means. Lipid droplets are also present in both layers and free in the core of the villus. In the trophoblast they are found principally within the cytoplasm but also occur extracellularly between cytotrophoblast and syncytium, or between the individual cells of the cytotrophoblast and also in the basement membrane. These droplets may represent fat in transit from mother to fetus, their numbers diminishing with advancing age. Membrane-bound granular bodies of moderate electron-density also occur in the cytoplasm, particularly in the syncytium; some of these are probably secretion granules of hormones or hormone precursors and are believed to arise in the Golgi apparatus. The lysosomes and phagosomes are evidently concerned in the degradation of materials engulfed from the intervillous space.

The core of the villus contains fibroblasts, large phagocytic *Hofbauer cells*, more numerous in early pregnancy, many plasma cells and free lipid granules. Electron microscopy shows fine collagen fibres which are thicker and collected into bundles in the villous stems. The fetal vessels include arterioles and capillaries. Their endothelial cells contain fine cytoplasmic filaments and they may provide bulbous projections into the lumen (Rhodin & Terzakis 1962, Terzakis 1963, Iklé 1961, 1964). They are surrounded externally by the usual periendothelial basement membrane (p. 689).

The characteristics of both syncytium and cytotrophoblast, however, vary considerably from the brief account just given in sites other than a villus and at different stages of development and for such details original sources should be consulted. There are, however, certain specialized regions of the villous syncytium which should be mentioned.

Many villi show localized ingrowths of syncytium (with some associated cytotrophoblast) into their mesodermal cores, the *stromal trophoblastic buds*. They may remain attached by stems to the overlying trophoblast, or become detached to lie free, and they may even approach and project into the lumina of the fetal blood vessels. In the latter site they may be a source of the syncytial masses which have been described in the blood of the umbilical vein. The frequency and fate of such fetal cellular emboli is uncertain. On the free surface of the villus at least two other types of specialization occur. The first, termed syncytial *knots* or *clumps*, are localized thickenings in which there is a close aggregation of a number of nuclei. Their significance for long remained obscure but in some cases appears to be related to the maintenance of a neighbouring delicate, non-nucleated, *epithelial plate* of syncytium which comes into particularly close apposition with a fetal capillary. An ultrastructural study of syncytial knots (Jones & Fox 1977) has shown that their nuclear aggregates exhibit marked degenerative changes, and it was suggested that they represent a sequestration phenomenon involving removal of senescent nuclear material from adjacent metabolically active areas of syncytium. Fusion of knots from adjacent villi appears to be one basis of *syncytial bridge* formation, and for the latter a mechanical role as an internal *placental strut* system has been advanced. The second specialization is termed a *syncytial sprout* which continues to be formed throughout pregnancy. Some sprouts are unquestionably initial stages in the development of a new branch villus. Many others, however, project into the maternal bloodstream and become detached, forming *maternal syncytial emboli* which pass to the lungs. It has been computed that there is a passage of some 100 000 of such sprouts daily into the maternal circulation. In the lungs they provoke little local reaction and apparently disappear by lysis but they may, on occasion, form a locus for neoplastic growth.

MATURATION AND FUNCTIONS OF THE PLACENTA

In the early stages of placental development the blood in the fetal vessels is separated from the maternal blood in the intervillous space by the fetal vascular endothelial cells and their basement membranes, the relatively abundant connective tissue of the villus, the subepithelial basement membrane and its covering of cyto- and syncytial trophoblast. These constitute a *placental barrier* interposed between the bloodstreams, but it is a permeable barrier and allows water, oxygen and other nutritive substances and hormones to pass from mother to fetus, and some of the products of excretion to pass from fetus to mother.

During the first half of pregnancy the placenta not only increases its surface area but reaches its maximum thickness; this accompanies increases in the size, length and complexity of branching of the villous stems and is not accompanied by any further invasion of the uterine wall. In the latter half of pregnancy the placenta further increases its surface area, doubling its diameter, the overall thickness remaining static (Stieve 1948, Hamilton & Boyd 1951). Placental weight has also been correlated with parity (Boyd & Hamilton 1970). These gross measurements might indicate a placental failure to keep pace with the functional demands of the growing fetus but, in compensation, the *placental barrier* becomes *reduced* in thickness. After the fourth month the villous trophoblast becomes reduced; as it ages the syncytium becomes directly related to the subepithelial basement membrane over an increasing area and it also becomes thinner. The fetal capillaries approach the surface of the villus but are always separated from the basement membrane by delicate connective tissue.

The mechanism of transfer of substances across the placental barrier is complex. The surface area of the villi has been variously estimated; it may, however, be as large as 14 square metres (Wilkin & Bursztein 1958). The volume of maternal blood circulating through the intervillous space has been assessed at 500 ml per minute (Assali et al 1960). Simple diffusion suffices to explain gaseous exchange and a transfer of many dissolved substances of low molecular weight (e.g. sodium, potassium, chloride, iodide, phosphate); some electrolytes, glucose and fatty acids involve facilitated diffusion, and active transport mechanisms carry other elctrolytes, amino acids and water soluble vitamins. In later pregnancy, water is interchanged between fetus and mother (in both directions) at about 3.5 litres per hour. The transfer of substances of high molecular weight such as complex sugars, some lipids, hormonal and non-hormonal proteins varies greatly in rate and degree, and is not so readily understood. Energy-dependent selective transport mechanisms, including micropinocytosis, are probably involved.

Lipids may be transported unchanged through and between the cells of the trophoblast to the core of the villus. The passage of maternal antibodies (immunoglobulins) across the placental barrier confers some degree of passive immunity on the fetus—in this instance transfer by micropinocytosis is widely accepted. The whole problem of investigations into transplacental mechanisms is complicated by the fact that the trophoblast itself is the site of synthesis and storage of certain substances, e.g. glycogen. For comprehensive reviews of placental transfer mechanisms consult Longo (1972), Boime & Boguslawski (1974).

The placenta is an important endocrine organ; some steroid hormones, various oestrogens, β endorphins, progesterone, human chorionic gonadotrophin (hCG), human chorionic somatomammotropin (hCS)—formerly named placental lactogen—are predominantly, perhaps exclusively, synthesized by the syncytium, whilst chorionic gonadotrophin releasing hormone (GnRH) is secreted by the cytotrophoblastic cells. It is of interest that steroid hormones are formed in isolated perfused placentae and also by placental explants in tissue culture. The trophoblast is rich in birefringent lipids and cytochemical methods show that it also contains enzyme systems which are associated with the synthesis of steroid hormones.

Leucocytes are more numerous in the blood of the umbilical vein than in that of the umbilical artery, suggesting that they may migrate from the maternal blood through the placental barrier into the fetal capillaries. It has also been shown that some fetal and maternal red blood cells may cross the barrier (Dancis 1959). The former may have important consequences, e.g. in rhesus incompatibility (p. 682). The vitamins pass the placental barrier with different degrees of facility; vitamins B, C and D pass readily, the remainder with greater difficulty.

The majority of drugs pass the barrier and many are apparently tolerated by the fetus, but some may exert grave teratogenic effects on the developing embryo (e.g. thalidomide, vide infra).

Finally, a wide variety of bacteria, spirochaetes, protozoa and viruses are known to pass the placental barrier from mother to fetus, although the mechanism of transfer is uncertain. The presence of maternal rubella in the early months of pregnancy is of especial importance in relation to the production of congenital anomalies (vide infra).

PLACENTAL VARIATIONS

As a rule the placenta is attached to the posterior wall of the uterus near the fundus, with its centre in or near the median plane. The site of attachment is determined by the point where the blastocyst becomes embedded but the factors on which this depends are not yet fully understood. The placenta, however, may be attached at any point on the uterine wall, but these variations offer no complications to a normal labour unless it is attached so low down that it overlies the internal os uteri, when it may give rise to serious antepartum haemorrhage, especially if it is nearly central in position. This condition, which occurs in about 0.5% of pregnancies, is known as *placenta praevia*. (*Extrauterine* sites of implantation are discussed on p. 131.)

The umbilical cord, although usually attached near the centre of the organ, may reach it at any point between its centre and margin, the latter known as a *battledore* placenta. Occasionally the cord fails to reach the placenta itself and ends in the membranes in its vicinity. With such a *velamentous insertion* of the cord, the larger branches of the umbilical vessels traverse the membranes before they reach and ramify on the placenta. A small *accessory* or *succenturiate* placental lobe is occasionally present, connected to the main organ by membranes and blood vessels; it may be retained in utero after delivery of the main placental mass and prolong postpartum haemorrhage. Occasionally other degrees of division occur (*bipartite* or *tripartite* placentae). Other variations include *placenta membranacea*, in which villous stems and their branches persist over the whole chorion, and *placenta circumvallata*, in which its margin is undercut by a deep groove. Pathological forms of adherence or penetration include *placenta accreta*, with exceptional adherence to the decidua basalis, *placenta increta*, in which the myometrium is invaded, and *placenta percreta*, when the invasion by placental tissue has passed completely through the uterine wall.

At birth, when ligature of the umbilical cord is delayed, the blood volume of the child is, on the average, appreciably greater than it is when the ligature is applied at the earliest possible moment (de Marsh et al 1942). It appears that in the former case much of the blood in the fetal placental vessels is transferred from the placenta to the fetus. The meaning of the phenomenon is far from clear, for in the first few days of life after late ligature of the cord the newly born suffers a loss both of plasma volume and of haemoglobin (Gotsev 1939).

Congenital Abnormalities—Teratology

The term teratology was at one time reserved for grosser examples of congenital abnormality—for the study of 'monsters'. Cleft palate or thalassaemia could scarcely be regarded as monstrosities—something to be pointed at with surprise or aversion. But the Greek τεραζ and the Latin *monstrum* both imply pointing of a different kind—a pointing to the future, a warning or portent. In primitive cultures the advent of abnormal offspring or prodigy, whether human or otherwise, was usually accepted as a portent of ill-omen. Hence records of human congenital malformations, in cave-paintings, sculptures and ultimately in writings, extend backwards into prehistory, as do also theories and beliefs in regard to their causes. Talipes, achondroplasia and conjoined

twins were portrayed in most ancient times, together with centaurs, sirens, mermaids and other fanciful creatures (Barrow 1971). The Hippocratic School identified hydrocephalus. Aristotle described many major and minor malformations with accuracy but, unlike his contemporaries and his successors through many subsequent centuries, he denied the magical and divinatory aspects of teratology, ascribing 'monsters' to natural causes, a view which was not reawakened until the times of Harvey, Wolff, von Haller and the Hunters. They and their contemporaries of the seventeenth and eighteenth centuries, stimulated by the growing knowledge of embryology, initiated the *theory of embryonic arrest* to explain malformations. Saint-Hilaire experimented on developing chick embryos in the early nineteenth century, and with this approach the study of teratology was consolidated as a science. In parallel, however, superstition and prejudice persisted, producing, e.g. the 'hybrid theory' which attributed monstrous births to unnatural hybridization, a groundless hypothesis which cost many innocent men and women their lives. Another old theory, which is scarcely dead even today, was the concept that the experiences of the pregnant mother, usually visual, could influence her unborn offspring in an adverse manner. That factors in the *maternal environment* may influence the embryo has, of course, proved true, but in a different sense, for Watson, as long ago as 1749, suggested that fetal disease, contracted by a transplacental route, might be a cause of congenital abnormality, citing variola as an example. This theory slowly dwindled, and was almost extinguished a century later by the authority of Virchow and His, whose views dominated teratological opinion through most of the second half of the nineteenth century. A contemporary, working in obscurity, was Mendel; and as his work became known and genetics flowered into the twentieth century attention inevitably turned to the hereditary aspect of congenital defects (already foreshadowed by Paré and John Hunter, centuries earlier). In 1941 Gregg's observation that congenital cataract is associated with the infection of pregnant mothers by rubella revived interest in environmental factors. Subsequent to this, teratology has been largely concerned with *genetic* and *environmental factors*, particularly in attempts to explain the mechanisms of abnormal development.

The expansion of experimental embryology has revealed a wide array of *environmental agents* capable of affecting normal development, including temperature variations, mechanical insult, variation in substances such as lithium and magnesium in culture media, exposure to irradiation, hypoxia, hypo- and hypervitaminosis, hormonal effects (especially with oestrogens and androgens), nutritional defects and exposure to various drugs and other chemicals. These experiments have stimulated and illumined research into teratogenic agents. Although much of such work has been pursued on the embryos of fish (minnow), amphibians (frog) and birds (chick), experiments on mammals in producing cleft palate, anophthalmia and other abnormalities suggest that similar mechanisms must operate in human maldevelopment. The identification of human teratogens may be said to have commenced with Gregg's demonstration of the effects of rubella virus. Other viral and bacterial maternal infections have since been implicated. But with the multiplication of drugs, for such purposes as abortion (aminopterin) and sedation (thalidomide), some of which have proved tragically teratogenic, teratological research has been much concentrated upon drugs. In parallel with this, however, has been the recognition of the genetic conditioning of a growing list of abnormalities (McKusick 1986), including metabolic aberrations (Garrod 1963). These remain the two major fields of current teratology, pharmacological and genetic.

While the great volume of recorded research has led to the identification of a large number of causal agents, the detailed mechanisms by which these produce abnormalities are for the most part obscure. In some cases it is clear that normal embryonic processes are delayed, arrested or accelerated, leading to agenesis or to varying degrees of hypoplasia or hyperplasia. The recognition that cell death plays a normal role in prenatal growth and differentiation, leading to the diappearance, modelling or reduction of structures (p. 103), has been extended to explanations of congenital defects. The available evidence suggests that cell death is a major factor in developmental aberrations associated with viruses, irradiation, nutritional defects and hypervitaminoses. Local hyper- or hypoplasia and disturbed morphogenetic movements of cells may obviously produce distortions of normal development. It cannot be doubted that such factors as these are concerned, but in most cases the explanations are partial and missing links in the causal chain persist (Saxén 1970, Johnston & Pratt 1975). This is not surprising, since the precise march of events in much of normal development is still imperfectly known.

A very large number of cytotoxic agents are now known, and many have been used as experimental teratogens, mostly on rodents. Some act as antimetabolites, amino-acid antagonists, anti-purines or spindle toxins and most are highly selective in their effects, which are produced only by *controlled dosage* at *specific periods* during development. Connors (1975) has collated two decades of reports in this field, emphasizing the complex array of variable parameters which help to determine whether an agent acts as a teratogen or not. These include embryonic age, the amount, route and mode of administration of the agent, placental and embryonic permeability, maternal or embryonic ability to inactivate the agent, the state of differentiation of target cells and their ability to recover. Sullivan (1975) has reviewed the literature concerning teratogenic drugs taken by pregnant women, classifying them on their sites of action, whether directly on the embryo (thalidomide, tetracycline antibiotics), on embryonic endocrine balance (oestrogens and androgens), on the placenta or on maternal tissues. These considerations are, of course, of intense clinical importance, but their contribution to *explanations* of teratogenic *mechanisms* is limited, except in so far as some drugs are known to be teratogenic at specific stages of development.

Genetic conditioning of congenital abnormalities, whether structural, metabolic or behavioural, has been the subject of very widespread research and observation. A long list of inheritable defects has accumulated (McKusick 1986). According to Polani (1973) about a third of recognized defects in the newborn are due to single gene abnormalities, a further twelfth to chromosomal errors and a further substantial, but unknown, fraction to polygenic interaction. About 2000 birth defects occur in mankind which are either known to have, or are presumed to have, a genetic background. Of these 1700 are probably autosomal and 150 sex-linked (McKusick 1986). Although much information is thus available which may prove of great value in genetic counselling, complete mechanisms from disturbed DNA coding to actual phenotypic expression of particular deformities or other aberrations are not likely to be definable. Such explanations are dependent upon a more complete knowledge of embryonic processes than is yet available. Presumably, different genetic errors may operate at different stages in the procession of events through multiplication, determination, aggregation, morphogenetic movement, differentiation, localized proliferation and cell death, each of which is itself a complex of biochemical activities. In some examples, however, it is possible to demonstrate or to hypothecate such events in detail, normal and abnormal metabolic processes in bacteria providing the most successful field. One of the earliest, if not the first of human abnormalities to be identified as genetic was alkaptonuria, now known to be due to deficiency of a single enzyme (homogentisic acid oxidase) and hence, presumably, to a single gene disturbance. Although the locus of the latter is not established as yet, the biochemical sequence during which 'alkapton' is produced is fully clarified. In sickle-cell anaemia, which is inherited as a mendelian recessive characteristic, there is demonstrably a defect in the production of the protein moiety of the haemoglobin molecule (in fact an amino-acid substitution). The actual 'sickling' of erythrocytes only occurs in certain conditions of local oxygen concentration, an interaction between genetic effect and environmental factor which appears to be involved in the development of many basically genetic abnormalities. In the case of more elaborate structural deformities it is obvious that complete explanations are dependent upon adequate clarification of embryogenetic processes as noted above.

A relatively common example of an autosomal genetic abnormality often cited is the complex termed Down's syndrome (mongolism), which occurs in 1 in 600 live births. It is due to a trisomy or tripling of chromosome 21. The incidence of Down's

syndrome increases with maternal age, suggesting that the aetiology is complicated and may not be simply genetic. The discovery that sex chromosomes can be identified has expedited the recognition of several sex-linked conditions, although, of course, familial history alone had indicated the sex-linked nature of haemophilia at a much earlier date. In Klinefelter's syndrome, which is characterized by testicular atrophy and hence sterility and eunuchoidism, associated with a variable depression of intelligence, there is a condition of X-polyploidy, such as XXY, XXXY and even higher states of X. Development of the gonad into a testis is ensured by the Y chromosome and the additional X chromosomes presumably retard differentiation. In another congenital deviation, Turner's syndrome, which features dwarfism, rudimentary ovaries, amenorrhoea and failure of the appearance of secondary sexual characteristics, the Y chromosome is absent (XO) or imperfect. A similar sex inversion (XX) occurs in males. As in the case of autosomal abnormalities, sex-linked chromosomal defects are common in spontaneously aborted individuals. (XO is said to be the commonest, at about 1% of all conceptions.)

It is clear from the foregoing that although the exact causology of the great majority of human congenital malformations is uncertain, the role of genetic and environmental factors (including teratogenic drugs) cannot be doubted. Wherever adequate familial studies can be established there is frequently an indication of genetic mechanism. However, an increased frequency of certain abnormalities may be equally associated with depressed socio-economic status, climate or geographical regions and maternal age.

Epidemiological studies of congenital aberrations are of considerable interest and value, not only in genetic counselling but also in attempts to unravel the complex problems of causation. The incidence of congenital abnormality may be as high as 6% in surviving infants. With the decline in incidence of, and death from, infectious and nutritional diseases, congenital abnormality is assuming a proportionately greater importance in the medical care of many populations. Several large epidemiological surveys, carried out in many countries, are now available (e.g. Kennedy 1967, WHO 1972). These show not only the overall incidence of abnormality but also the comparative frequency of various malformations and the regional and racial variations which some display. For example, neurulation defects such as anencephaly and spina bifida, while being relatively frequent abnormalities, also show much variation in frequency. (Particularly high incidences have been recorded in Belfast and Bombay.) Galactokinase deficiency was identified about 15 times more often in a Canadian series (Manitoba) than in the USA (Massachusetts). Such variations are at present largely inexplicable; but the well-known coincidence of sickle-cell gene for haemoglobin S and of the thalassaemia trait with the distribution of malaria are interesting exceptions.

The prenatal identification of certain malformations and aberrations must be mentioned. Amniocentesis and examination of the amniotic fluid and its suspended cells permits the diagnosis of some metabolic disorders and potentially all chromosomal aberrations. It is of particular value in conditions of high incidence and early lethal effect such as Tay-Sachs disease, which occurs about 100 times more often in Ashkenazi Jews than in other races. Radiology alone may reveal anencephalic or hydrocephalic fetuses (Russell 1969); but the hazards of this technique have led to the substitution of ultrasonography, which is presumed to be safer and can discover similar conditions (Taylor 1978). Amniography consists in radiological examination after the injection of a water-soluble radio-opaque substance into the amniotic fluid; fetography is a variant of this technique which employs an oily radio-opaque injectant (Wiesenhaan 1972). By absorption of the radio-opaque substance in the vernix caseosa, the latter technique is claimed to yield clearer delineation of surface features. (For literature consult Persaud 1977.)

Twinning

Twinning occurs once in about every 80 births. Twins may be *dizygotic* (binovular or fraternal) or *monozygotic* (uniovular or identical), of which the former occurs more frequently. Twin boys are most common, less common are a boy and a girl and least common two girls.

Dizygotic twins result from the discharge and fertilization of two ova, either from two separate or a single ovarian follicle. Each embryo develops in its own chorionic sac, but occasionally synchorial fusion occurs. The twins are of different genetic constitution and may be of the same or different sex. They bear no greater resemblance to one another than other siblings of the same family. There is evidence that dizygotic twinning may be hereditary. The development of ovarian follicles and the release of ova at ovulation is under the hormonal control of circulating *gonadotrophins* produced by the β cells of the anterior lobe of the hypophysis cerebri. The control mechanisms are far from clear, but it has been demonstrated in a variety of mammals that raising the circulating gonadotrophic level by injections increases the number of ova discharged (Hammond 1952). Similar considerations apply to women who have had such treatment for long-standing amenorrhoea (Gemzell & Roos 1966). In one series of about 100 cases so treated there were 43 pregnancies including 20 singletons, 14 twins, 2 triplets, 3 quadruplets, 1 quintuplet, 2 sextuplets and 1 septuplet. At the time of writing, the clinical exhibition of gonadotrophins in cases of infertility has become commonplace.

Monozygotic twins arise from a single ovum fertilized by a single sperm. At some stage up to the establishment of the axis of the embryonic area and the development of the primitive streak the formative material separates into two parts, each of which gives rise to a complete embryo. The twins may share one or have independent chorionic sacs and possess an individual or a common amniotic sac. The twins are of the same sex, have the same blood groups and tissues of identical antigenic potencies. They resemble each other closely. Monozygotic twinning is a hereditary character.

Interestingly, a number of workers have suggested that in addition to the widely recognized two foregoing types, a *third type* of twin (with several variants) may exist. Essentially this type is *uniovular* but *dispermatic* following an irregular meiotic cycle during oögenesis. It is considered that either the ovum, or the secondary oöcyte, or the primary oöcyte may undergo an equal cytoplasmic division (instead of throwing off a diminutive polar cell). Evidently each of the three variants would have different degrees of genetic dissimilarity depending upon the stage at which such an equal division occurred.

Multiple births greater than twinning, such as triplets or quadruplets, can arise from multiple ovulations or a single ovum, the formative material of which later separates into several parts, or from a combination of these mechanisms.

Conjoined twins or double monsters arise from the incomplete division of the formative material of a single early ovum. There is, however, no evidence that the condition is hereditary or that it occurs more frequently in families given to uniovular twinning. The conjoined twins are usually united by corresponding regions and the degree of duplication of parts varies.

For an excellent review of the types, frequency, inheritance and embryology of twinning, the diagnosis of zygosity, the course and outcome of twin pregnancies, their possible evolutionary significance and some post-natal characteristics of twins, the interested reader should consult Bulmer (1970).

DEVELOPMENT OF INDIVIDUAL SYSTEMS

Embryonic development has so far been considered as a whole but, as the definition of its structures proceeds, overall description becomes so complicated as to actually impede the clarity of appreciation of the events occurring. It is hence customary and convenient to limit attention to individual systems in their further development; but it must never be overlooked that the analysis of a whole organism into such divisions—however attractive on morphological and functional grounds—is largely a product of the sequential nature of human perception. Not only do the several systems into which we divide the organism develop simultaneously, they also interact and modify each other. This necessary interdependence is not only supported by the evidence of experimental embryology but is also emphatically demonstrated by the phenomena of growth anomalies, which cut across the artificial boundaries of systems in most instances. For these reasons it is most desirable that the development of any one individual system should be frequently related to others, especially those most closely associated with it (both spatio-temporally and causally).

So far the development of the embryo has been taken to an age of between 3 and 4 weeks, the stage of early somite formation, equivalent to Horizons X or XI on the scale established by the studies of Streeter and others (1942–1949). (See also the analysis into 'Stages' by O'Rahilly 1973 and p. 261.) It is only partly constricted from the yolk sac, but the head and tail folds are well formed, with enclosure of the foregut and hindgut (proenteron and metenteron). The forebrain projection dominates the cranial end of the embryo, the oropharyngeal membrane and cardiac prominence being caudal and ventral to this. The intraembryonic mesoderm has begun to differentiate and its paraxial region is undergoing segmentation into somites. Neural groove closure is progressing to a neural tube and is separated from the dorsal aspect of the gut by the notochord. The earliest blood vessels have appeared and a primitive tubular heart occupies the pericardium. The chorionic circulation is soon to be established, after which the embryo rapidly becomes completely dependent for its requirements upon the maternal bloodstream. The intraembryonic part of the coelom consists of the transmedian pericardial cavity, leading dorsocaudally into right and left pericardioperitoneal canals (coelomic ducts). The canals occupy mesenchyme dorsal to the septum transversum, caudal to which they expand into the peritoneal cavity. This establishes, for a time, a free communication with the extraembryonic coelom (**2**.27, 28).

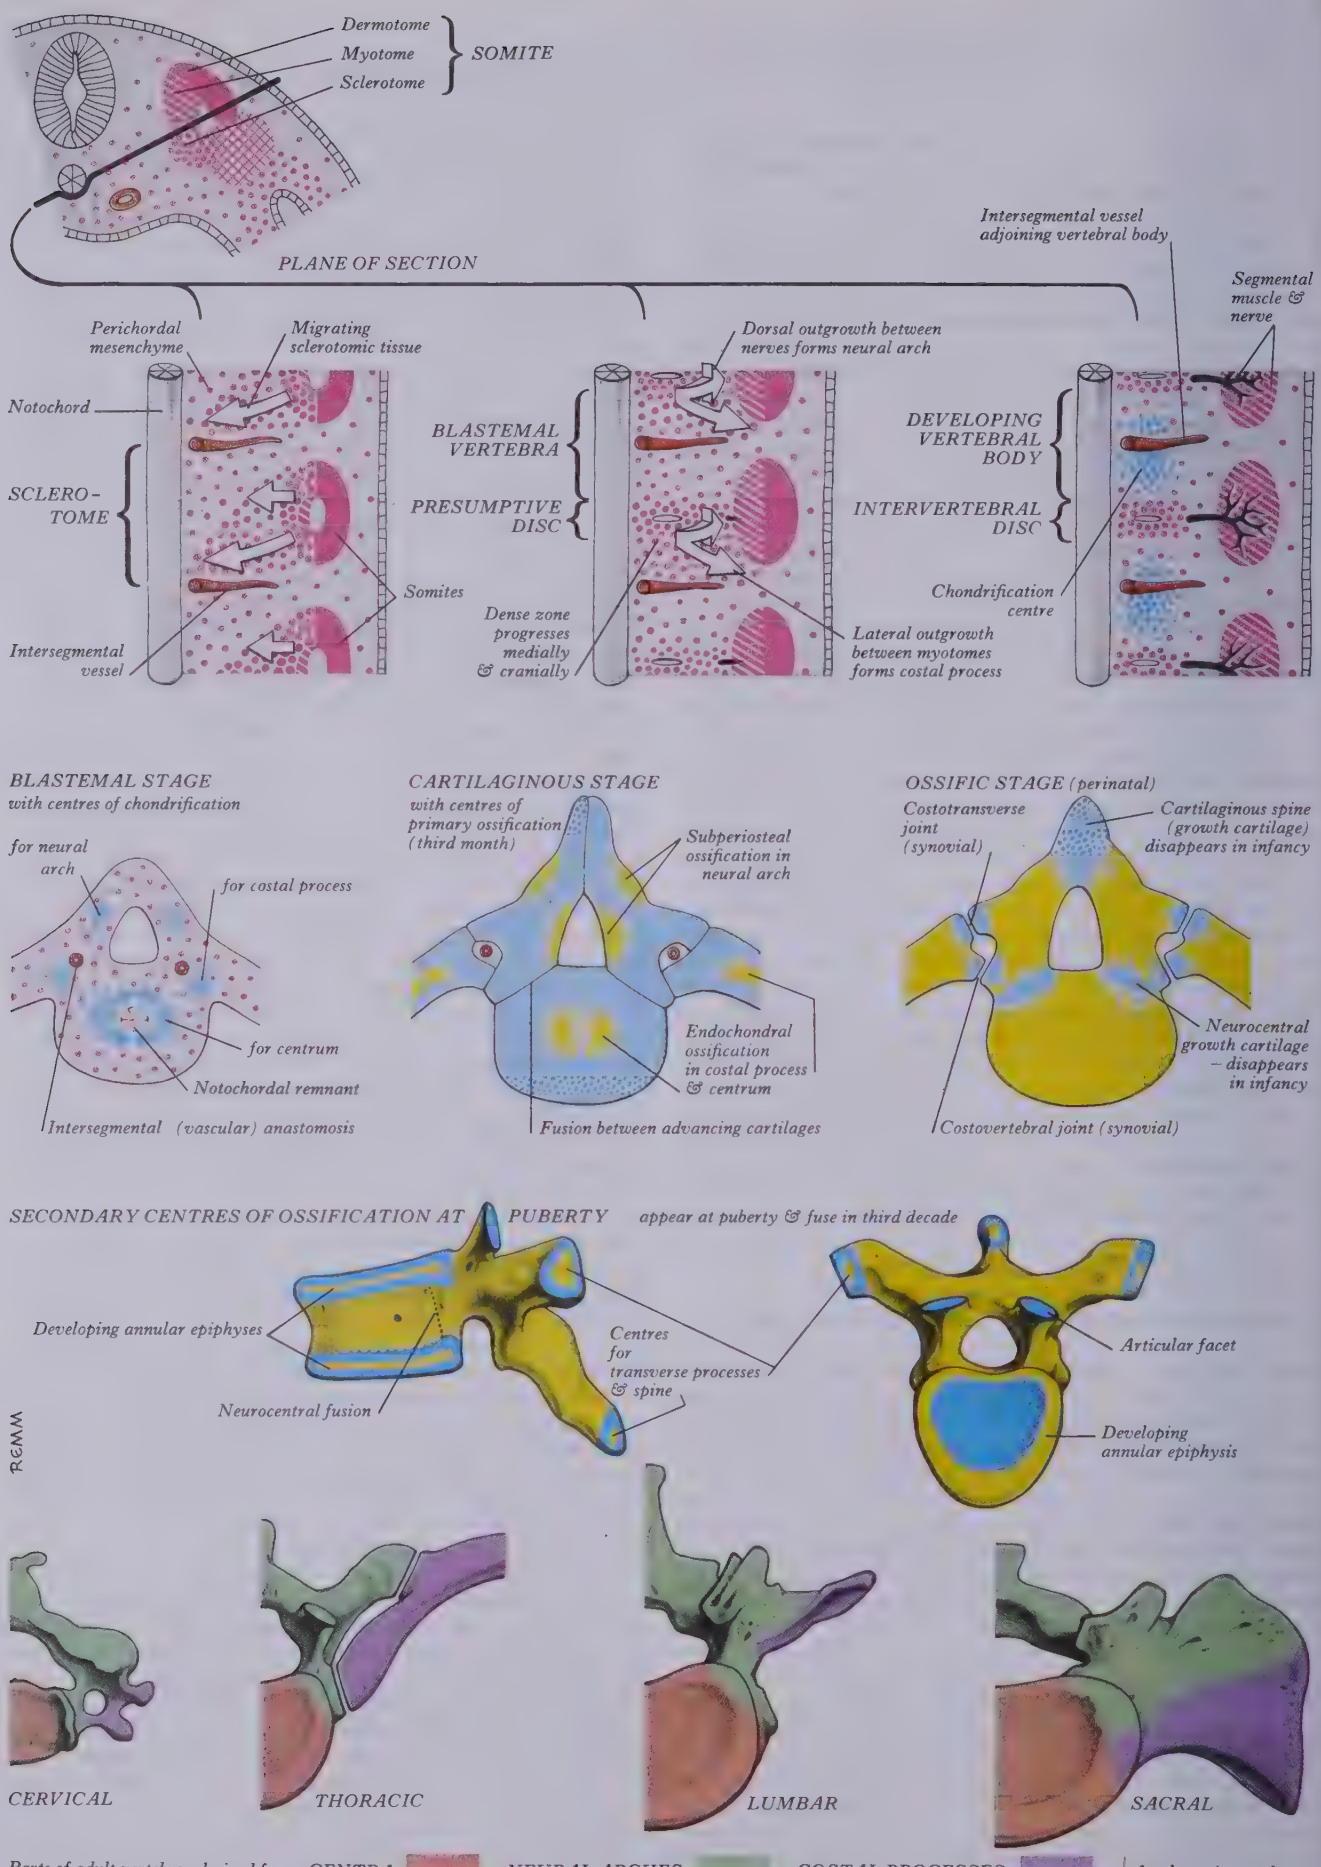
Development of the Skeletal System

The skeleton is a derivative of mesoderm (and in some parts neural crest), including not only its axial and appendicular divisions but also all accessory ossicles such as sesamoid bones and the osseous and cartilaginous elements of the branchial arches. Most of these parts initially enter a *blastemal stage* of mesenchymal condensation and this transforms into a *cartilaginous stage* before becoming ossified. In some bones, however, ossification follows immediately upon the blastemal stage, the intermediate phase of chondrification being omitted (p. 300). For a review of embryonic cartilage see Glenister (1976).

THE SKELETAL AXIS

Before reaching its final condition the skeletal axis passes through three preliminary states (Präder 1947, Sensenig 1949, Peacock 1951, 1952, Walmsley 1953, Tondury 1958, Verbout 1976, 1985 and **2**.44). First it is formed by the *non-segmental notochord*, a flexible rod of cells enclosed by a thick, membranous sheath. The notochord is not, however, limited to the region in which the vertebrae will replace it, for it extends into the head as far as the caudal limit of the hypophysis cerebri, this cranial extension being subsequently incorporated into the basilar part of the occipital bone and the caudal part of the body of the sphenoid (**2**.45A).

In the second stage, the notochord provides a framework around which a *blastemal* or *mesenchymatous vertebral column* is formed. On each side fusiform cells of the sclerotomes multiply rapidly and migrate ventromedially enclosing the notochord in a mesenchymal sheath (**2**.44), which at first retains traces of its segmental origin. Sclerotomic cells later migrate dorsally around the spinal cord, passing between and lateral to the rudimentary spinal ganglia and ventrolaterally into intervals between myotomes.



Around the notochord each sclerotomic segment is divided into equal cranial and caudal parts by a transitory transverse split or loosening between the two groups of cells, the *sclerotomic fissure* (**2**.44). The parafissural mesoderm condenses to form a dense transverse plate, a *perichordal disc*, whilst the less dense, caudal part of one segment fuses with the slightly smaller also less dense cranial part of the adjoining segment. This fusion defines the blastemal centrum of a vertebra. In the dorsal extensions of the sclerotomes segmental condensations between the spinal ganglia define the neural arch and later its processes, while their ventrolateral extensions outline the costal processes, which are continuous dorsomedially with the perichordal disc.

In the third stage the vertebral components become more clearly defined and chondrification of these mesenchymatous models produces a *cartilaginous vertebral column*. Each centrum is chondrified from a pair of centres which appear during the sixth week and quickly coalesce. Each half of a neural arch is chondrified from a centre starting in its base and extending ventrally into the pedicles, to meet, expand and blend with the centrum, and dorsally into the laminae; but the latter do not meet in the midline until the fourth month. Thus the presumptive vertebral *body* is compound—a centrum with dorsolateral accessions, expansions from the pedicles of the neural arch. The transverse and articular processes are chondrified in continuity with the neural arches; intervening zones of mesenchyme which do not become cartilage mark the sites of their intervertebral and costovertebral joints, and synovial cavities appear later in these. The costal processes chondrify separately and in the thoracic region they extend ventrally, the more cranial members curving round in the body wall to reach the developing sternal plates. They are separated from the developing transverse processes by non-chondrified mesenchyme in which the costotransverse joints will appear. A similar process affects the sites of most of the capitular costovertebral joints involving the perichordal disc and adjacent parts of the neural arch-derived dorsolateral parts of the bodies. At other than thoracic levels the developing costal process (or pleurapophysis) becomes incorporated into the 'transverse process' of descriptive adult anatomy (**2**.44).

In both the blastemal and chondrifying stages, the cranial and caudal aspects of each perichordal disc proliferate, contributing to the growth of adjoining centra and eventually merging with them. The main, intermediate mass of each perichordal disc (which contains the sclerotomic fissure), together with an enclosed part of the notochord, becomes an *intervertebral disc*. (Vide infra for further reviews.)

HYPOCHORDAL ELEMENTS

A structure which, though present during the blastemal stage, only becomes clearly recognizable as an entity during chondrification is the *hypochordal arch* or bow. This connects the vertebral ends of two costal processes to each other and spans the ventral surface of a centrum; it is prominent only with the first three or four cervical vertebrae in man. Only in the case of the *atlas* does the hypochordal arch chondrify and become ossified during the first post-natal year; it forms the anterior arch and the ventral parts of the lateral masses of this vertebra. (The hypochordal arch may correspond to the paired intercentra, ventral elements in the development of vertebrae in many other animals. They may persist at any level, forming such arrangements as haemal or intercentral arches, which enclose the caudal vessels.) Some authorities, however, have tentatively suggested that certain

2.44 Sequential diagrams of vertebral development from early somitic and perichordal stages through blastemal, cartilaginous, and pre- and post-natal ossificatory stages. For views concerning segmentation see text. Bottom row indicates principal morphological parts of adult vertebrae.

collagenous, ventral, transcentral structures, e.g. part of the thoracic, costovertebral radiate ligaments, may have hypochordal origins.

The homologies of the various elements which fuse to form vertebrae are still subject to disagreements (Jollie 1962). It does, however, now appear certain that the original concept of Gadow (1933), that all tetrapod vertebrae can be derived from four paired elements (basidorsals, basiventrals, interdorsals and interventrals) must be abandoned. Subsequent authorities, provided with much more extensive evidence, especially embryological data, have not substantiated Gadow's somewhat theoretical views (Williams 1959, Jenkins 1969). Another widely accepted view—that the centrum of the atlas is united with that of the axis as its dens—has been thrown into doubt by observations on developmental stages in mammals (Jenkins 1969). In the case of the axis and succeeding vertebrae the hypochordal arches degenerate, either disappearing entirely or becoming incorporated into the ventral parts of the adjoining centra.

NOTOCHORDAL VESTIGES

The notochord may be identified for some time traversing the cartilaginous centra, but these parts of it ultimately atrophy and vanish. Between the developing vertebrae it expands as localized aggregates of cells with intervening mucoid matrix together forming the *nucleus pulposus* of the intervertebral disc. This nucleus is surrounded by the intermediate part of each perichordal disc which forms the *anulus fibrosus* and differentiates into an external laminated fibrous zone and an internal cuff around the nucleus pulposus. This inner zone contributes to the growth of the outer, and near the end of the second month of embryonic life it begins to merge with the notochordal tissue, being ultimately converted into fibrocartilage. After the sixth month of fetal life notochordal cells in the nucleus pulposus commence to degenerate, being replaced by cells from the internal zone of the anulus fibrosus. This degeneration continues until the second decade of life, by which time all the notochordal cells have disappeared (p. 490). Thus, in the adult, notochordal vestiges are limited, at the most, to non-cellular matrix.

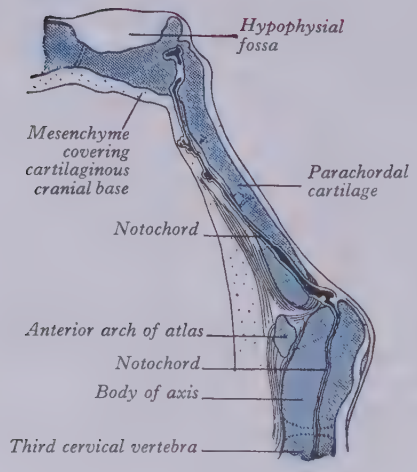
SUMMARY

Each vertebra was thus usually described as formed from parts of two adjacent sclerotomes. The rearrangement of segmentation was said to result in an alteration in position of vertebrae with respect to myotomes, bringing the intersegmental vessels into line with the vertebral bodies, a relationship which persists in the lumbar and lower thoracic regions. However, an extensive study of the behaviour of the perichordal and sclerotomic mesenchyme in the embryos of sheep suggests that, in this species at least, '*resegmentation*' of this kind does not occur, the primordia of vertebrae arising in their *definitive* positions, without any movement into new sites relative to surrounding structures (Verbout 1976, 1985). The essence of this view is that the vertebral *processes* and *centra* have different mesenchymal origins, the former from cells closely associated with myotomes (*sclerotomic tissue*), the latter from the non-segmented *perichordal mesenchyme*. The processes develop in a caudal condensation within their segment and are caudal to the numerically corresponding spinal nerve. It is suggested that a *gradient of segmentation* spreads medially from the myotomes to the precursors of the vertebral processes and from these to the perichordal tissue (2.40). For further data and an extensive review of these topics consult Verbout (1985).

Towards the end of the second month ossification commences in the cartilaginous vertebrae and the column then enters the fourth and last stage in its development. The further details of this are described elsewhere (p. 327).

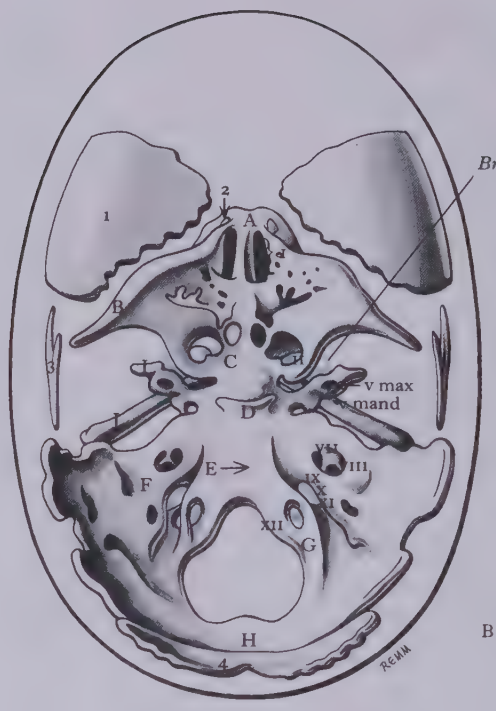
RIBS, COSTAL CARTILAGES AND STERNUM

The ribs develop from the costal processes of the primitive vertebral arches, extending between the myotomic muscle plates. In the thoracic region (2.44) of the vertebral column these processes grow laterally to form a series of *precartilaginous ribs*. The transverse processes grow laterally behind the vertebral ends of the costal processes, at first connected by mesenchyme which later becomes differentiated into the ligaments and other tissues of the costotransverse joints. The capitular costovertebral joints are similarly formed from mesenchyme between the proximal end of the costal processes and the perichordal disc, and adjacent, neural arch derived parts of usually two (sometimes one) vertebral bodies. In *cervical vertebra* (2.44) the transverse process is dorsomedial to the foramen transversarium, while the costal process, corresponding to the head, neck and tubercle of a rib, limits the foramen ventrolaterally and dorsolaterally. The distal parts of these cervical costal processes do not develop, but occasionally they do so in the case of the seventh cervical vertebra, even developing costovertebral joints. Such *cervical ribs* may reach the sternum (p. 328). In *lumbar vertebrae* (2.44) the costal processes do not develop distally, but their proximal parts become the 'transverse processes' of these vertebrae, whose morphologically *true* transverse processes may be represented by their accessory processes (p. 322). Occasionally, movable ribs may develop in association with the first lumbar vertebra. Only the upper two or three *sacral costal processes* usually develop (2.44). They fuse into the lateral mass of the sacrum, forming its ventral part. The *coccygeal* vertebrae are apparently devoid of costal processes.



The sternum is formed from bilateral mesenchymatous condensations, sternal plates, which begin in the dorsolateral region of the body wall. They are immediately ventral to the rudiments of the clavicles and ribs, but are independent of them in their formation, in so far as experiments on their primordia in the mouse can testify to the human condition (Chen 1952). These plates chondrify, move ventrally towards each other from both sides as the costal processes lengthen, and they eventually fuse together across the midline in a craniocaudal direction. This forms a longitudinal cartilaginous bar, with which the clavicles and upper seven pairs of costal cartilages establish contact. The xiphoid process develops as a caudal extension of the sternal bar. Hypertrophy of the cartilage cells as a preliminary to ossification occurs opposite future intercostal spaces, as the first indication of segmentation of the sternum into manubrium, four sternebrae for the 'body', and xiphoid process. The ossification and further growth of the sternum and ribs is described later (pp. 332, 335).

Development of the Cranium (2.45)



The bones of the skull are developed in the mesenchyme which surrounds the cerebral vesicles but, before the osseous state is reached, the cranium passes through blastemal and cartilaginous stages like other parts of the skeleton. However, not all parts pass through a phase of chondrification; and hence the *chondrocranium* is incomplete, the remainder comprising the mesenchymatous, *blastemal desmocranium*. Most of the cranial vault and limited parts of its base are thus not preformed in cartilage. Though the mesenchymatous (membranous) and cartilaginous parts of the skull will, for convenience, be considered in sequence, they develop together and complement each other in forming the complete cranium, some of whose bones are composite structures derived from both sources. All elements, of course, pass first through a mesenchymatous phase (2.45A-F).

THE DESMOCRANIUM

The blastemal skull (desmocranium) begins to appear at the end of the first month as a condensation and thickening of the mesenchyme which surrounds the developing brain, forming localized masses which are the earliest distinguishable cranial elements. The first masses evident are in the occipital region, outlining the basilar (ventral) part of the occipital bone. These form an *occipital plate*, from which two extensions on each side grow laterally and spread to complete a foramen around each hypoglossal nerve. At the same time the mesenchymal condensation extends forwards, dorsal to the pharynx, to reach the primordium of the hypophysis, thus establishing the clivus of the cranial base and the dorsum

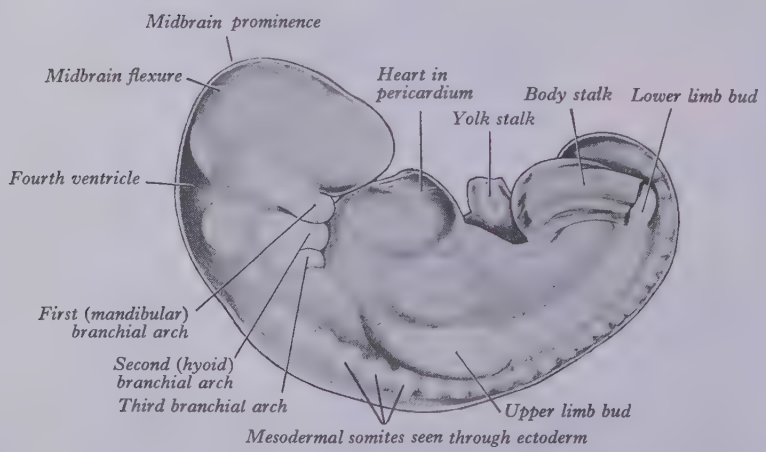
sellae of the future sphenoid bone. Early in the second month it surrounds the developing stalk of the hypophysis and extends ventrally and rostrally between the two halves of the nasal cavity, where it forms the anlage of the ethmoid bone and of the nasal septum. The notochord traverses the ventral occipital plate obliquely, being at first near its dorsal surface and then lying ventrally, where it comes into close relationship to the epithelium of the dorsal wall of the pharynx, being for a time fused with it. It then re-enters the cranial base and runs rostrally to end just caudal to the hypophysis (**2**.45A).

During the fifth week bilateral *otocysts* (auditory vesicles) become enclosed in their mesenchymal *otic capsules*, which soon differentiate into dorsolateral *vestibular* and ventromedial *cochlear* parts, enveloping the primordia of the semicircular canals and the cochlea. Between these two regions the facial nerve lies in a deep groove. The otocysts fuse with the lateral processes of the occipital plate, leaving a wide hiatus through which the internal jugular vein and the glossopharyngeal, vagus and accessory nerves pass. At this stage the mesenchyme around the developing hypophysial stalk, which is forming the rudiment of the postsphenoid part of the sphenoid bone, spreads out laterally to form the future greater wings of this element. Smaller processes rostral to this indicate the sites of the lesser wings of the sphenoid, while other condensations reach the sides of the nasal cavity and also blend with the still mesenchymatous septum.

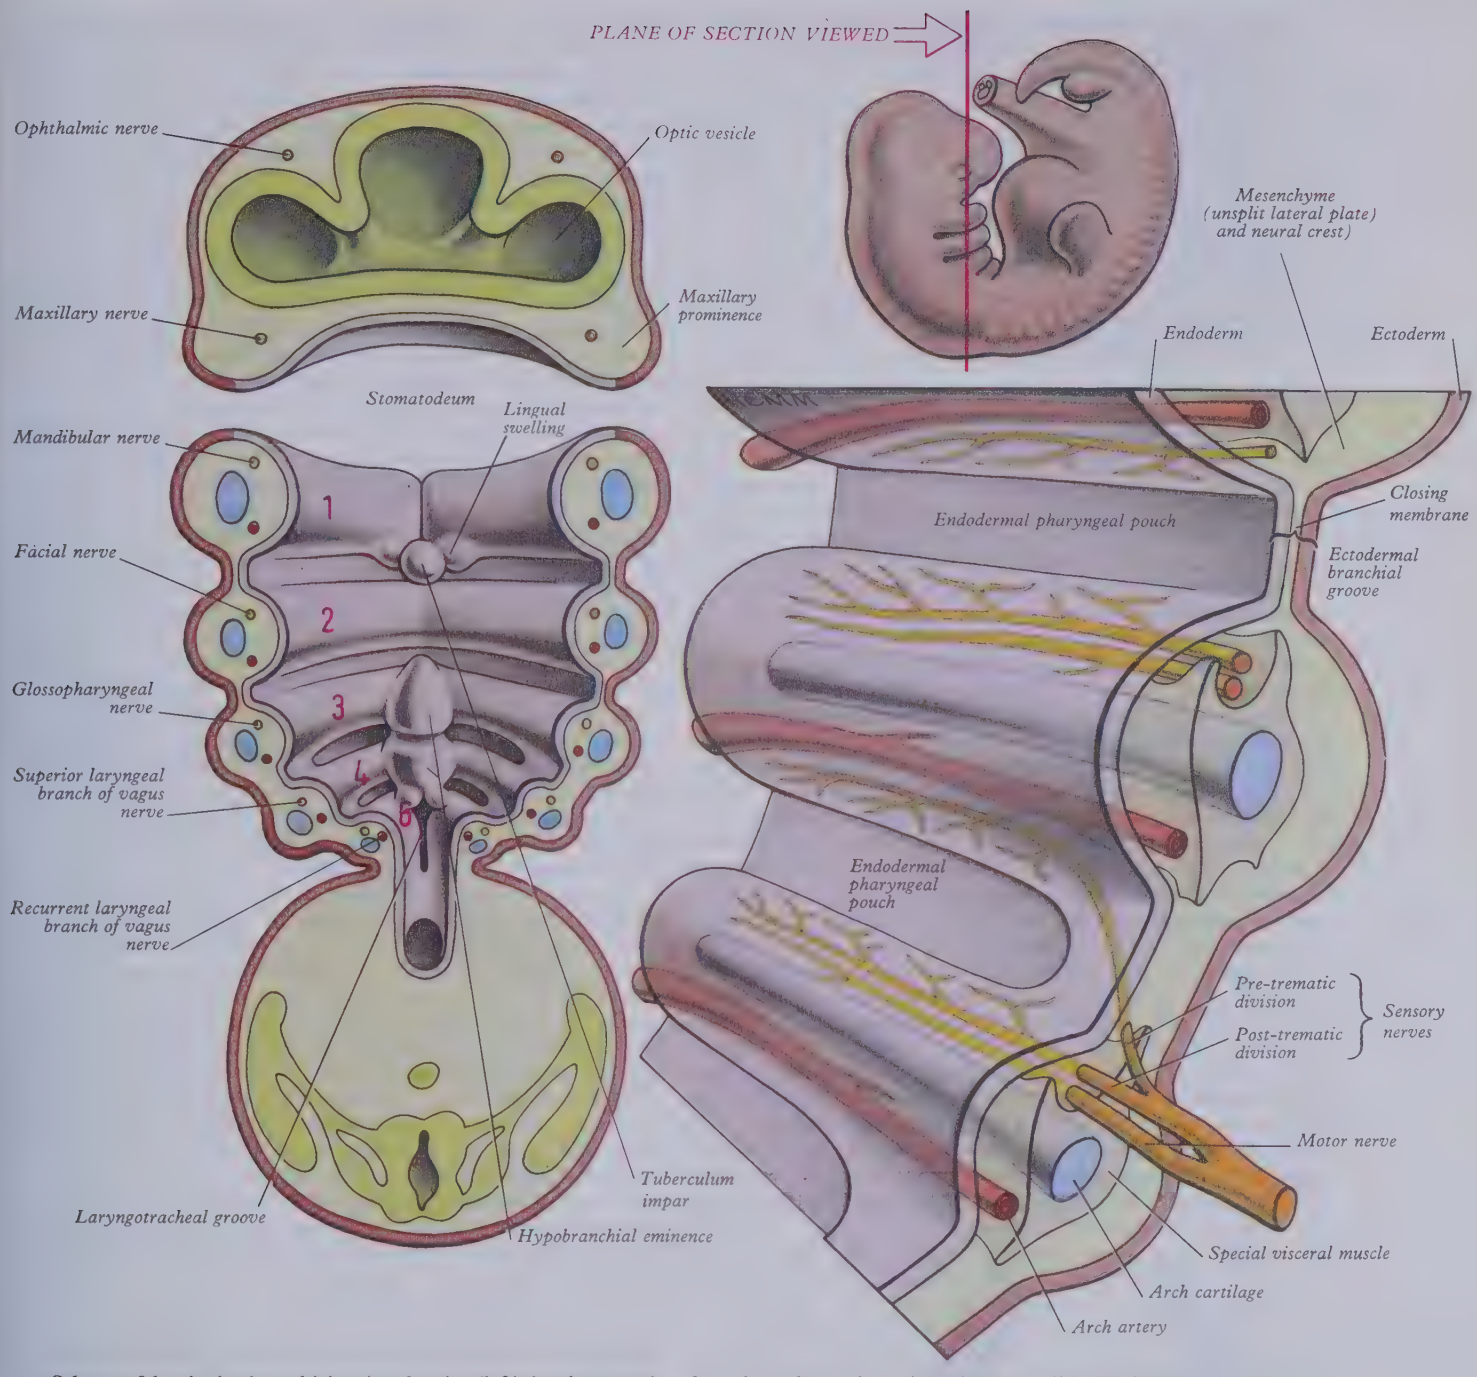
The first signs of the vault or upper neurocranial part of the skull appear about the thirtieth day; they consist of curved plates of mesenchyme at the sides of the skull and gradually extend cranially to blend with each other; they also extend towards and reach the base of the skull, which will become part of the chondrocranium.

THE CHONDROCRANIUM



Chondrocranium (**2**.45) is a term applied to the parts of any vertebrate skull which pass through, and sometimes remain in, a cartilaginous stage. (In Chondrichthyes, the cartilaginous fishes, such as sharks, all the cranium chondrifies and persists in this state—see p. 340.) The crania of all land animals, the tetrapods, contain variable regions which ossify directly from mesenchyme. Such *dermal* (membranous) elements form much of the cranial vault, and in mammals *chondrification* is limited to the basal regions of the skull (**2**.45). This mammalian change occurs primarily in three regions: (1) caudally, in relation to the notochord; (2) intermediately, in relation to the hypophysis; and (3) rostrally, between the orbits and the nasal cavities. These may be named *parachordal, hypophysial* and *interorbitonasal* regions. The parachordal cartilage is developed from the mesenchyme related to the cranial end of the notochord; caudally it exhibits traces of four primitive segments separated by the roots of the hypoglossal nerves. The hypophysial cartilage ossifies to form the postsphenoid part of the sphenoid bone, but its morphological status is uncertain. The interorbitonasal cartilage is perhaps to be equated with the trabeculae cranii of lower vertebrates and is usually known as the *trabecular cartilage*, which is a bilateral structure developing from two centres of chondrification. The trabeculae cranii may largely be derived from branchial arch (neural crest) mesoderm, i.e. from the **viscerocranium**, having been adapted into the cartilaginous or basal part of the **neurocranium** or 'brainbox'. From the evidence in embryos of earlier vertebrates most of the chondrocranium and the majority of the viscerocranium are derived from neural crest tissue, including almost all of the branchial skeleton. Only the caudal parts of the trabeculae, the parachordal bars, the otic capsules and the second basibranchial appear to be derived from general head mesenchyme. For these and other details of development and morphology of the mammalian chondrocranium, see references (Fawcett 1911, 1917, 1918, de Beer 1937, Hörstadius 1950, Stark 1965, Balinsky 1981).

In the human embryo cranial chondrification begins in the second month; cartilaginous foci first appear in the occipital plate, one on each side of the notochord (parachordal cartilages); these later fuse at the end of the seventh week surrounding the notochord, whose oblique transit through the region has been mentioned (**2**.45A). The cartilaginous posterior part of the sphenoid is formed from two hypophysial centres, flanking the stalk of the hypophysis and uniting at first behind, then in front, enclosing a *craniopharyngeal canal* containing the hypophysial diverticulum. The canal is usually obliterated by the third month; its association with the derivation of the anterior lobe of the hypophysis from the pharyngeal diverticulum of Rathke has been denied (p. 230).



The otic capsules, presphenoid, bases of the greater wings and lesser wings of the sphenoid, and finally the nasal capsules, in turn become chondrified. The whole nasal capsule is well developed by the end of the third month, consisting of a common median septal part (sometimes initially termed the *interorbitonasal septum*) and two lateral regions. The free caudal borders of the latter incurve to form the inferior nasal conchae, which ossify during the fifth month and become separate elements. Posteriorly each lateral part of the nasal capsule becomes ossified as the ethmoidal labyrinth, bearing on its medial surface ridges the future middle and superior conchae. Part of the rest of the capsule remains cartilaginous as the septal and alar cartilages of the nose; part is replaced by the mesenchymatous vomer and nasal bones.

The ventral surface of the chondrocranium is associated with the cartilages of the branchial arches, the *viscerocranium*, the development of which will be considered later (vide infra). The bones of the cranial base which are thus preformed in cartilage are the occipital (excepting the upper part of its squama), the petromastoid part of the temporal, the body, lesser wings and roots of the greater wings of the sphenoid, and the ethmoid. These constitute the cartilaginous part of the neurocranium, the rest of which, the mesenchymatous (membranous) neurocranium, corresponding to the cranial vault, is not preformed in cartilage. Its elements, frequently described as *dermal* bones because of their probable origin (p. 340), are the frontal bones, the parietals, the squamous parts of the temporal bones and the upper (interparietal) part of the occipital squama. To summarize, therefore, the base of the skull—except for the orbital plates of the frontal and the lateral parts of the greater sphenoidal wings—is preformed in cartilage, while the whole of the vault is ossified directly in mesenchyme (**2**.45B-F).

Ossification commences before the chondrocranium has fully developed, and as this change extends, bone overtakes cartilage until little of the chondrocranium remains. However, parts of it still exist at birth and small regions remain cartilaginous in the adult skull. At birth unossified chondrocranium still persists at: (1) the alae and septum of the nose, (2) the spheno-ethmoidal junction (p. 376), (3) the spheno-occipital and spheno-petrous junctions (p. 376), (4) the apex of the petrous bone (foramen lacerum), and (5) between ossifying elements of the sphenoid bone and between elements of the occipital bone. Most of these regions function as growth cartilages (p. 474). For further

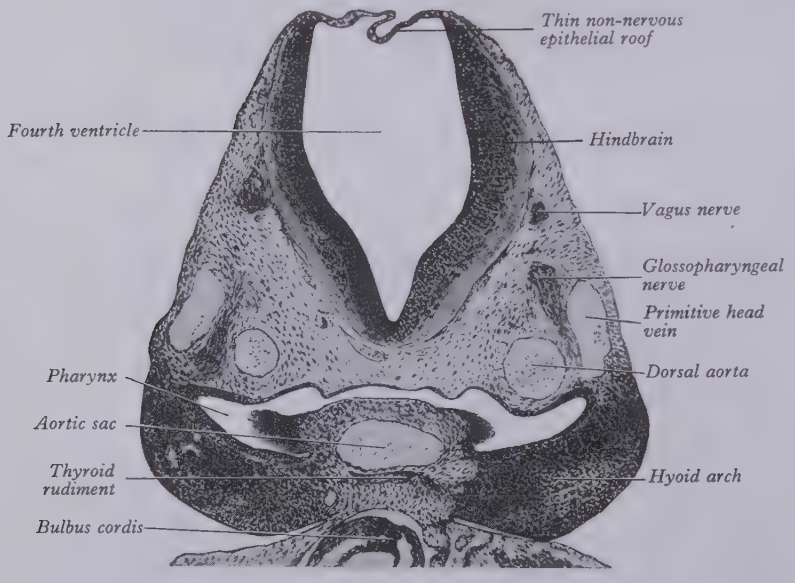
development of these areas and cranial bones in general see Section 3, Osteology and Section 4, Arthrology.

THE VISCEROCRANIUM

Certain cranial components are derived from the branchial or visceral arches, the *viscerocranium*, and therefore their skeletal development will be considered next, before that of the appendicular skeleton (p. 174). It is also convenient to include a general consideration of the branchial apparatus.

The Branchial Apparatus



After head fold formation, the *stomatodeum* or primitive mouth is bounded cranially by the projecting forebrain and caudally by the cardiac prominence (2.46). The mandibular region and the whole of the neck, which will subsequently intervene between mouth and developing thorax, are absent, but will be formed by the appearance and modification of six paired **branchial arches**, which develop in the lateral aspects of the head adjacent to the hindbrain (2.47, 48, 49). In the earliest vertebrates, which were jawless (*Agnatha*), the arches were a uniform series of bars between the gill clefts; but long before the evolution of the terrestrial vertebrates, remarkable adaptations had occurred in them. Structures commonly regarded as the first pair of arches became the jaws, upper and lower, of the jaw-bearing vertebrates (*Gnathostomata*), including most fish; they are, therefore, usually named the *mandibular arches*. (The term 'mandibular arch' is widely used but not entirely appropriate because of the numerous maxillofacial, nasal, otic and palatopharyngeal derivatives from its dorsal end.) It should, however, be noted that since this early

2.48 An oblique section through the pharynx of a human embryo. C.R. length—2 mm. Magnification × *c.* 50. (Norris, 1938.)

identification, strong evidence has accumulated that, at least, a pair of *pre-mandibular arches* existed and have become adapted as the *trabeculae cranii* of subsequent vertebrate embryos. These are probably represented by the interorbitonasal cartilage of the human embryo, as mentioned above (p. 164), forming the visceral or branchial element in the chondrocranium. The next (*post-mandibular*) arch in the series is the *hyoid arch*; its skeletal derivatives form the varied hyoid elements present in all vertebrates with jaws. The most dorsal of the latter, the *hyomandibula*, is already present in cartilaginous fish as a strut between the skull and the primitive jaw joint, thereby reducing the cleft between the mandibular and hyoid arches to a small opening, the *spiracle*. The interesting further evolution of this region in land animals in connection with the auditory apparatus will be considered later (p. 204). The hyoid arch also contributes to the formation of a gill cover, or *operculum* in bony fish, and the remaining arches persist as the supports of the gill apparatus.

The mesenchyme of the branchial region (p. 138) at first exists as a thin sheet between the ectoderm and endoderm but, as growth proceeds, it proliferates to form a series of cylindrical masses which constitute the mesodermal cores of the *branchial arches*, covered, of course, by the two epithelia mentioned. At first the arches produce rounded ridge-like prominences both of the overlying ectoderm and of the endodermal lining of the lateral walls and floor of the pharynx. In the furrows between these prominences the ectoderm and endoderm are in virtual contact. The thin membranes so formed break down in gill-breathing vertebrates but persist in the tetrapods, in which open channels or 'true clefts' are not formed. However, the external *branchial grooves* which correspond to them are frequently, less appropriately, called *branchial clefts* and their internal counterparts are the *pharyngeal sacs* or *pouches*. At this stage in the human embryo the pharynx is transversely wide at its cranial end but rapidly narrows in a caudal direction; it is also so dorsoventrally compressed that there is limited, or virtually no, true lateral wall (**2**.49).

2.49 Oblique section through the head of a mole embryo, 4.5 mm long. The section passes through the hindbrain, the pharynx, the second (hyoid) and a part of the third branchial arches.

In gill-breathing vertebrates the exchange of respiratory gases is directly from solution in water to solution in blood. From the cranial end (arterial, but carrying deoxygenated blood) of the heart emerge two *ventral aortae* which traverse the ventral pharyngeal wall, sending branches curving dorsally into the branchial arches, where they feed capillary plexuses in the gills. These are drained by corresponding arteries, which join two *dorsal aortae* supplying the general circulation. As water is taken in through the mouth and passed back through the gill clefts, its dissolved oxygen diffuses through the pharyngeal endoderm and endothelium of the gills to reach the blood, carbon dioxide diffusing out of the latter into the water. The intimate relationship between the developing mouth, branchial apparatus and heart in water-breathing vertebrates is repeated in the embryos of their tetrapod descendants, but with many modifications necessary to changed respiratory function.

The human circumoral *first branchial arch* (**2**.47, 50) consists, on each side, of two main regions — a *ventral part* or *mandibular prominence* and a *dorsal part* or *maxillary prominence*. Each mandibular prominence grows ventromedially in the floor of the pharynx to meet its fellow in the midline, being situated between the primitive mouth and the cardiac (pericardial) prominence. The *second* or *hyoid arches* are caudal to the maxillo-mandibular and similarly grow ventrally to meet and fuse in the midline. The *third* and *fourth arches*, especially the latter, are not prominent, being largely sunk in a depression produced by the caudal overlapping of the hyoid arch. The *fifth* and *sixth arches* cannot be recognized externally and can only be identified by the arrangement of the mesenchyme and by slight projections into the pharynx. In their development the branchial structures are dependent upon the proximity of pharyngeal endoderm, removal of which aborts branchial development. However, the first arch is, in part at least, dependent upon ectoderm of the stomatodeum.

Each branchial arch consists of an ectodermal exterior, a mesenchymal core and an endodermal interior (**2**.47, 48, 49). The mesenchyme produces a presumptive *skeletal element*, which subsequently chondrifies either wholly or in part of its length; if this change is complete the element extends dorsally until it comes into contact with the mesenchymatous cranial base lateral to the hindbrain. Much of the remainder of the core of mesenchyme becomes *striated muscle*, which usually migrates and may lose connection with the skeletal elements in arches which cease their original respiratory function. The identities of these muscle masses, where they assume new functions, can nevertheless be inferred by reference to their nerve supply. Motor nerves from the adjacent hindbrain (**2**.47, 49, 64) pass directly into the arches, which are ventral to it. However far muscle masses migrate from their sites of development, their original innervation almost always persists. The mandibular division of the trigeminal nerve innervates the musculature of the mandibular prominence, the facial nerve supplies the hyoid arch, the glossopharyngeal, the third arch, and the vagus and accessory nerves the rest of the arches. The recurrent laryngeal may be the nerve of the sixth arch and the superior laryngeal that of the fourth. The nerve of the fifth arch, itself difficult to identify in the human embryo, is uncertain.

The branchial arches play a large part in the formation of the face, oronasal cavities, neck, pharynx and larynx, but before the development and adaptations of each of the latter are detailed it is convenient to describe the general events which lead to the construction of the face and nasal cavity.

THE FACE, NASAL CAVITY AND PALATE

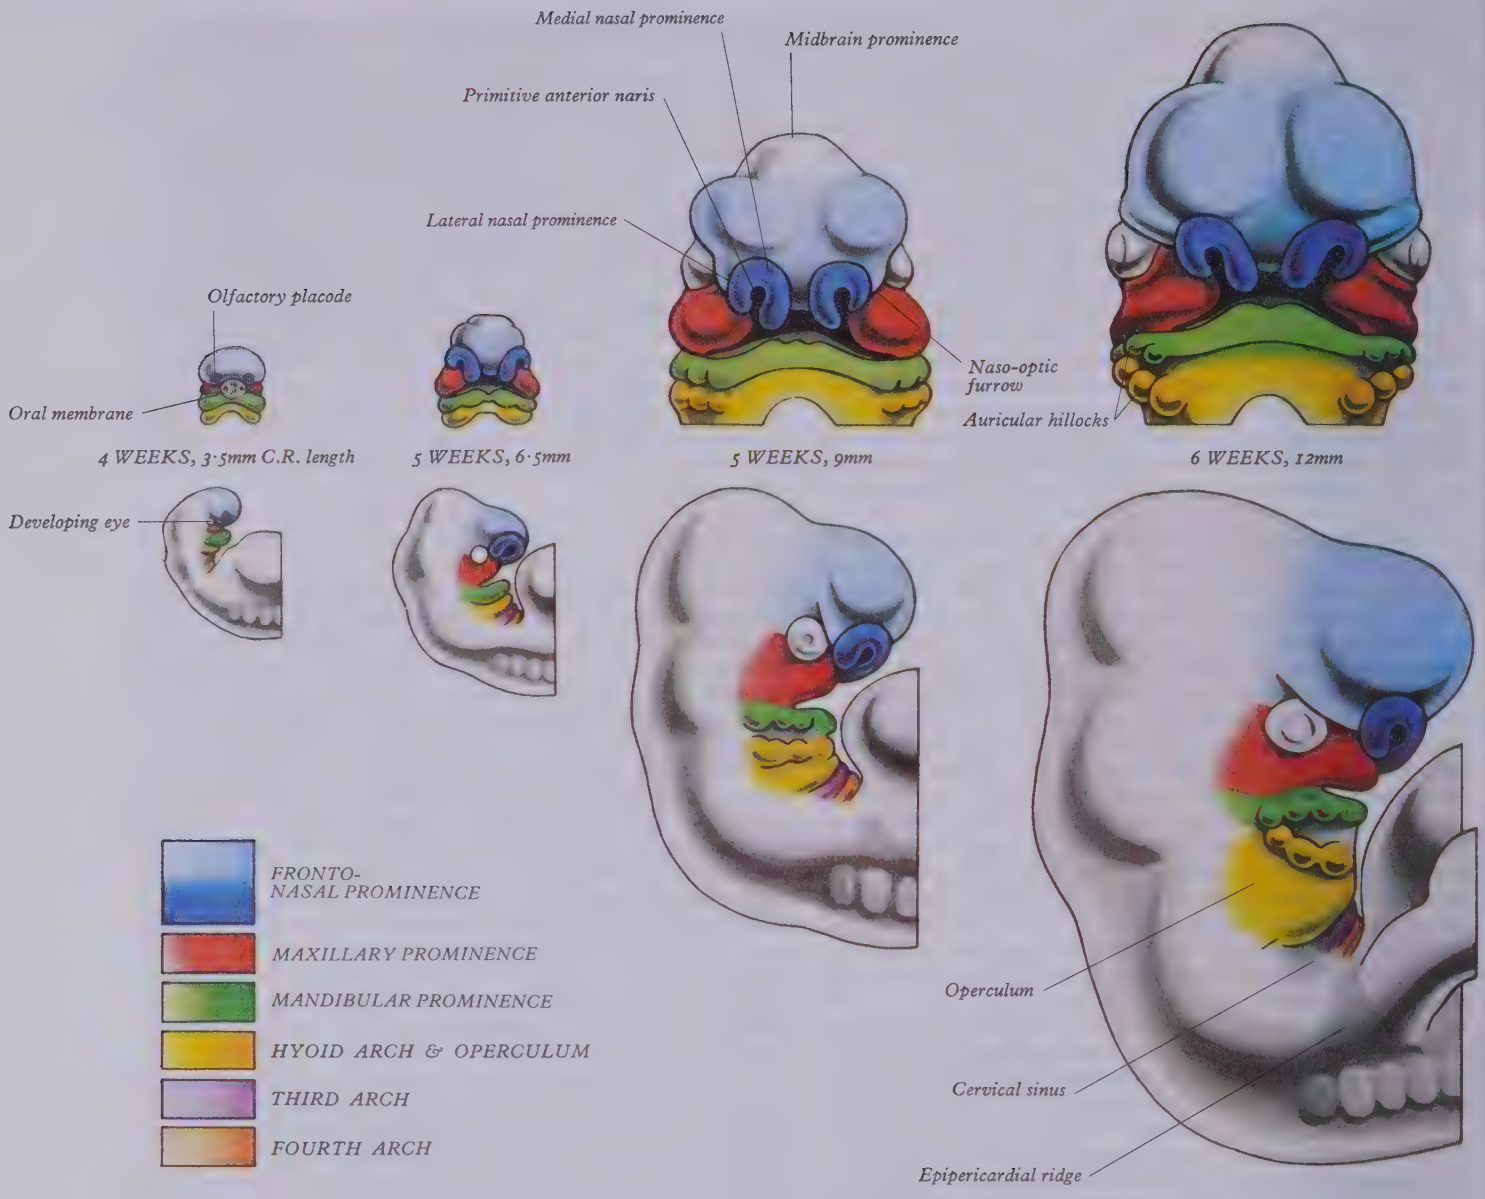
While the **mandibular prominence** is invading the floor of the pharynx, the mesenchyme between the central aspect of the

forebrain and the epithelial roof of the mouth proliferates and bulges under the ectoderm to form the *frontonasal prominence*. During the fifth week a thickened plaque of ectoderm develops on each side ventrolateral to the frontonasal prominence, dividing the latter, on each side, into *medial* and *lateral nasal prominences* or folds; these thickenings are the *olfactory* or *nasal placodes*. The placodes are at first widely separated and coplanar with the surface ectoderm but, as the prominences develop, they soon become depressed to form the *olfactory pits* (nasal sacs). The olfactory placodes are the anlage of the olfactory and vomeronasal epithelia; the extensive epithelia of cavities yet to form are respiratory. The lateral nasal prominences are the more evident (**2**.50, 51B), but the medial nasal prominences, still separated by the median remainder of the frontonasal field, project caudally beyond the former. Extensions of mesenchyme from the medial prominence into the roof of the stomatodeum proliferate to form the *premaxillary* or globular fields—the globular prominences of His. Each nasal sac has a ventral fold from which develops an epithelial *nasal fin* passing caudally to fuse with the stomatodeal roof.

While these changes are progressing a somewhat triangular elevation swells ventrally from the cranial aspect of the dorsal region of the mandibular prominence. This is the **maxillary prominence**, and like the frontonasal prominence it consists of proliferating mesenchyme covered by ectoderm. The maxillary prominence grows in a ventral direction and fuses with the lateral nasal prominence, the two being at first separated by a *nasomaxillary groove* (*naso-optic furrow*) (**2**.50, Streeter 1948). The opposed margins of the lateral nasal and maxillary prominences growing together thus establish continuity between the side of the future nose and the cheek (**2**.50). The ectoderm along the boundary between them does not entirely disappear; it gives rise to a solid cellular rod, which at first develops as a linear surface elevation, the *nasolacrimal ridge*, and then sinks into the mesenchyme (Politzer 1952). Its caudal end proliferates to connect with the caudal part of the lateral nasal wall, while its cranial extremity later connects with the developing conjunctival sac. The solid rod becomes canalized to form the *nasolacrimal duct* (**2**.51B).

(It should be noted that the epithelial folds and elevations due to loci of proliferation of underlying mesenchyme were long termed processes. The International Nomenclature Committee felt that this was not entirely appropriate and their revised term 'prominence' has been adopted here.)

The relatively wide primitive mouth or *stomatodeal fissure* is progressively reduced, and the epithelial and connective tissues of the cheek enlarged, by fusion between the adjacent surfaces of the mandibular and maxillary prominences. This proceeds from the paraotic region to the angle of the definitive *oral fissure*.



THE NASAL CAVITY

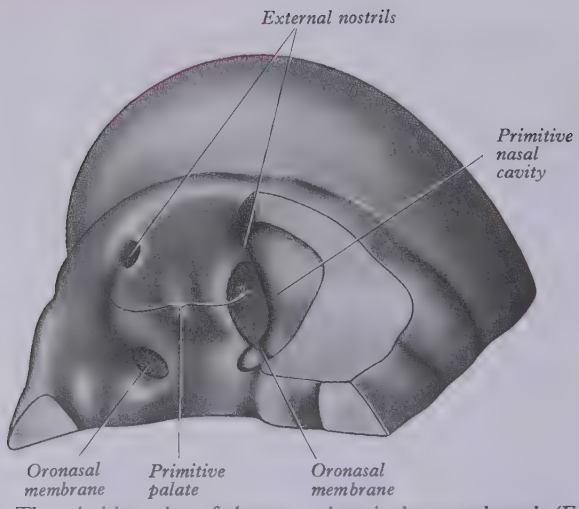
The rounded apex of the triangular maxillary prominence extends beyond the lateral nasal prominence, crossing the caudal end of the olfactory pit to meet and fuse with the *premaxillary elevation* developing at the extremity of the frontonasal field. This closes off the lower or caudal edge of the olfactory pit, the upper part of the opening of which is thus defined as the primitive *external naris*. The growth of the surrounding mesenchyme leads to a deepening of the pit to become a primitive nasal cavity, or *nasal sac*, the epithelial wall of which, in the dorsocaudal part of its extent, the nasal fin, retains contiguity with the epithelium of the stomatodeal roof. This contact area becomes progressively greater as growth continues, and the nasal fin is eroded, ultimately forming a thin layer, the *oronasal membrane*, which also disappears later. Thereafter the primitive nasal cavity communicates with the stomatodeum through a primitive *internal naris (choana)*, which is at this stage still well forward or ventrally situated in the stomatodeal roof (Warbrick 1960). By these changes a new cranial boundary is set for the oral opening, consisting of the fused premaxillary and maxillary regions. This is the future upper lip, but it has not yet become separated from the deeper tissues which will form the maxillary alveolus. At the same time the nasal cavity acquires a floor through the fusion of the nasal prominences and the maxillary prominences. At this stage the two external nares are still widely separated by an area derived from the frontonasal field, but this separation becomes reduced by the fusion of the premaxillary mesenchyme from the two sides. According to some investigators the mesenchyme of the maxillary prominences invades the premaxillary regions, the mesenchyme of which is said to become buried, to form later the premaxilla or os incisivum (p. 389, Boyd 1933, Baxter 1953). The maxillary mesenchyme is thus considered by some to contribute substantially to the formation of the philtrum of the upper lip, thus accounting for its maxillary innervation. Others, however, maintain that the philtrum is derived wholly from premaxillary tissue (Warbrick 1960, Keith 1948, King 1954, Wood et al 1967). The maxillary nerve primarily innervates the maxillary mesenchyme but apparently extends later into the territory of the frontonasal prominence. (See also p. 1103.) It should be added that some workers deny that sensory nerve distribution is a reliable guide to migration of mesenchyme in the case of the maxillary prominence.

THE PALATE

Once the primitive nasal cavities are defined the ventral part of the roof of the oral cavity can be regarded as the *primitive palate (median palatine prominence)* (**2**.51A). It is formed by the premaxillary regions and maxillary prominences, which become confluent and establish continuity with the thick median *nasal septal prominence* (primitive nasal septum). As the head grows in size, the region of mesenchyme between the forebrain and oral cavity increases greatly by proliferation and the nasal cavities deepen, extending towards the forebrain. Simultaneously they also extend dorsally from the primitive choanae as two narrow and deep grooves in the oral roof (**2**.51B,C) which are separated by a partition. The grooves and the partition deepen together, and the latter becomes the *nasal septum*, continuous rostrally with the *primitive nasal septum* (**2**.51B). The broad dorsocaudal border of the nasal septum is at first in contact with the dorsum of the developing tongue (**2**.51B), the right and left nasal cavities still communicating freely with the mouth except where the nasal floor is already established ventrally by the primitive palate.

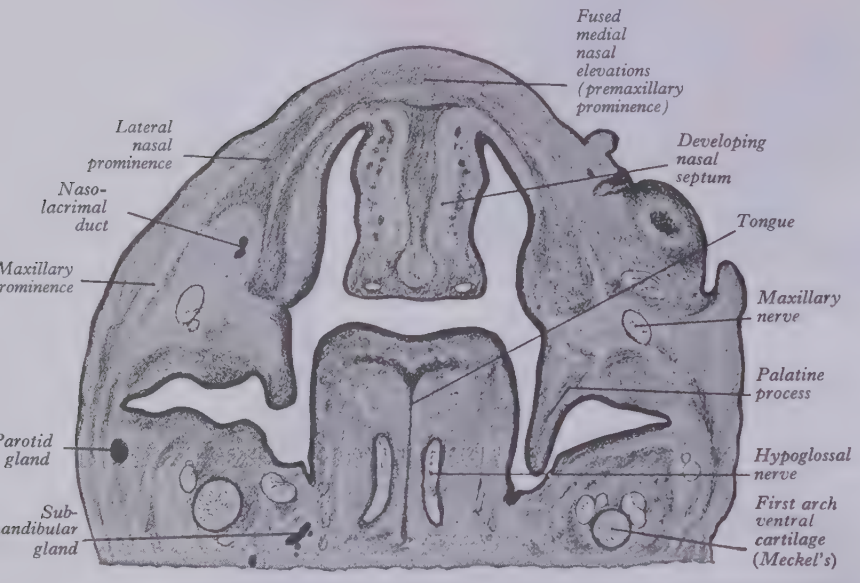
During the sixth week the internal aspects of the maxillary prominences produce *palatine processes*, which grow towards the midline but are for some time separated from each other by the tongue. At this stage the roof of the oral cavity projects ventrally beyond its floor and the tip of the developing tongue actually lies in contact with the cranial (superior) surface of the primitive palate. A coronal section dorsal to this shows the maxillary palatine processes contiguous with the sides of the tongue and bent into a vertical position on each side of it (**2**.51B). With further growth, the mandibular region and the tongue are carried forwards (ventrally), and the lingual tip passes round to the caudal surface of the primitive palate. By some mechanism, still subject to much controversy (Kraus et al 1969), the palatine processes assume a horizontal position which allows them to grow towards each other and thus to fuse (**2**.51C); this occurs from before backwards. The change of position occurs very rapidly in some experimental animals and may be due to a sudden increase in turgor in the processes (Ferguson 1977). Other views, such as active contraction of neighbouring striated and non-striated muscle, have been advanced (e.g. Wee et al 1976). The change is also said to be rapid in the case of the human palate. These events obviously may have a direct bearing on maldevelopment of the palate (vide infra). Palatal elevation in mankind occurs during the eighth week; the development of the neck, allowing some descent of the tongue and floor of the mouth, is then also occurring and may be an additional factor in the elevation. This permits the palatine processes to grow medially along the inferior borders of the primitive choanae, uniting with them and with the margins of the median palatine prominence, except over a small area in the midline where a *nasopalatine canal* maintains connection between the nasal and oral cavities for some time and marks the future position of the incisive fossa. (The plates which form the early (primitive) palate are sometimes known as *median* palatine processes, the

2.50 A sequence of diagrams showing the superficial contributions of the facial prominences and branchial elements to the development of the face, including the external nose, circumorbital structures, external acoustic meatus and pinna, and neck. All diagrams are drawn to scale. Note changes in general proportions and relative positions.



maxillary contributions being then named the *lateral* palatine processes.) As the medial borders of the maxillary palatine processes fuse together, fusing also with the free border of the nasal septum, the nasal and oral cavities are progressively separated and the tongue is excluded from the former. The nasal cavities are thus extended dorsally and the choanae reach their final position, leaving the caudal edge of the nasal septum free in about its dorsal quarter as the partition between them. Slightly later the dorsomedial extremities of the palatine processes, which extend dorsally beyond the choanae, fuse together rostrocaudally to form the future epithelia and connective tissues of the soft palate (**2.51C**). This fusion, as is the case with most of the processes and prominences which form these regions, is more apparent than real, the epithelial cleft between the two processes being pushed to the surface by mesenchymal growth (Burdi & Faist 1967). There is later an upgrowth of myogenic mesenchyme from the third (and probably other) branchial arches into the palate and around the caudal margins of the auditory tubes, along a line corresponding in the final state to the palatopharyngeal arches (Baxter 1953).

On each side of the nasal septum, in a ventral or anterior position just above the primitive palate, placodal ectoderm is invaginated to form a pair of small diverticula, which extend dorsally and cranially into the septum. These are vestiges of the *vomeronasal organs* (**2.51C**), whose openings are close to the junction between the two premaxillae and the maxillae; they are always rudimentary in mankind, but are well-developed auxiliary olfactory organs in many vertebrates (pp. 1095, 1173, 1175). For bibliographies in the field of facial development consult Latham (1973).



Anomalies

Congenital malformations consequent upon arrest of development and failure of fusion of components in the formation of the face and palate are not uncommon. At the simplest, one maxillary prominence may fail completely to fuse with the corresponding premaxillary region (globular prominence), leading to a persistent fissure between the philtrum and lateral part of the upper lip on that side, *cleft lip* (less appropriately 'hare' lip). A similar but rare malformation follows failure of fusion between the maxillary prominence and the lateral nasal prominence, *facial cleft*, in which the nasolacrimal duct persists as an open furrow, a condition usually associated with a cleft lip on the same side. The palatine processes may fail to fuse with each other and the nasal septum to

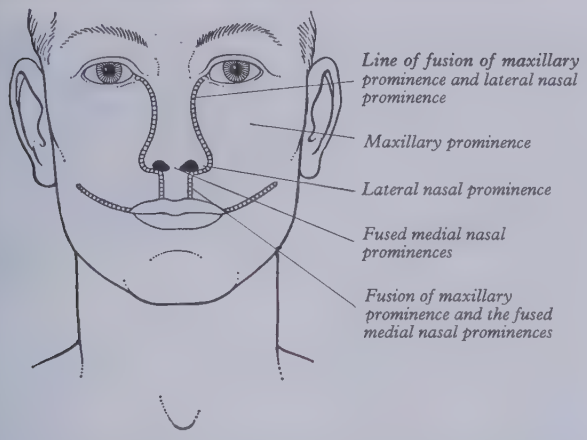
variable degrees. In its severest form fusion is wholly lacking, leaving a wide fissure between the palatine processes through which the nasal septum is visible. On each side the premaxillary parts of the palate are separated from the maxillary palatine processes by clefts which are continuous ventrally with bilateral clefts in the upper lip. In such cases the philtrum is a separate entity, continuous cranially and dorsally with the nasal septum. The floor of the nasal cavity is deficient throughout its extent and the choanae are not completed. Many varieties of milder degrees of cleft palate have been observed; the commonest type is unilateral, only one side of the nasal cavity being in communication with the mouth, the extent of the cleft being variable. In the mildest forms only the soft palate is cleft, or even merely the uvula. Such examples of arrested development may be associated with disturbances in embryonic nutrition during the second and the third months of gestation (p. 156) and the grosser varieties are usually coupled with malformations in other regions of the body. In such cases the premaxillary region protrudes, with associated extension forwards of the nasal septum. For discussion see Latham (1973). Certain midline anomalies are rarely encountered, *median cleft lip* (true hare lip), *cleft nose* and *cleft lower jaw*. More common are minor degrees of *cleft chin* and *micrognathia* —under-development of the lower jaw.

The further growth of the face during the fetal period has received little attention, although this period is by no means characterized entirely by incremental growth. It is during fetal life that human facial proportions develop. The facial and cranial parts display different patterns of growth, though each influences the other. For an interesting analysis of the data observed from 280 fetuses consult Lavelle (1974).



Further Branchial Development

As has already been described to some extent, the branchial arches contribute extensively to the growth of the face, neck, nasal cavity and mouth, as they also do in the case of the palate, larynx and pharynx. Although there are never complete clefts between the arches, the external ectodermal *branchial grooves* and internal endodermal *pharyngeal pouches* make various contributions. The first branchial groove does partly persist as, and contributes to, the external acoustic meatus but it is closed by the tympanic membrane. The remaining grooves disappear, except in so far as such derivatives of their corresponding pharyngeal pouches as the tympanic cavity, auditory tube, tonsil, thymus, parathyroid and thyroid glands can be counted. It should be noted, however, that some contend that the surface course of the second groove persists as the curved submandibular *cervical flexure line*.

ECTODERMAL DERIVATIVES

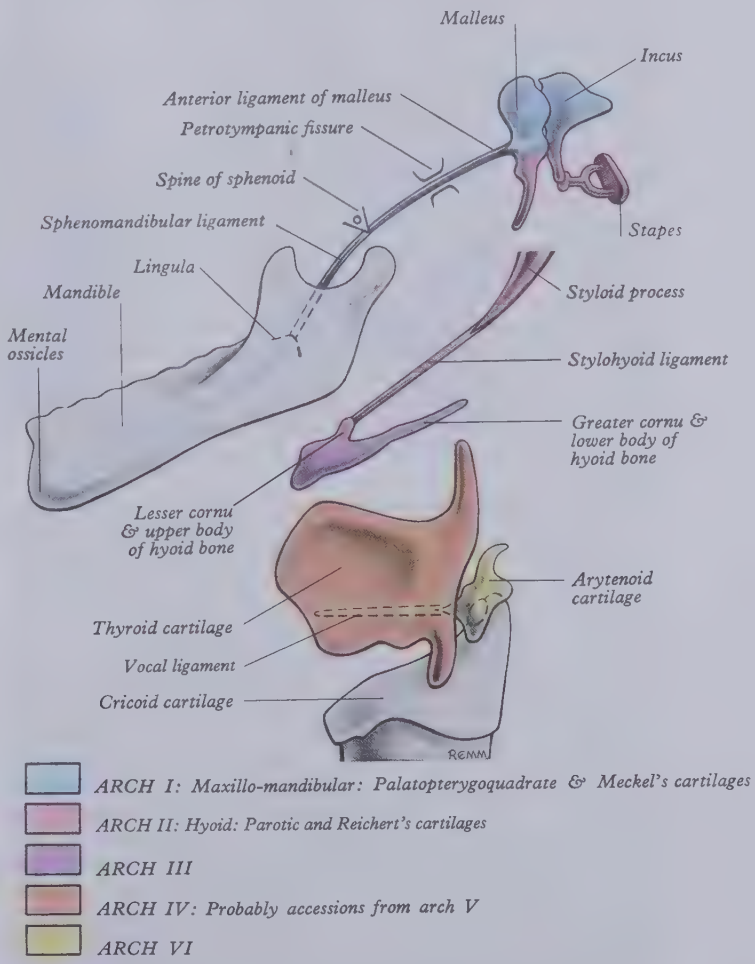
The ectoderm over the mandibular prominences becomes the skin of the mandibular region of the face (2.50, 52), and it also takes part in forming the tragus of the auricle (p. 1220). Its surface facial contribution is roughly triangular; the apex includes the tragus, the upper border extending to the lateral angle of the mouth and free border of lower lip; its lower border curves to follow the principal submandibular flexure line of the neck. The ectoderm on the arched cranial aspects of these prominences thickens along a curve which later becomes the *labiogingival* (vestibular) *groove*. This epithelial proliferation invades the subjacent mesenchyme and subsequently breaks down to separate the lower lip from the developing gum. Before this, however, an epithelial lamina develops from its internal surface (8.78) from which the enamel organs of the teeth will eventually be derived (p. 1313). Similar phenomena occur in the caudal, arched circumoral border of the maxillary prominence. Its surface facial contribution extends from the supratragic point to the lateral angles of eye and mouth, includes the lower eyelid and follows the paranasal line of the nasolacrimal duct, finally including a controversial amount of the upper lip.

The first branchial groove is obliterated ventrally, as in all but the most ancient vertebrates. In man its dorsal end deepens to form the epithelium of the external acoustic meatus and the

2.52 Diagram to show the parts of the adult face which are derived from the nasal elevations, and the maxillary and mandibular processes.

external surface of the tympanic membrane. (For details see p. 204.)

At the dorsal ends of the first, second and fourth branchial grooves thickened patches of ectoderm appear, the *epibranchial placodes*. These are closely related to the developing ganglia of the facial, glossopharyngeal and vagus nerves, to which they contribute (p. 199): these, and other placodal cells (*dorsolateral* and *suprabranchial*) also contribute to the trigeminal and vestibulocochlear ganglia. The interrelation, relative contribution and precise definition of placodal cells, and cranial neural crest remains speculative.



At the end of the fifth week the third and fourth arches are sunk in a retrohyoid depression, the *cervical sinus*. Cranially the sinus is bounded by the hyoid arch, dorsally by a ridge produced by ventral extensions from the occipital myotomes and by mesenchyme developing into sternocleidomastoid and trapezius. Caudally, the smaller *epipericardial ridge* separates the sinus from the pericardium and curves cranially near the midline, and then with its fellow reaches the lingual swelling of the mandibular prominence and the hypobranchial eminence. The muscle cells which are often held to migrate from the occipital myotomes to the tongue follow the epipericardial ridge together with the hypoglossal nerve (but see p. 175). The long held view that the sinus is obliterated by caudal growth of the hyoid arches to fuse with the cardiac elevation, excluding the succeeding arches from any part in the formation of the skin of the neck, has been criticized; an alternative view is that the sinus is reduced by gradual approximation of its walls from within outwards. During these changes the epibranchial placodes sink inwards as small vesicles which ultimately lose connection with the surface ectoderm, and are then more closely associated with possibly the trigeminal and with the acousticofacial, glossopharyngeal and vagus nerves. The vesicle derived from the fourth groove placode is also for a time associated with the rudiments of the thymus and parathyroid arising from the third endodermal pharyngeal pouch (p. 229, Garrett 1948), but there is no evidence that the human thymus receives any substantial contribution from this vesicle.

Experiment clearly shows that in lower vertebrates the trigeminal, acousticofacial, glossopharyngeal and vagus nerves derive elements from the overlying epibranchial placodes, or are dependent upon the associated placode for their full development. All the foregoing nerves also receive large accessions from the cranial neural crest, and the acousticofacial from the otocyst. In man, the placodal vesicles associated with the glossopharyngeal and vagus nerves are believed largely to regress, abnormal persistence giving rise to *branchial (lateral cervical) cysts*, which are lined by stratified squamous epithelium and are situated between the carotid sheath and sternocleidomastoid. It is claimed that branchial cysts, lined by columnar epithelium, may be derived from persistent remnants of pharyngeal pouches, and that *branchial (lateral cervical) fistulae* may result from the second branchial cleft or possibly the cervical sinus (Martins 1961). Blind ended *sinuses*, with varying epithelia and either an external or internal opening, may have a similar origin. In contrast, *preauricular sinuses* may result from failed fusion between auricular hillocks, the forerunners of the pinna.

MESODERMAL DERIVATIVES

The mesoderm of the branchial arches (of mixed *unsplit lateral plate, neural crest and possibly placodal* origin) is still 'pluripotential'; the term is used here to indicate the ultimate variety of its derivatives (and does not imply the immediate premitotic potential of individual cells—p. 108). The derivatives include the following: (1) An endothelial tube, an *aortic arch*, develops in the substance of each arch, connecting the aortic sac, ventral to the pharynx (p. 214), to the dorsal aorta, which is dorsal to it. There are thus six pairs of aortic arches, but the appearance of the fifth pair in man is questioned; its position and connections are subject to disagreement (Shaner 1921, Barry 1951). For further details see p. 216. (2) Some of the mesodermal cells, many of neural crest origin, condense to form a skeletal element in each arch; and this is typically a bar of cartilage connected by its dorsal end to the caudal region of the chondrocranium and meeting its fellow ventrally in the midline. (3) Other mesodermal cells differentiate into 'special visceral' striated muscle tissue; and partly associated with this developing *branchial musculature* is to be noted the invasion of the mesoderm by a nerve supply. The proportion of branchial mesoderm from each of its various sources noted above that contributes to the different types of derivative is uncertain (except for comparative experimental results implying neural crest predominance in the cartilage).

Typically each arch is invaded by two nerves, derived from the hindbrain. One runs along the rostral border of the arch and is

2.53 Schema illustrating the skeletal derivatives (osseous and cartilaginous) of the branchial arches (viscerocranium). (Modified from Williams et al 1969)

hence described as *post-trematic*, because it is behind or caudal to the cleft or *trema* rostral to the arch. Similarly the other nerve, which is close to the caudal border, is *pretrematic*—with respect to the cleft caudal to it and its derivation as a branch from the principal post-trematic nerve of the immediately succeeding arch. In the human embryo the pre- and post-trematic nerves cannot be identified with certainty.

In arches 1–4 the aortic arch is caudomedial and the nerve rostromedial to the cartilage: in arch 6 the reverse obtains, with respect to the positions of artery and nerve.

The mesoderm of the branchial region also contributes to the fibro-areolar and other connective tissues of the face, tongue and neck. In the third arch it gives rise to some cellular elements of the *carotid glomus* or body (see p. 1473), which may also receive neuroblasts from the glossopharyngeal nerve and the developing superior cervical sympathetic ganglion (Boyd 1937, Adams 1958, Rogers 1965). Similarly *para-aortic* bodies are developed in association with the fourth and sixth arches, receiving accessions of neuroblasts from the ganglia of the vagus nerve (Hammond 1941).

DERIVATIVES OF THE BRANCHIAL SKELETON

(Throughout consult **2**.53)

The first arch contains on each side a dorsal and ventral element. The former represents the *palatopterygoquadrate bar*, a prominent element in earlier vertebrates forming part of the upper jaw, but much reduced in mammals. In human embryos its early appearance seems transient and its contribution to some permanent cranial structures, such as the maxilla, is uncertain (but vide infra for other derivatives). The *ventral cartilage* (of Meckel, **2**.53) extends from the developing otic capsule into the mandibular moiety of the first arch, meeting its fellow at its ventral end. The dorsal end of Meckel's cartilage becomes separated, and was often held to form the rudiments of both *malleus* and *incus*. However, there is strong paleontological (Romer 1970) and comparative anatomical (Shute 1956) evidence that the incus is, in part, to be regarded as a homologue of the *quadrate bone* of reptiles, and it is therefore probably more correctly regarded as a derivative of the palatopterygoquadrate cartilage. This cartilage may also contribute to the ala major of the sphenoid bone and the roots of its pterygoid plates. A more precise developmental analysis of this region was needed (vide infra). Beyond the rudiment of the malleus, the intermediate part of Meckel's cartilage disappears, but its sheath persists as the *anterior malleolar* and *sphenomandibular ligaments*. The ventral part, much the largest, is enveloped by the developing mesenchymatous mandible (p. 369); a small fraction of this, extending from the mental foramen almost to the site of the future symphysis, probably becomes ossified from invading mandibular tissue, into which it is incorporated, while the remainder of the cartilage is ultimately absorbed.

The cartilaginous element of the second arch (Reichert's cartilage) also extends from the otic capsule to the midline. Its dorsal end also separates and becomes enclosed in the developing tympanic cavity as the *stapes*. Thereafter the cartilage gives rise to the *styloid process*, *stylohyoid ligament*, the *lesser cornu* and probably the *cranial rim* of the body of the *hyoid bone* (**2**.53).

Early development of the auditory ossicles outlined above was based on comparative and paleontological evidence and studies of centres of chondrification and ossification in staged embryos and fetuses. This gained fairly wide acceptance, but is open to revision following close scrutiny of earlier embryos to establish the sources of mesenchyme that provided the condensations of the initial *blastemal ossicles* (Hanson et al 1962). The presumptive palatopterygoquadrate mesenchyme provided the body and short process of the incus; the dorsal moiety of Meckel's mesenchyme provided the head, neck, anterior and lateral processes of the malleus. Between them lay the interzone of the incudomalleolar joint. The dorsal parieties of the condensing core of the *second* arch contributed the long process of the incus and the handle of the malleus. The dorsal tip of the second arch condensation, after receiving accessions from the otic capsule, encircled the stapedial artery forming the anlage of the stapes. Thus each ossicle was derived from at least *two* distinct main sources. Subsequent chondrification and ossification proceeded as detailed elsewhere.

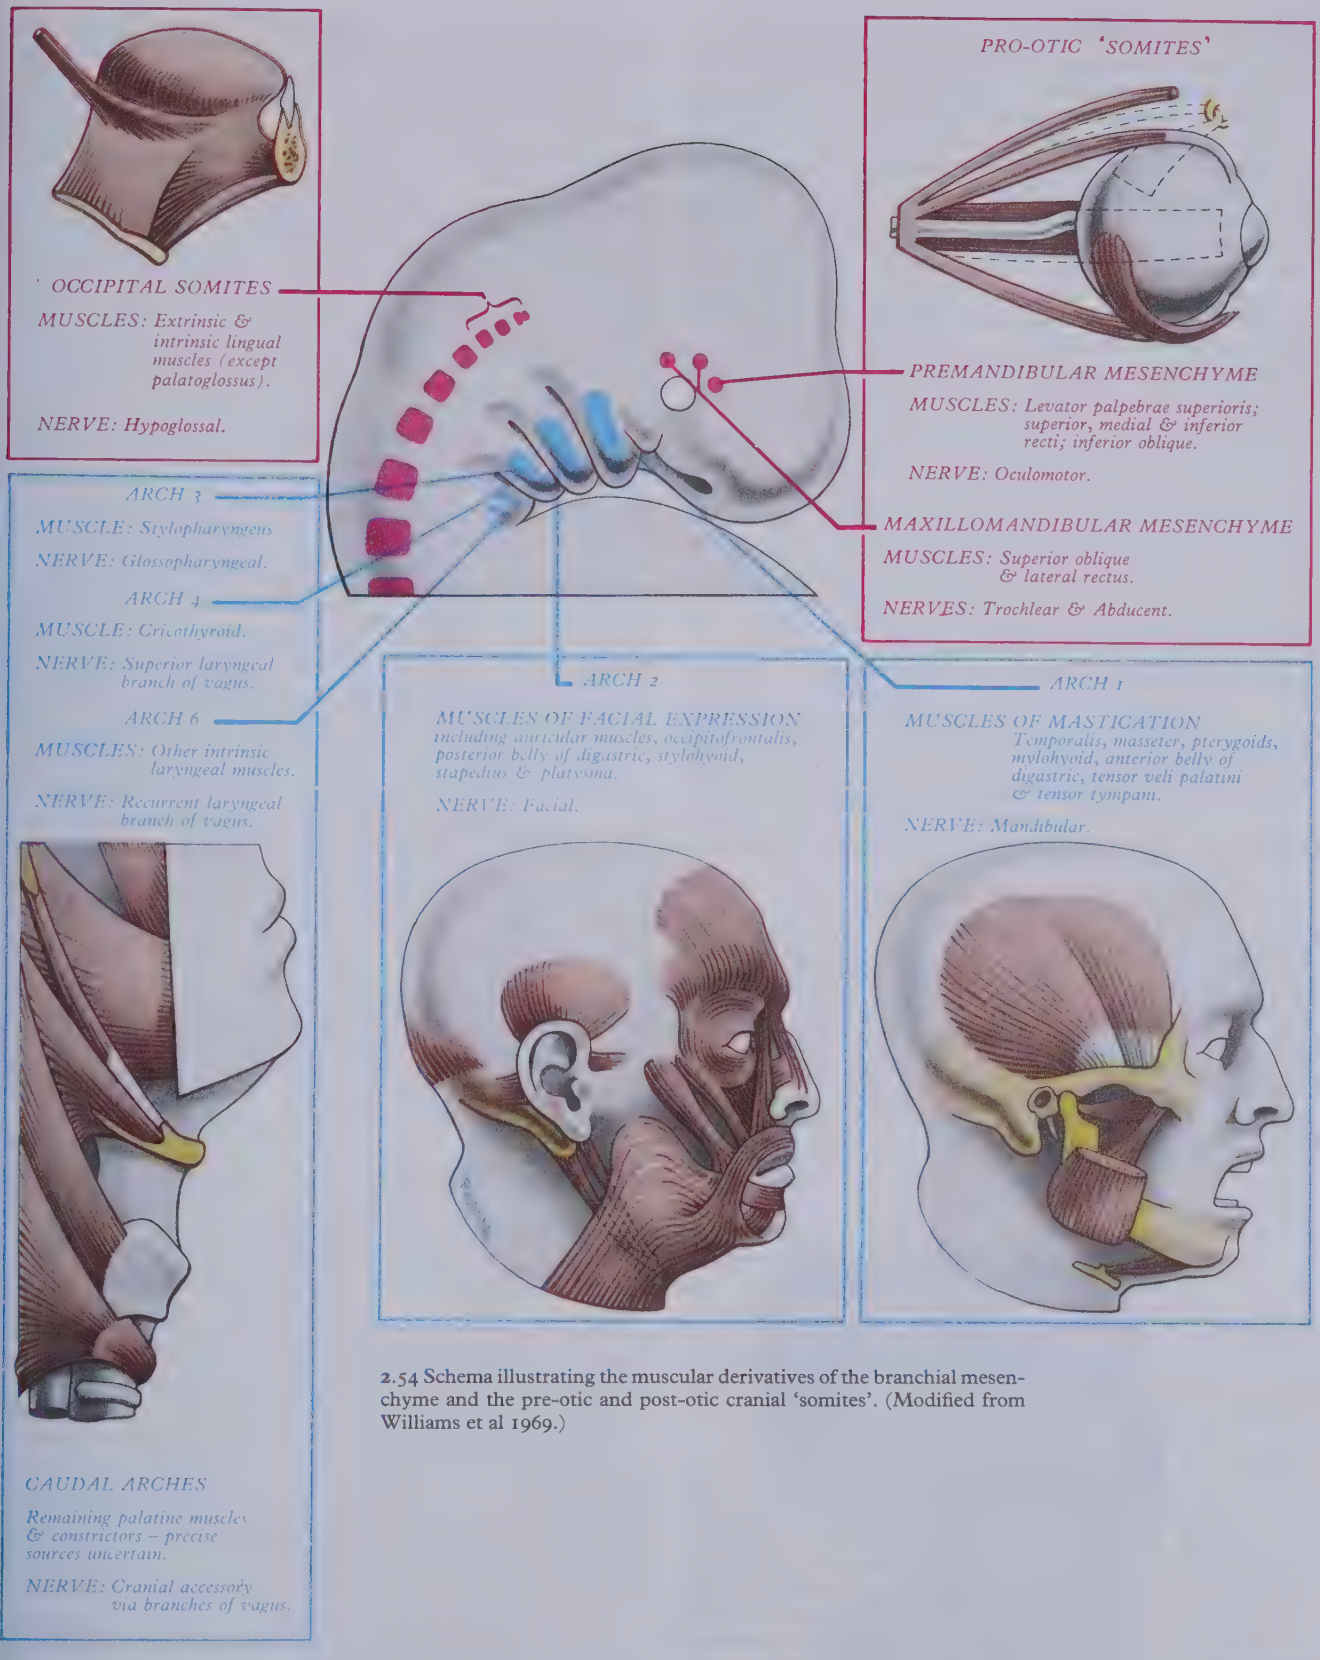
Chondrification does not occur in the dorsal parts of the skeletal elements of the third to sixth arches. The ventral cartilage of the third arch becomes the *greater cornu* of the *hyoid bone* and the *caudal part* of its *body*. (The whole of the body may be formed from the third arch cartilage.) Alternatively, the hyoid body may be derived from cartilage formed in the base of the hypobranchial eminence (p. 228) and thus from third arch tissue alone (Frazer 1926), acquiring its connection with the second arch cartilage secondarily.

The final adaptations of the cartilages of the skeletal elements in the fourth, fifth and sixth arches are a source of disagreement, but the following represents a fairly general view. The thyroid cartilage develops from the fourth and fifth arches, which may also give rise to the arytenoid, corniculate and cuneiform cartilages. The cricoid cartilage may be derived from the sixth arch cartilage, or it may be a modified tracheal ring. The epiglottis is developed in the substance of the hypobranchial eminence and probably not from 'true' branchial cartilage.

DERIVATIVES OF BRANCHIAL MUSCULATURE

(Throughout consult **2**.54 and colour coded diagrams of skull muscle attachments in Osteology.)

The muscle mass of the mandibular part of the first arch forms the *tensor tympani*, *tensor veli palatini* and the *masticatory muscles*, including *mylohyoid* and the *anterior belly* of *digastric*, all being supplied by the mandibular nerve, the mixed 'post-trematic' nerve of the arch. The tensor tympani retains its connection with the skeletal element of the arch through its attachments to the malleus, and the tensor veli palatini to the base of the medial pterygoid process, which may be derived from the dorsal cartilage of the first arch, but the masticatory muscles transfer to the mandible, a dermal bone. The muscles derived from the hyoid arch mesoderm for the most part migrate widely but retain their original nerve supply from the facial. The *stapedius*, *stylohyoid* and *posterior belly of digastric* remain attached to the hyoid skeleton, but the *facial musculature*, *platysma*, *auricular muscles* and *epicranius* all lose connection with it. Their migration is facilitated by the early obliteration of some of the first cleft and pouch. (This cleft, the spiracle in fishes, is already much reduced in all but the earliest vertebrates.)



The muscle masses from the remaining arches are adapted to form the musculature of the *pharynx*, *larynx* and *soft palate*. The stylopharyngeus can be attributed to the third and the cricothyroid to the fourth arch; the rest of the laryngeal muscles are derived from the sixth arch, but the precise origin of the remaining palatal muscles and the pharyngeal constrictors is uncertain in man. A mixed origin, partly from branchial mesoderm and partly from adjacent myotomes, has been attributed to sternocleidomastoideus and trapezius (McKenzie 1955).

NEURAL ELEMENTS OF THE BRANCHIAL ARCHES

(Throughout consult **2**.47,64.)

The nerves of the branchial arches, derived from the hindbrain, immediately enter the dorsal ends of them (**2**.47, 64). They are typically mixed, their motor component supplying the muscles of the arch and their sensory fibres innervating the skin and mucous membrane derived from the region. In fish the trunks of the branchial nerves and their ganglia are close to the dorsal ends of the true clefts existing in these forms, each sending a post-trematic branch into its own arch and a pretrematic branch into the arch cranial to this. In mammals, some have claimed that both types of branch can be identified in the first arch, but only a single nerve can be identified with certainty in the second to sixth arches, with the exception of the fifth, the nerve of which is unknown and may have disappeared.

The trigeminal mandibular division is the post-trematic nerve of the first arch; the chorda tympani, or greater petrosal, have sometimes been regarded as its pretrematic nerve derived from the facial. The latter supplies the second arch, the glosso-

2.54 Schema illustrating the muscular derivatives of the branchial mesenchyme and the pre-otic and post-otic cranial 'somites'. (Modified from Williams et al 1969.)

pharyngeal the third, the superior laryngeal branch of the vagus the fourth and the latter's recurrent laryngeal branch the sixth. In lower vertebrates the fifth arch is also supplied by a vagal branch. Other branches that have, on occasion, been proposed as pretrematic are the tympanic branch of the glossopharyngeal and the auricular branch of the vagus. However, none of the foregoing fulfil sufficient criteria for them to be classified as pretrematic with confidence.

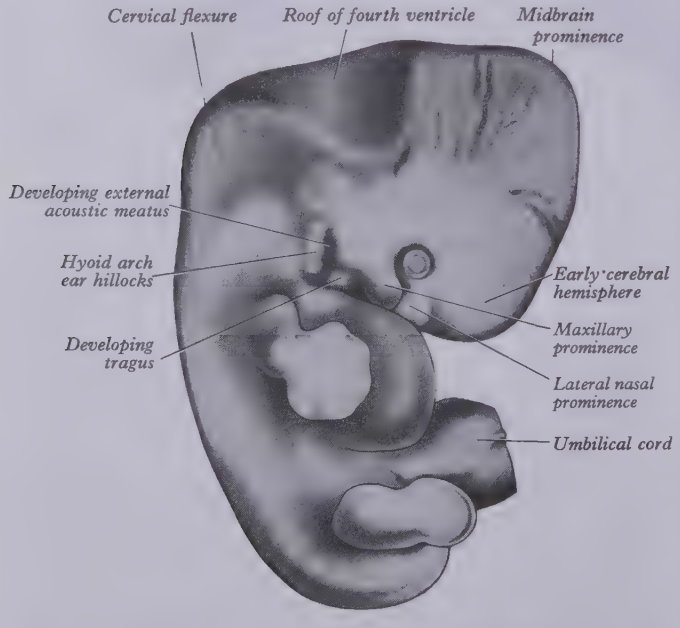
The difference in the courses of the recurrent laryngeal nerves can be explained by the development of the aortic arches. In arches 1–5 the arch nerve enters rostral to its aortic arch. However, the nerve enters its sixth arch *caudal* to the aortic arch, retaining this position on the left side and hence being caudal to and looping round the ligamentum arteriosum in its final disposition. However, on the right, owing to the disappearance of the dorsal part of the sixth aortic arch and the whole of the fifth, the nerve loops round the caudal aspect of the *fourth* aortic arch, i.e. the subclavian artery.

DERIVATIVES OF THE PHARYNGEAL POUCHES

The first four pharyngeal pouches appear in sequence craniocaudally, and their endoderm approaches the ectoderm of the overlying branchial grooves to form thin *closing membranes* (2.47, 48). The blind recesses of the second, third and fourth pouches are prolonged dorsally and ventrally as angular, wing-like diverticula. From the fourth a diverticulum grows caudoventrally and is at first demarcated from the pouch by a groove in which may occur a transient fifth aortic arch artery. From this diverticulum a fifth pouch may develop and establish a connection with ectoderm. The remainder of this diverticulum is the *ultimobranchial body*. This, together with the fourth pouch and the transitory fifth, when present, constitute the *caudal pharyngeal complex*. Its communication with the cavity of the pharynx is the *common pharyngobranchial duct*. The ultimobranchial body is almost a constant feature of vertebrate development (Watzka 1955). Its form in the *human* embryo, however, has been a matter of controversy. Apparently it is incorporated into the rest of the caudal pharyngeal complex and contributes to the development of the lateral thyroid rudiment (p. 228). Ultimobranchial bodies exist in the adults of many lower vertebrates and *calcitonin* has been isolated from such tissue (Copp et al 1967). There is thus a strong presumption that the parafollicular cells of the human thyroid gland, which are a source of calcitonin, are derived from ultimobranchial tissue. (See proceedings of a symposium on: *Thyrocalcitonin and the C cells*, Taylor 1968, Bussolati & Pearse 1967, also pp. 304, 1463).

The further development of the endodermal derivatives of the pharyngeal pouches is intimately associated with that of the mouth, pharynx and larynx, and is considered with them (p. 228).

Development of Locomotor Structures



EARLY DEVELOPMENT OF THE LIMBS

Near the end of week four the limbs appear as small elevations, the **limb buds**, from slight lateral ridges extending the length of the trunk (2.46, 55). The forelimb bud shows first, opposite the more caudal cervical segments, the hind-limb bud being level with lumbar and upper sacral segments. Each bud contains a small proliferating mass of mesenchyme derived from the somatopleure, covered by ectoderm. At this stage the limb bud is not more than a slight accentuation of the lateral ridge, or *crest of Wolff*, which—though not identified in all embryos—is considered to correspond to the *finfold of Gegenbaur*, the hypothetical origin of vertebrate limbs. From their initial appearance, the limb buds display an external crest at their developing apices, the *apical ectodermal ridge* or cap; and despite some disagreement over details there is general concurrence that *interaction* between the mesenchymal core and the apical ectoderm is essential to limb formation. Most experimental evidence admittedly applies only to amphibian (Tschumi 1957), reptilian (Milaire 1957) and avian (Saunders 1948, Amprino & Camosso 1955, Amprino 1968, MacCabe et al 1974) embryos some confirmation in mammalian limb buds has also been recorded and observations on human embryos (Horizons XII to XVII), have indicated the occurrence of ectodermal ridges (O'Rahilly et al 1956). This evidence indicates that the ectoderm of the apical region of the limb bud, though itself relatively undifferentiated, is necessary to the development of successive accretions of mesenchyme as the bud grows. The potentiality of the initial mass of somatopleuric mesoderm is limited to the formation of proximal limb elements, i.e. the girdle region. The mesodermal development of the successive segments of the limb is induced in a proximo-distal sequence (cf. meristematic growth) by the ectodermal ridge, the cells of which apparently do not proliferate to add to the covering of the growing bud. The necessary increase in ectoderm for this appears to be derived by interstitial growth and from the body wall ectoderm. The apical ridge also appears to establish the polarity of the limb with respect to its pre- and post-axial borders and the arrangement of its basic vascular pattern. The evidence for these views has been surveyed by Zwilling (1961). Specific histochemical changes associated with morphogenetic events in the developing limb bud have been reviewed by Milaire (1965). Ultrastructural studies of the zone of epithelio–mesenchymal interaction at the apex of the bud have been reported (Kelley 1973). The evidence suggests that the sculpturing of the interdigital clefts is a process involving mesenchymal cell death with phagocytic removal (p. 103) accompanied by active epithelial invagination. For a detailed review and bibliography concerning these phenomena see Hinchliffe (1982).

The mesenchyme of the limb buds is invaded by the ventral rami of adjoining spinal nerves—fourth cervical to second thoracic for the fore-limb, twelfth thoracic to fourth sacral for hind-limb. The axial region of mesenchyme proliferates and condenses to produce the blastemal skeleton of the limb, chondrification and ossification following as the limb bud grows. The musculature of the limbs is developed in situ from the mesenchyme surrounding the skeletal elements. It is important to emphasize that there is no apparent migration of myotomic mesoderm into the limb bud, the so-called plurisegmental nature of the muscles in the limbs referring solely to their nerve supply. Such muscles as latissimus dorsi, with extensive attachments to the axial skeleton when fully developed, reach them secondarily by active migration.

The early stages of development of fore- and hind-limb buds are alike, except that the former precedes the latter in time by a few days in the human embryo (2.46, 262). Differentiation in general proceeds in a proximo-distal direction. Flexion creases appear indicating the sites of elbow, wrist, knee and ankle; and the hands and feet are at first mere plate-like expansions (2.55, 262). Near the end of the sixth week there is little difference in shape and posture between the arm and leg, the long axis of each being approximately orthogonal to the trunk with the prominences of elbow and knee both directed laterally (2.55, 2.262). As intimated the pre- and post-axial borders of the limbs are respectively cranial and caudal in orientation.

Preliminary observations on human limb buds, removed from embryos of 4–6 weeks and cultured for 4–18 days in vitro, have been reported (Yasuda 1973). There was a general retardation of development in vitro, and the effect more marked in fore- than in hind-limb buds but, amongst tissues, cartilage was the least retarded.

2.55 A human embryo, 15.5 mm long. Compare the upper and lower limb buds, concerning their stage of differentiation and degree of rotation. (Streeter 1948)

LIMB ROTATION

(Follow progress on pp. 262, 263 and fig. 2.125.)

During the seventh and eighth weeks differential growth rates are

exhibited by the limbs which bring them into a position of adduction towards the ventral aspect of the trunk, and flexion at elbow and knee is increased. By the end of the eighth week the limbs have attained the *fetal position*, with the conspicuous differences that the elbow points caudally and the knee in a rostral direction. This divergence of final positioning is of the utmost importance in the future functioning of the limbs (p. 398); it is achieved by a kind of rotation in each limb around its axis, presumably in part due to growth changes, for it occurs before any joints are fully defined. The upper limb rotates laterally, so that its pre-axial border becomes lateral and its ventral surface rostral or anterior. The changes are the reverse of this in the hind-limb; medial rotation carries the pre-axial border into a medial position, turning the dorsal surface to face anteriorly. The same reorientation is illustrated by the radius and tibia, both pre-axial primitively in their limbs, the former becoming the lateral fore-limb bone, the tibia taking up a medial position in the foreleg. Inevitably this affects the hand and foot, whose pre-axial digits, thumb and great toe, take up lateral and medial positions. It should be noted that reverse *forearm* rotation at a later stage in most mammals, and the retention of joint mediated supination-pronation activity in the primate forearm, modify this arrangement (p. 398). The cutaneous nerve supply follows these movements and this explains the cutaneous innervation of the 'lateral' aspect (pre-axial border) of the human upper limb from the more cranial nerves of the brachial plexus (p. 1130) and the 'medial' border by its more caudal nerves. In the hind-limb the pattern is similar but less clear; but as a generalization, the upper spinal nerve elements in the lumbosacral plexus innervate the medial border, the lower ones the lateral (7.266, 267, see also p. 1152.)

The foot and hand resemble each other closely at first, as flattened expansions at the terminations of the limb buds. The mesenchyme in the periphery of these plates condenses to outline the pattern of the digits, and the thinner intervening regions break down from the circumference inwards. If this process is incomplete or becomes arrested varying degrees of webbing or *syndactyly* result. For a detailed study and review of phylogeny and ontogeny consult Čihák (1972).

Further development and ossification of the skeletal elements of the limbs is described in Section 3, Osteology. For the chronology of appearance of human embryonic ossific centres consult O'Rahilly & Gardner (1972).

DEVELOPMENT OF JOINTS

Except in the vertebral column and the caudal region of the chondrocranium, which derive from sclerotomes (pp. 140, 159), the mesenchyme from which other skeletal elements are derived *at first* shows no differentiation into primordia of individual bones. The skeletal mesenchyme appears as a continuous condensed mass not initially demarcated clearly from the surrounding myogenic tissue. However, centres of chondrification and ossification now develop in this mesenchymal core and rapidly extend to delineate individual skeletal elements, each containing its own centre or focus of change, the process of bone or cartilage formation spreading in an orderly and characteristic manner from it (Streeter 1949). Each element becomes limited by a compact layer of apparently undifferentiated cells from surrounding tissues; this layer proliferates and differentiates to produce chondroblasts and osteoblasts, which contribute to growth by surface accretion. This lamina gradually becomes more clearly demarcated from the underlying cartilage or bone as *perichondrium* or *periosteum*, continuing to generate chondroblasts and osteoblasts (p. 291). It appears to be an important factor in the determination of major bone growth characteristics in the formation of individual elements (Fell 1939, Barnett et al 1961, also p. 293 et seq).

Connecting adjacent skeletal elements as they become defined from continuous mesenchyme masses are regions which do not initially progress into cartilage or bone but persist as plates of *interzonal mesenchyme*. These, the sites of future joints, and their development varies according to the type of joint formed. In fibrous joints the interzone is converted into collagen, as the definitive connecting medium between the bones involved. In synchondroses it becomes cartilage of the modified hyaline type, whereas in symphyses the tissue is predominantly fibrocartilage, but retaining narrow para-osseous laminae of hyaline cartilage. The interzonal mesenchyme of developing synovial joints becomes trilaminar, due to the appearance of a more tenuous intermediate zone between two dense strata next to the cartilaginous ends of the skeletal elements of the region. These latter are continous peripherally with the adjoining perichondrium and, like it, are chondrogenic and thus concerned with growth of cartilaginous epiphyses (p. 304). In some synovial joints, however, this trilaminar interzone may be modified (Gardner & Gray 1953). The intermediate stratum merges with the general mesenchyme of the limb, which is vascularized. From this, a cuff condenses as the fibrous capsule of the joint, in continuity with the perichondrium of the bones concerned. A thinner layer of vascular mesenchyme is enclosed within this as the precursor of the synovial capsule (Haines 1947, Gardner & Gray 1950, Gray & Gardner 1951, Gardner & O'Rahilly 1968).

As the skeletal elements chondrify and in part ossify, the dense strata of the interzonal mesenchyme also become cartilaginous and cavitation of the intermediate zone establishes the cavity or discontinuity of the joint. The synovial mesenchyme now forms the synovial membrane and probably also gives rise to all other intra-articular structures, such as tendons, ligaments, discs and menisci. In joints containing discs or menisci and in compound articulations more than one cavity may appear initially, sometimes merging later into a complex single one. As development proceeds thickenings in the fibrous capsule can be recognized as the specializations peculiar to a particular joint. In some, however, such accessions to the fibrous capsule are derived from neighbouring tendons, muscles or cartilaginous elements. For a review of the literature concerning the chronology of events in human embryonic limbs consult O'Rahilly & Gardner (1975).

DEVELOPMENT OF SKELETAL MUSCULATURE

With the exception of certain muscles of the head and neck, which are developed from branchial mesenchyme (p. 172), and the limb muscles, which develop in situ from the mesenchyme of the limb buds (p. 174), most somatic (striated or skeletal) muscles are derived from myotomes (p. 138). (The term 'voluntary muscle', although frequently encountered, is often misleading and its use is to be discouraged.) Typically, each myotome divides into dorsal (*epaxial*) and ventral (*hypaxial*) regions, the former sited dorsolateral to the vertebral column and innervated by the dorsal ramus of the corresponding spinal nerve, the latter migrating ventrally in the body wall or somatopleure and innervated by the corresponding ventral ramus. Primitively, in fishes, these two primary divisions of the myotomes are separated by vertebral transverse processes and a fibrous septum extends from these to the lateral body line. The myogenic masses derived from the myotomes may divide longitudinally or tangentially and the resultant parts may remain separate, e.g. intercostal muscles, or they may fuse with corresponding parts of adjacent myotomes to form sheets of muscle, such as the abdominal oblique and transverse layers. In mammals the derivatives of the ventral regions of the myotomes may subsequently migrate over the derivatives of their dorsal parts. Consequently, such muscles as the serrati posteriores, which reach the vertebral spines superficial to the erectores spinae, are nevertheless supplied by ventral rami of spinal nerves, indicating their origin from ventral myotomic mesoderm. It should be added that from experiments on chick embryos it is apparent that some parts of the intercostal and anterolateral abdominal musculature are not derived from myotomes but from the lateral plate of mesoderm (Straus & Rawles 1953). However, observations on amphibian (Detwiler 1955) and mammalian (Theiler 1957) embryos support their myotomic origin. Some muscles may also *migrate* in rostral or caudal directions, the latter as in the case of latissimus dorsi, which is derived from lower cervical myotomes and is innervated accordingly.

Although it is usually stated that the lingual muscles are derived from three or four pairs of occipital myotomes (Bates 1948, Deuchar 1958), with which the morphology of their supply from the hypoglossal nerve accords, the evidence for this in the human embryo is negligible, and earlier views that they arise in

situ from mesenchyme associated with the developing tongue have not been controverted (Frazer 1926). The hypoglossal nerve is composite, representing the ventral roots of an uncertain number of segmental nerves cranial to the cervical series. It is considered to have acquired cranial status in the earliest land tetrapods, its exclusion from the modern amphibians being a secondary adaptation.

In lower vertebrates the extrinsic ocular muscles are developed from three paired head cavities which are considered to be three persistent pro-otic somites (Neal 1918). There is no direct evidence of this origin in man, although it is claimed that the most rostral of these cavities, the *premandibular*, is derived from mesoderm originating in the prechordal plate (see p. 136 and Gilbert 1952). This condensation is held to give rise to the muscles innervated by the oculomotor nerve. The remaining extra-ocular muscles are considered to develop from a mass of mesenchyme dorsal to the region of conjunction of the mandibular and maxillary prominences (which may correspond to the mandibular and hyoid head cavities identifiable in sharks, and which has been termed *maxillo-mandibular mesenchyme* by some authors). The dual origin of this mass is at least in accord with the innervation of these muscles by the trochlear and abducent nerves. The same mass is said to contribute to the formation of the scleral tunic of the eye (Gilbert 1957).

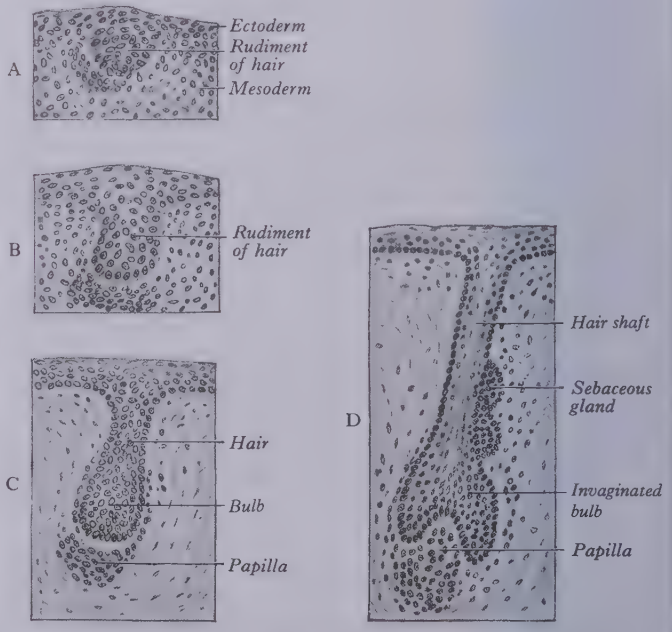
In the differentiation of striated muscle the primitive muscle cells, *myoblasts*, may arise from mesenchymatous *promyoblasts* of somite or non-somite (e.g. branchial, ventral pharyngeal, upper post-branchial, perianal or limb bud) origin. The myoblasts multiply by mitosis, but further recruitment from neighbouring mesenchyme also occurs. The cells elongate to form multinucleated *myocytes*, in which the nuclei move to the periphery as a myofibrillar structure and cross-striation begins to appear. Their maturation is described in more detail, with related bibliography, on p. 553. New fibres are said to form until mid-fetal stages of development, sometimes by splitting of pre-existing fibres. Thereafter growth of muscles is accomplished by enlargement of individual fibres (Cuajunco 1942). Muscle spindles can be identified as early as the twelfth week (Cuajunco 1940). The tendons of muscles develop independently in mesenchyme and their connection with their muscles is secondary.

In man and other higher vertebrates some derivatives of myotomes degenerate and some disappear entirely. Others may persist as fibrous tissue vestiges; in some instances regions formed from myotomes, and/or lateral plate mesoderm, which are muscular in ancestral forms, e.g. may become aponeurotic or ligamentous, the aponeuroses of the abdominal muscles and the sacrotuberous ligament.

SKIN AND APPENDAGES

The epidermis and its specialized appendages—hairs, nails, sudoriferous and sebaceous glands—are derivatives of the ectoderm, while the *dermis* (corium) is formed from the somatic layer of the mesoderm, with some contribution from dorsolateral aspects of the mesodermal somites (p. 140), and the neural crest. The ectoderm at first consists of a single stratum of cuboidal cells, but by the sixth week these have proliferated to form a double layer—a superficial *periderm*, or *epitrichium*, of flattened cells and a subjacent *stratum germinativum*. The cells of the latter are at first cuboidal but become columnar. By multiplication and differentiation of these cells the characteristic layers of the epidermis are developed. The periderm is merely a temporary covering stratum. By the sixth month most of the periderm, which becomes keratinized, has disappeared and the strata granulosum, lucidum and corneum of the epidermis are established. The superficial cornified cells, together with sebaceous secretion and the remains of the periderm, form a cheesy or caseous material, the *vernix caseosa*, which may exercise the function of protecting the underlying epidermis from maceration by amniotic fluid. Vernix caseosa is characteristic of the surface of the fetus during its final 3 months of intrauterine existence, finally desquamating soon after birth. The developing epidermis has a high content of glycogen which, apart from its metabolic role, may aid in repelling the amniotic fluid, which also has a high concentration of glycogen.

Ultrastructural studies of the human periderm show that its cells possess microvilli, in contact with the amniotic fluid (Whittaker & Adams 1971). The functional significance of this transient surface layer remains obscure.



At an early, but still undetermined age, neural crest cells invade the developing skin and differentiate into both epithelial and connective tissue potential pigment cells, such as *melanoblasts*. These assume a branching form and hence are named *dendritic cells*. In negro fetuses many of these cells become truly melanoblastic developing granules of melanin (Rawles 1948, Billingham & Silvers 1960, Boyd 1960), which can be transferred to neighbouring non-dendritic cells in postnatal life. In less pigmented races similar cells exist in the epidermis and deeper tissues which, though normally containing little or no pigment, retain a melanogenic potentiality by which, given appropriate stimulation such as intense sunlight, they are able to form melanin granules.

For a summary of non-cutaneous ectodermal derivatives see p. 136.

The dermis is a mesodermal derivative, and it is widely assumed that some at least of its cells develop from the lateral wall of the somites—regions termed *dermatomes*. It is also held that dermal tissue is partly derived from mesenchyme associated with the somatopleuric sheet of lateral plate mesoderm and also the neural crest. Perhaps all such regions contribute; at present evidence is insufficient for quantification.

Towards the end of the third month the subepidermal mesoderm begins to condense and define the dermis, deep to which areolar connective tissue appears. A month later dermal papillae can be identified and the characteristic patterns of ridges on the ventral hairless skin of the extremities, best seen and most familiar as fingerprints, are quickly established and remain substantially unchanged in the individual apart from areal growth (Cummins & Midlo 1961, Hale 1952). The histological elements of the dermis differentiate at varying times; thus, collagenous fibres begin to appear and to aggregate during the third month, whereas elastic fibres become identifiable 2 or 3 months later.

Hairs initially appear in the third month as solid cylinders of epidermis which grow *obliquely* into the dermis (**2**.56), each *hair bud* having an external layer of columnar cells and a core of polygonal elements (Hale 1952). The obliquity of the buds (later hair follicles) varies in *degree* but they are roughly parallel in adjacent hairs; their corporate *direction* being specific for each region of the body. The deepest part of the bud

2.56 Successive stages in the development of hair.

expands into a *hair bulb*, which becomes invaginated by a mesodermal *hair papilla*. The central cells become keratinized to form the substance of the hair itself; and as further cells are added from the inner layer of the bulb these also contribute to the shaft of hair, which lengthens and begins to project above the skin surface. Further growth is due to continued proliferation of the epidermal cells around the mesodermal papilla (see also p. 90, 91). Hairs appear first on the face, and by the end of the third month there is a general covering over the body of somewhat scattered fine hairs, the *lanugo*. These are shed before birth and are replaced by thicker hairs arising in a new set of follicles. Melanoblasts become associated with developing hairs at an early stage and these produce much melanin in dark-haired individuals during the later months of gestation. For further details of hair structure, growth, associated glands and arrectores pili muscles see p. 90–92.

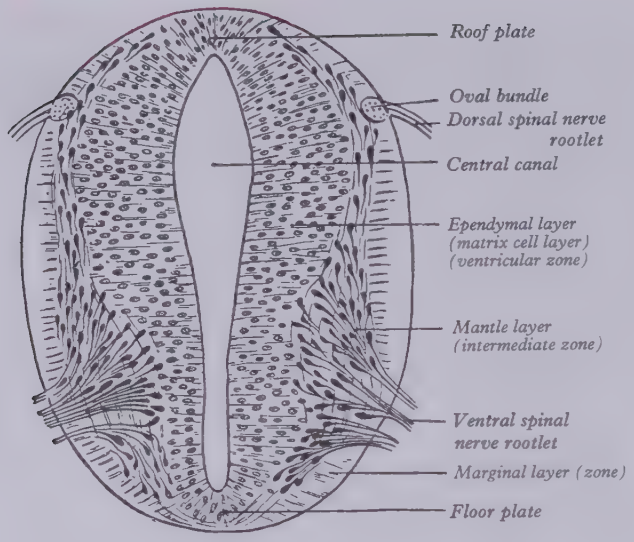
Sudoriferous glands first begin to develop in the skin of the palms and soles during the fourth month initially, like hairs, as solid downgrowths of epidermis into the dermis. These elongate and their deeper parts coil to form the main secreting part of the sweat glands. A lumen develops and opens superficially at about the seventh month. Both the duct and the coiled 'body' of each gland is double-layered, the inner epithelial, the outer, fine fibroareolar, with an intervening basal lamina. The paraluminal cells vary from cuboidal to polygonal (p. 93, 94) surrounded by contractile myoepitheliocytes (p. 55). External to the basal lamina the fibroareolar sheath invests the body of the gland, also its cylindrical duct, whilst near the general epidermis it merges with the superficial layers of the dermis. Some glands arise from the superficial parts of hair follicles, acquiring a surface opening later. Specialized sudoriferous glands are formed in some sites, such as in the skin of the axillae, eyelids and external acoustic meatuses (Montagna & Ellis 1961).

Sebaceous glands develop as solid epidermal buds from the cuboidal cells of the oblique hair follicles during the fifth month. They arise from that aspect of the follicle making an obtuse angle with the skin. The buds extend into the mesenchyme, branching into several oval alveoli, the lining cells of which are derived from the stratum germinativum. These proliferate, the older cells being pushed centrally, where they degenerate to form sebum, this being extruded into the hair follicle. Sebaceous glands develop independently of such follicles in the nostrils, eyelids (as tarsal glands) and in the anal region. The arrectores pilorum develop near the sebaceous glands and hair follicles, but at some little distance from them, arising independently from the mesenchyme; their attachment to follicles is a secondary development (Pinkus 1958). Some of the independent sebaceous glands continue forming after birth.

Nails are demonstrable as rudiments in the third month, appearing as *primary nail fields* of proliferative ectoderm on the *tips* of the terminal segments of the digits. The thickened ectoderm of these fields is in fact only transiently at the tips of the digits; but continued proliferation of the nail fields in a proximal direction progressively defines their final dorsal position. Due to their relatively slow rate of growth the fields become somewhat depressed, and the epidermis overlaps their sides and proximal ends to form *nail folds*. The distal ends of the nail fields are bounded by a shallow groove. The proximal part of each nail field proliferates to form the root of the nail, which becomes the *formative zone*. From the stratum germinativum of the root the actual substance of the nail, consisting of modified stratum lucidum cells, is continuously formed. The stratum at first covers the nail as the *eponychium*, but this disappears for the most part, remaining only as a narrow proximal crescentric fold overlying the *lunule* of the nail. The *hyponychium* is an accumulation of epidermal cells beneath the free edge of the nail (massive in claws and hooves). Fetal growth of the nails is gradual and their extremities have merely reached near the tips of the digits at birth, the fingers being rather more advanced than those of the toes.

Anomalous development of the epidermis and its derivatives is relatively common. Excessive or diminished growth, or even complete absence, may affect sebaceous or sudoriferous glands and hair, either locally or generally. Similarly, the epidermis may be excessively pigmented (*melanism*) or lack melanocytes (*albinism*). Excessive keratinization leads to *ichthyosis*. A *naevus* or 'mole' is a locus of excessive pigmentation.

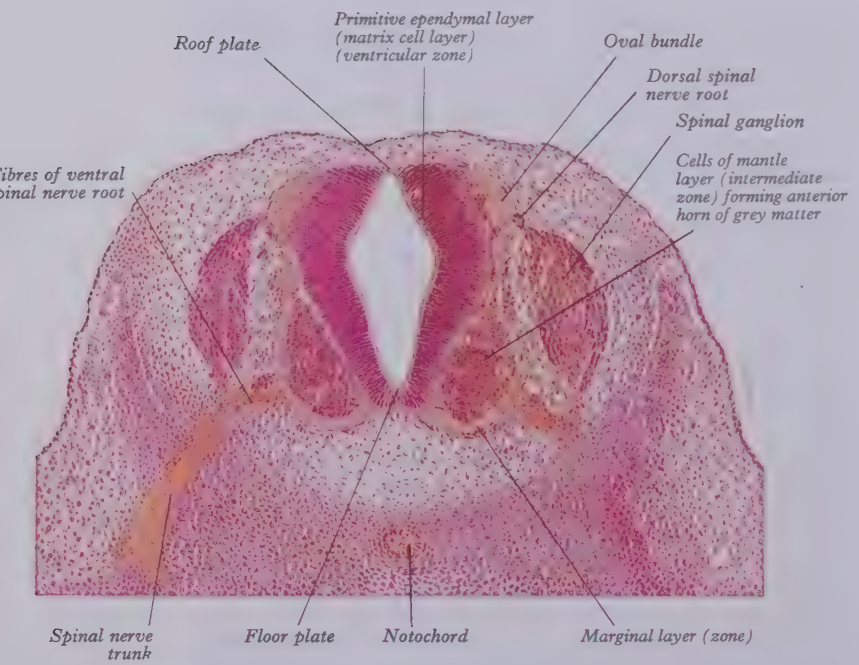
Mammary glands are considered to be much modified sudoriferous glands and as such they are basically ingrowths from the ectoderm, which forms their ducts and alveoli, supported by vascularized connective tissue derived from the mesenchyme. In embryos at about the fifth or sixth week two ventral bands of thickened ectoderm, the *mammary ridges*, extend from axilla to the inguinal region, and in many mammals paired mammary glands develop at intervals along these ridges. In the human embryo the ridges are not prominent features, and only a single pair of glands develops in the pectoral region. The ridges disappear later in embryonic life, but before this the cranial third of each begins to show proliferation to form the two glandular rudiments. Supernumerary rudiments may form anywhere along the path of the mammary ridges and may develop into actual mammae or merely accessory or supernumerary nipples.



As each mammary primordium develops, its ectodermal ingrowth branches into 15–20 solid buds of ectoderm which will become the lactiferous ducts and their associated lobes of alveoli in the fully formed gland. These are surrounded by mesenchyme which forms the connective tissue, fat, vasculature, and is invaded by the mammary nerves. By proliferation, elongation and further branching the alveoli are formed and the duct system defined. During the last 2 months of gestation the ducts become canalized and the epidermis at the point of original development of the gland forms a small *mammary pit*, into which the lactiferous tubules open. Perinatally the nipple is formed by mesenchymal proliferation. Should this fail the ducts open into shallow pits, a malformation known as inverted nipple. At birth the mammary glands are alike in their stage of development in both sexes, and in both some transient secretory activity may be observed, due presumably to circulating prolactin in the mother (Smith 1959). In males, thereafter, the mammary glands remain undeveloped, but in females at puberty, in late pregnancy and during the period of lactation they undergo further, hormone dependent, developmental changes (p. 1434 et seq). For reviews of the prenatal histogenesis and ultrastructural appearances of mammary tissues consult Tobon & Salazar (1974); for postnatal reviews, p. 1434 et seq.

The Nervous System and Special Sense Organs

The gross initial appearance of a neural plate and the development within it of a median neural groove bounded on each side by neural folds, which meet dorsally and fuse in the fourth week to form a neural tube, have been outlined (p. 133 and **2.27**A–E).



Reference has also been made to the wealth of comparative experimental data, largely from submammalian forms, which indicate the fundamental role of *primary embryonic induction* in these early stages of development of the nervous system (p. 107).

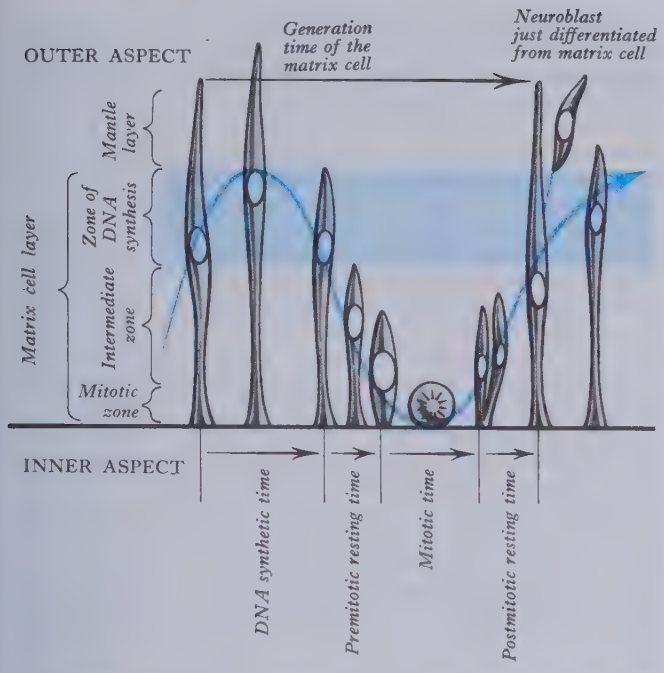
Briefly, during gastrulation, the chorda-mesoderm, which is invaginated through the dorsal lip of the blastopore, forms a midline strip in the roof of the archenteron which is continuous cranially with the endoderm of the prechordal plate (p. 100) and becomes closely applied to the superjacent ectoderm. For a period the latter is competent to react to the inductive influence of the chorda-mesoderm and, in this manner, neural plate formation is initiated. The early midline neural tube is thus co-extensive with the notochord, stretching from the dorsal lip of the blastopore (primitive knot) to the orpharyngeal membrane. Further analyses also demonstrated a regional specificity in the inductive capacity of the various rostrocaudal regions of the archenteric roof. The region first invaginated, i.e. the endoderm of the prechordal plate and rostral tip of the notochord, induces the formation of forebrain and eyes, etc. (the so-called *archencephalon*); the intermediate part of the chorda-mesoderm induces hindbrain and associated structures (the *deuterencephalon*), whilst the remaining (caudal) roof of the archenteron operates as a *spino-caudal* inducer promoting the formation of spinal cord and neighbouring muscle masses.

2.57 Transverse section through the developing spinal cord of a human embryo four weeks old. (After His.) Historically early terminology is retained; more recent terms in parenthesis.

Although the search for the chemical identity of inducing substances continues, as pointed out on p. 107, there has, in recent years, been a great change of emphasis on the part of developmental biologists. Nevertheless, despite the profound developmental modifications introduced by the secondary reduction of yolk in mammalian ova associated with viviparity (p. 98), it is widely assumed that similar primary mechanisms operate throughout the Chordata, including mankind. Thus, from the outset, the development of the nervous system is heavily dependent upon morphogenetic influences from neighbouring non-nervous structures. (For penetrative reviews of early neurogenesis consult Hughes 1968, Jacobson 1970, Gaze 1970, Bellairs 1971, 1974, Gottlieb 1974, Berry 1974, 1982, Berry et al 1980a,b,c,d, Schmitt & Worden 1979, Rakic & Goldman-Rakic 1982, Smart & McSherry 1982, Smart 1982, 1983.)

2.58 Transverse section of the developing spinal cord in the cervical region of a human embryo early in the sixth week. CR length = 8 mm.

THE NEURAL TUBE (NEURAXIS)

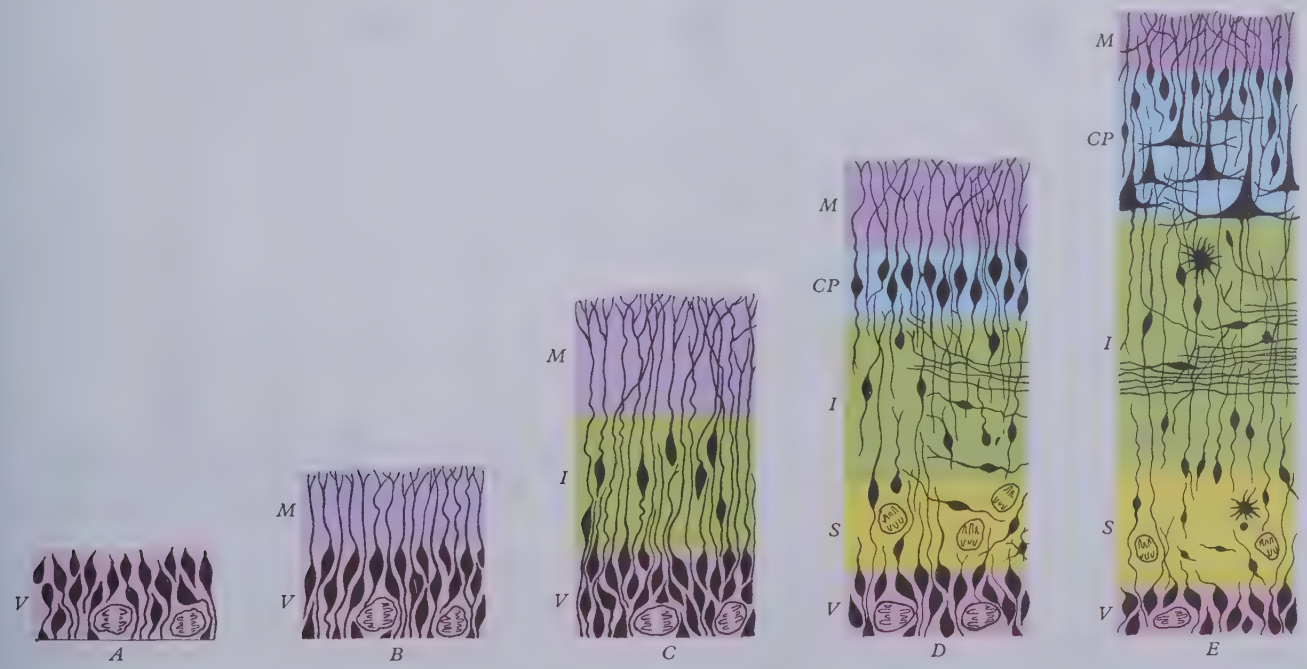


When the neural tube is closing, its walls consist of a single layer of columnar *neural epithelial cells*, the extremities of which abut on internal and external limiting membranes. The mechanism of rounding up of the neural plate into a neural tube has been studied particularly closely in amphibia (Burnside 1971). The columnar cells increase in length and develop numerous longitudinally disposed microtubules, whilst the borders of their luminal ends are firmly attached to adjacent cells by junctional complexes, the cytoplasmic aspect of the complexes being associated with a dense paraluminal web of microfilaments (see pp. 49, 106; **1.13**, **2.5**, also Watterson 1965). It is proposed that this disposition of organelles imparts a slight wedge conformation on the cells resulting in neural groove and eventually neural tube formation. As the cells elongate their nuclei become clustered at varying depths in the deeper part of the wall (i.e. nearer the internal limiting membrane) and, for a period, the epithelium is *pseudostratified* with an inner nucleated zone and an outer zone composed of the peripheral cytoplasmic processes of the cells. Soon, however, some of the peripheral cytoplasmic processes become detached from the (basal) external limiting membrane and rounded cells appear close to the inner membrane which, by their repeated mitotic division, form descendants which *migrate* outwards to take up an intermediate position in the wall of the tube. Histologically at this stage therefore, the wall of the tube presents three zones or layers (**2.57**, 58, 60). The internal **ventricular zone** (variously termed the *germinal*, *primitive ependymal* or *matrix layer*) consists of the nucleated parts of the columnar cells and the round cells undergoing mitosis. The **intermediate zone** or *mantle layer* consists of the migrant cells from the divisions occurring in the deeper layer just described. The outer **marginal zone** for a period consists of the external cytoplasmic processes of some of the original columnar cells, but they are soon invaded by tracts of axonal processes which grow from neuroblasts developing in the intermediate zone, together with varieties of non-nervous cells (glioblasts and later vascular endothelium and perivascular mesenchyme).

HISTOGENESIS OF THE NEURAL TUBE

The classical view of neural tube histogenesis was first propounded by Wilhelm His in 1890 and soon, sometimes with minor modifications, gained quite wide acceptance (e.g. Kölliker 1896, Ramón & Cajal 1911). His proposed that almost from the first the wall of the tube was *stratified* and contained a *variety* of distinct cell types—*spongioblasts*, *neuroblasts* and *germinal cells*. (Some contemporary cytologists claimed that the early neuroepithelium was syncytial, but this gained little acceptance.)

The primitive spongioblasts, originally elongate cells attached to both limiting membranes, with their nuclei in the ventricular zone, were considered to differentiate into a number of *sustentacular cell* varieties. By losing contact with one or both limiting membranes, they may differentiate into either astroblasts and astrocytes, oligodendroblasts and oligodendrocytes, or, retaining an internal attachment, into the definitive ependymal cells which line the central canal and regionally specialized tanycytes (pp. 894, 1454). The *neuroblasts*, one of the cell types found in the intermediate zone, differentiated into the wide array of neurons. The round deeply placed *germinal cells* or *medulloblasts* (Glees 1963) he regarded as undifferentiated stem cells, which by repeated division gave further generations of both spongioblasts (*glioblasts*) and neuroblasts. On this view, therefore, which constituted a *polyphyletic theory of neurogenesis*, the early neural epithelium was regarded as a *heterogeneous* grouping of cells and their various derivatives developed *simultaneously*.



The meticulous cytological studies of Sauer (1935a,b, 1936) led him to oppose the classical view, and he maintained that the early neural epithelium, including the deeply placed ventricular mitotic zone, consists of a *homogeneous* population of pluripotent cells, the varying appearances merely reflecting different phases in a *proliferative cycle*, the sequence being termed by Sauer *interkinetic migration*. This proposal was essentially a *monophyletic theory of neurogenesis*. In subsequent years much experimental

2.59 Diagram showing the cytogenetic cycle in the matrix cell layer and mantle layer in the wall of the developing neural tube. Note the various zones and their associated time scales, through which the matrix cell nuclei pass during their postulated 'elevator movement' or 'interkinetic migration' which is described in greater detail in the text. (From S Fujita, with kind permission of the author and the *Journal of Comparative Neurology*, 1963.)

evidence based upon colchicine studies (e.g. Watterson et al 1956), spectrophotometric nuclear analysis (e.g. Sauer & Chittenden 1959) and upon autoradiographic studies following the distribution of cells at varying times after labelling with tritiated thymidine (e.g. Sidman et al 1959, Sidman 1970, Fujita 1963, Fujita & Fujita 1963) and ultrastructural studies (e.g. Hinds 1971), in the main, supported the latter proposition. The scheme amplified by Fujita in a series of later publications is illustrated in **2.59**. The ependymal layer of earlier workers (termed by Fujita the *matrix layer*) is considered to be populated by a single basic type of *matrix cell* and to exhibit three '*zones*' (the M or mitotic, the I or intermediate, and the S or synthetic zones). As they pass through a complete inter-mitotic and mitotic cycle, the matrix cells show an 'elevator movement' progressively approaching and then receding from the internal limiting membrane. DNA replication occurs whilst the cells are extended and their nuclei occupy the S zone; they then enter a pre-mitotic resting period whilst the cells shorten and their nuclei pass through the I zone. The cells now become rounded close to the internal limiting membrane (in the M zone) and undergo mitosis; thereafter they elongate again, their nuclei passing through the I zone during the post-mitotic resting period, finally to enter the synthetic zone once again. The cells so formed may then start another *proliferative cycle* but others, presumably after a 'critical' or 'quantal' mitosis (see p. 108), rapidly migrate outwards (i.e. radially) and differentiate into *neuroblasts* as they approach and enter the adjacent stratum; possibly this differentiation is initiated as they pass through the I zone during the post-mitotic resting period. The *proliferative cycle*, with the production of clones of vast numbers of neuroblasts, continues for a time, but eventually neuroblast formation wanes; however, the mitotic activity of the remaining matrix cells continues for varying times, but then begins to decline as their progeny differentiate into *ependymal cell* and *macroglial cell* varieties. Thus the *simultaneous* appearance of cell varieties, implicit in the polyphyletic theory, contrasts with their partly successive nature in the monophyletic theory, in which maximal neuroblastosis *precedes* maximal glioblastosis.

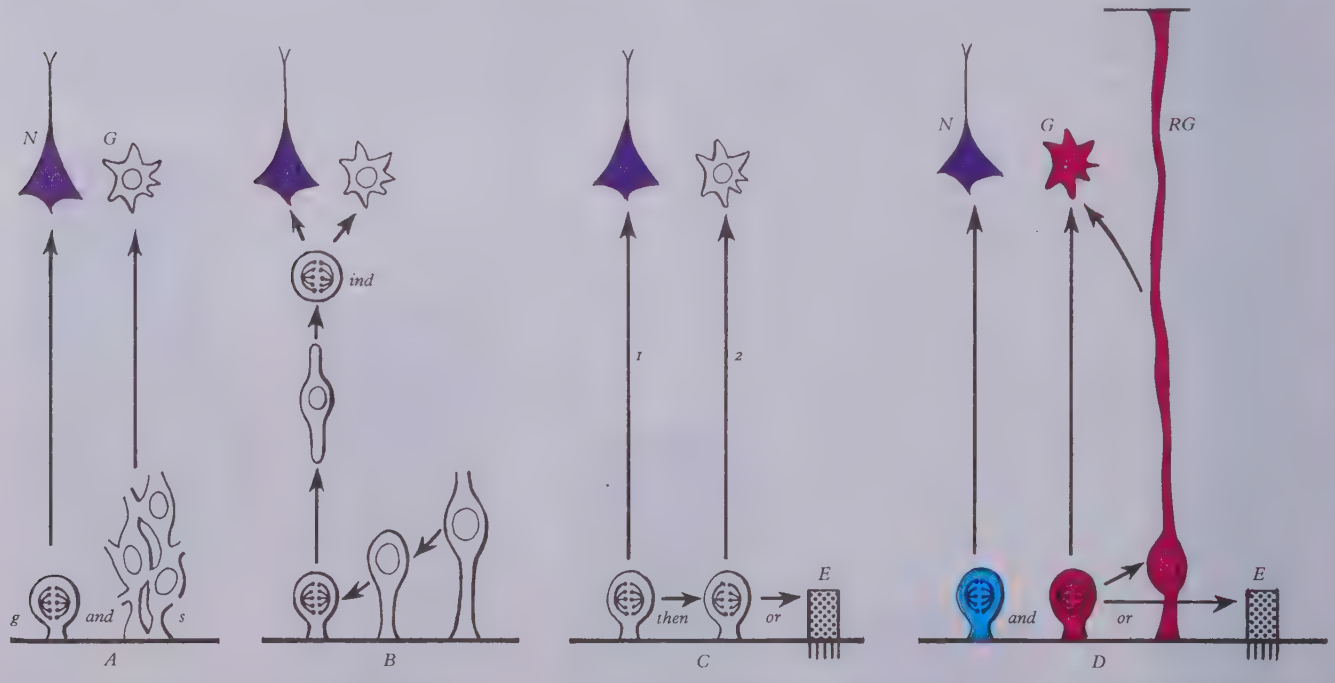
It should be emphasized here that differences of opinion persist (and have increased in the last decade), concerning the precise details of the proliferative cycles, differentiating mitoses, migrations and timing, in different species, sites in the central nervous system and the possible mechanisms involved. Further, considerable confusion has obtained between different neuroembryologists in relation to the *terminology* to be adopted for the various '*layers*' or '*zones*' at different times and places in the developing neural tube. An international group of neurocytologists (The Boulder Committee, 1970) proposed a less ambiguous nomenclature which is increasingly adopted. They termed the early pseudostratified neuroepithelium, in which the 'elevator movement' occurs, the *ventricular zone* (its

2.60 Schema of five sequential stages (A to E) in the development of part of the neural tube's wall in section to form cerebral cortex. Spinal cord development is limited to stages A to C. (Modified from Boulder Committee *initial* recommendations 1970.) V—ventricular zone; M—marginal zone; I—intermediate zone; S—subventricular zone; CP—cortical plate. New research techniques led Rakic (1982) to advance many significant alterations and additions to these proposals: see p. 197 and **2.72**.

further development is summarized below, on pp. 188, 185, and in 2.60). For an excellent review of the biological and terminological problems posed, and an extensive bibliography to the date indicated, consult Berry (1974), and for further comments on the natural history of neurons see p. 917.

Illustration 2.60 summarizes the main stages of development of the neural tube and the nomenclature as *initially* proposed by the Boulder Committee (1970), the complete series of stages A–E applying to the cerebral neocortex: only stages A–C are relevant in the context of the spinal cord. As detailed in the caption, it will be seen that the early pseudostratified *ventricular* zone (V) is followed by the sequential appearance of *marginal* (M), *intermediate* (I), *subventricular* (S) zones and, concurrently with the latter, the early *cortical plate* (CP) (see p. 195). It is unfortunate that this use of the term *zone* for these *major ontogenetic strata* does *not* correspond to the M, I and S zones of Fujita detailed above (and in 2.59), the latter applying to subdivisions of the early neural tube only. More than a decade of research employing technical innovations, induced Rakic (1982) to suggest a series of additional features and modifications of the original Boulder proposals. These are mentioned at various points in the text, and summarized in relation to the neocortex on p. 195 and 2.72A-G.

Illustration 2.74 (which is based on the work of Berry & Rogers 1965, Berry 1974) may be noted here for comparison with 2.72; it stems from labelling studies on the *patterns of migration* of neuroblasts in the developing neocortex of the rat and will be briefly mentioned later on p. 195 et seq.



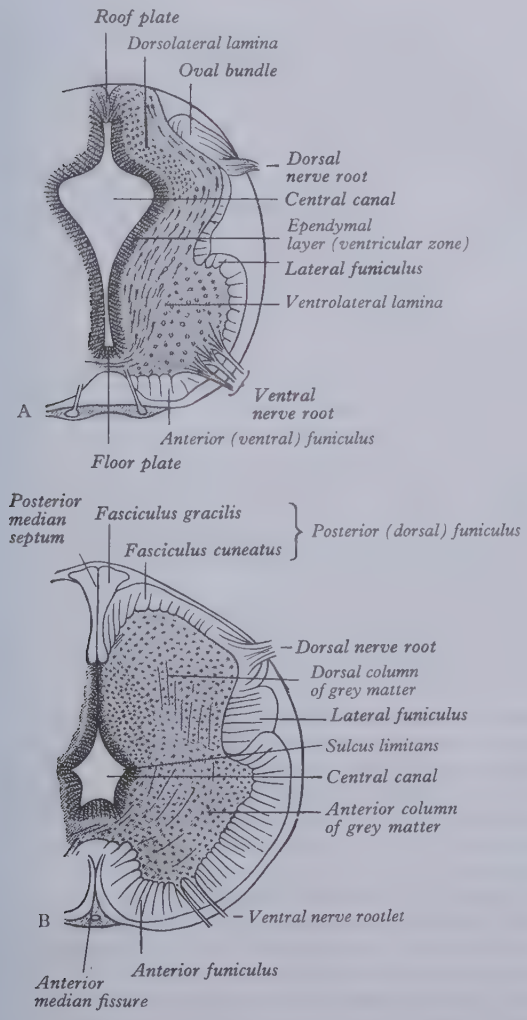
The following decade, and to the time of writing, has seen accelerating, enthusiastic application of newer, more refined techniques to these and related problems: in particular immunohistochemistry and computer analysis of neurocellular geometry. This has resulted in reappraisal of some foregoing conclusions. The cytokinetics of the early pseudostratified neuroepithelium ('elevator' movement, or interkinetic migration) has been substantiated, as has the establishment of the principal zones proposed by the Boulder Committee. However, the latter has been modified (at least in the forebrain) by the recognition of an additional (though transient) stratum deep to the early cortical plate—the *subplate zone* (SP), see p. 195—and many further features of cortical and subcortical maturation. Throughout most of the neuraxis, proliferative cell cycles are limited to the ventricular (V) and subventricular (S) zones, but their homogeneous nature has been challenged. Immunochemical methods for demonstrating glial fibrillary acid protein (GFA) strongly suggests that *at least two* cell varieties are present in the early tubal neuroepithelium, perhaps in a precise mosaic pattern. (This may be classified as an *oligophyletic theory of neurogenesis*). The early disposition of radial glial fibres is proposed by some to have a profound morphogenetic significance. The latter concerns not only their spatially ordered array, but the probability that they provide migration paths, by contact guidance, for at least the earlier generations of migratory neuroblasts, thus specifying their destinations. Neuronal geometry is further considered on pp. 183, 188, 195. (See bibliographic reviews in: Berry 1974, 1982, Berry et al 1980a,b,c,d, Schmitt & Worden 1979, Levitt & Rakic 1980, Rakic & Goldman-Rakic 1982, Smart 1982, 1983.)

Illustration 2.61, based on and slightly modified from Rakic (1981, 1982), is a simplified analysis of earlier and current theories of some cell varieties and lineages in neural tube histogenesis. In a recent presentation (Levitt et al 1981) some aspects of all earlier theories have been incorporated, others rejected. See caption and text above for further comments.

THE SPINAL CORD

In the future spinal cord the median *dorsal lamina* (*roof plate*) and *ventral lamina* (*floor plate*) of the neural tube do not participate in the cellular proliferation affecting the lateral walls and hence remain thin. Their cells contribute largely to the formation of ependyma.

The neuroblasts of the *lateral* walls of the tube are large and at first round or oval (*apolar*). Soon they develop processes at opposite poles, becoming *bipolar neuroblasts*. One process is, however, withdrawn and the neuroblast becomes *unipolar* although



2.61 Simplified schemes of successively held theories of cell lineages during early neurogenesis. A His (1889) recognized two major cell varieties in the matrix layers (ventricular zone) lining the central canal and ventricles. Spheroidal, proliferative, germinal cells (g) their progeny migrating to form neuroblasts (N); neighbouring spongioblasts (s) had progeny forming varieties of glioblast (G). B Schaper (1897) held that ventricular zone mitoses gave outwardly migrating indifferent cells (ind), further division of which produced neuroblasts, glioblasts, or both. C Fujita (1963), using autoradiography, believed that a single proliferative type of matrix cell *firstly* gave migratory generations of neuroblasts, *secondarily* (later) of glioblasts, finally, the persistent remainder formed ependymal cells (E). D Currently, electron immunohistochemistry has demonstrated at least two distinct cell varieties, — GFA (glial fibrillary acid protein) positive and negative, present in extremely early ventricular zones. The negative cells (blue) gave migratory neuroblasts (purple). The positive cells (magenta) gave, firstly, radial glioblasts (RG) that span the neural tube joining homologous internal and external points; later, directly or indirectly, generations of definitive glioblasts, and finally ependymal cells. The radial glial extensions probably provide contact guidance paths for echelons of neuroblast migration. (Modified after Rakic 1982.)

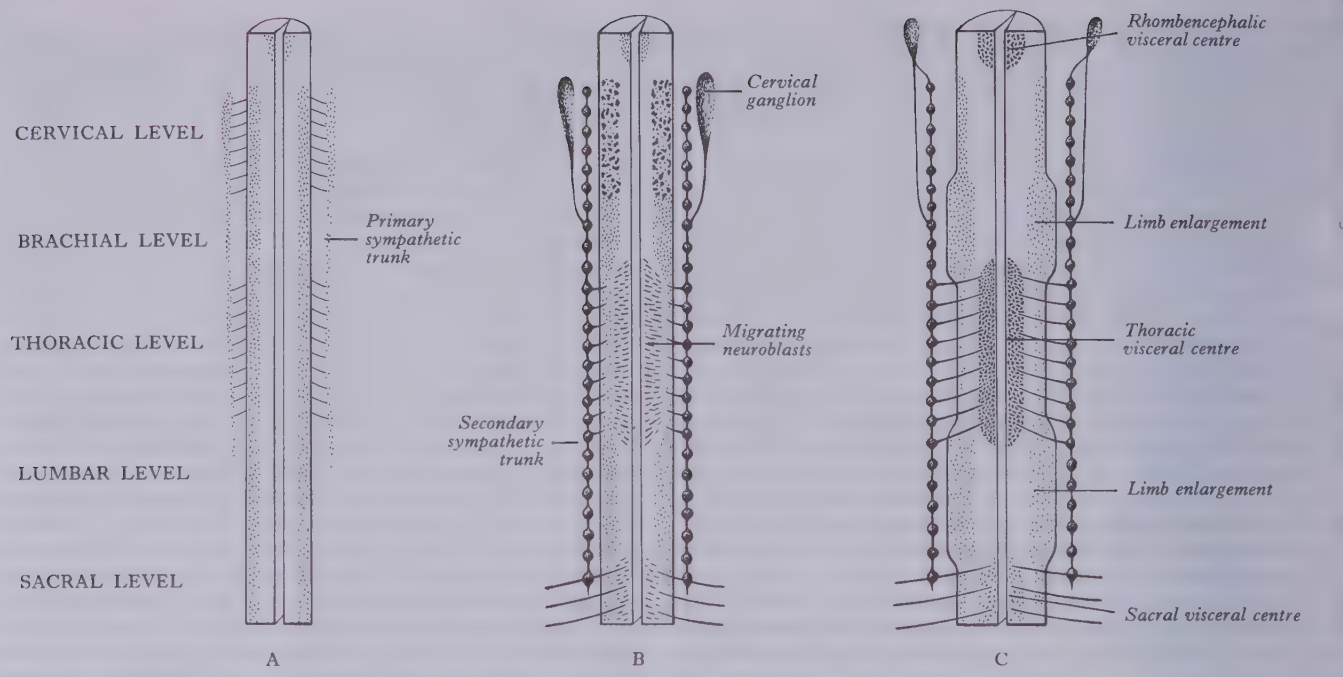
this is not invariably so in the case of the spinal cord. Further differentiation leads to the development of dendritic processes and they become typical *multipolar neuroblasts*. In the developing cord they occur in small clusters representing clones of neuroblasts.

At first the neural tube is oval in outline and its lumen is narrow and slit-like (**2.57**). As the lateral walls thicken, the lumen widens in its dorsal part and is somewhat diamond-shaped on cross-section (**2.58**). The widening of the canal is associated with the development of a longitudinal *sulcus limitans* on each side. This divides the ventricular and intermediate zones (ependymal and mantle layers) in each lateral wall into a *ventrolateral (basal) lamina* and a *dorsolateral (alar) lamina*. This separation indicates a fundamental functional difference, for neuroblasts in the ventrolateral lamina include the motor cells of the anterior and lateral grey columns, while those of the dorsolateral lamina exclusively form 'interneurons' (both short and long axoned), some of which receive the terminals of primary sensory neurons. (It should, perhaps, be mentioned at this point that the scientific utility of the term 'interneuron' has been seriously challenged—see Gray 1974.) Caudally the central canal of the cord exhibits a fusiform dilatation, the *terminal ventricle*.

(It will be apparent in the preceding paragraphs that the long held and widely used terms (1) roof plate, (2) floor plate, (3) alar lamina and (4) basal lamina have been, in the main, changed to: (1) dorsal lamina, (2) ventral lamina, (3) dorsolateral lamina and (4) ventrolateral lamina. These new terms were officially introduced in the *Nomina Embryologica* associated with *Nomina Anatomica* (Fourth Edition) by the International Anatomical Nomenclature Committee (Tokyo 1975). The modified names are more apposite *throughout* the *early* neural tube (i.e. spinal cord and brainstem).

2.62 Transverse sections through the developing spinal cord of human embryos. A About 6 weeks old. B About 3 months old. (After His.)

However, these terms become much less appropriate in the rostral half of the medulla oblongata and caudal half of the pons, with the profound positional changes accompanying the formation of the pontine flexure—see p. 185. Nevertheless, for consistency they have been retained here.)



The cells of the ventricular zone are closely packed at this stage and arranged in radial columns (**2.58**). For experimental studies of radial migration patterns consult Berquist (1932, 1968), also bibliographies in Rakic (1981, 1982). Their disposition may be partly determined by contact guidance along the earliest *radial array* of glial fibres that traverse the *full thickness* of the early neuroepithelium. The cells of the intermediate zone are more loosely scattered, and they increase in number at first in the region of the ventrolateral (basal) lamina. This enlargement outlines the *anterior (ventral) column* of the grey matter and causes a ventral projection on each side of the median plane, the ventral lamina (floor plate) remaining at the bottom of the shallow groove so produced. As growth proceeds these enlargements, further increased by the development of the anterior funiculi, encroach on the groove until it becomes converted into the slit-like anterior median fissure of the adult spinal cord (**2.62**A, B). The axons of some of the neuroblasts in the anterior grey column traverse the marginal zone and emerge as bundles on the anterolateral aspect of the spinal cord as the *ventral spinal nerve rootlets*. These constitute, eventually, both the alpha-efferents which establish motor end plates on extrafusal striated muscle fibres and the gamma-efferents which innervate the contractile polar regions of the intrafusal muscle fibres of the muscle spindles (p. 915). (The histogenesis of beta-efferents is, of course, completely uncharted.)

In the thoracic and upper lumbar regions some intermediate zone neuroblasts in the dorsal part of the ventrolateral lamina outline a *lateral column*. Their axons join the emerging ventral nerve roots and pass as preganglionic fibres to the ganglia of the sympathetic trunk or related ganglia, the majority eventually myelinating to form *white rami communicantes*. The fibres constituting the rami establish synapses with the autonomic ganglionic neurons (pp. 199, 200), and the axons of some of the latter proceed as post-ganglionic fibres to innervate smooth muscle cells, adipose tissue or glandular cells. Some of the preganglionic sympathetic efferent axons pass to the cells of the suprarenal medulla (p. 1469). The innervation of other 'chromaffin' tissues is less certain (but see the carotid body, p. 1473). Similarly an autonomic lateral column is also laid down in the mid-sacral region and gives origin to the preganglionic parasympathetic fibres of the pelvic splanchnic nerves (p. 1166).

A number of investigations have been directed towards an understanding of the cell dynamics involved in the elaboration of the distinctive groupings of cells seen in the mature spinal cord of various species (Levi-Montalcini 1950, Hamburger 1952, Harris 1965, Romanes 1951, 1953, 1964).

The changes in cell number, position and density as seen in a longitudinal section of the chick spinal cord, based on investigations of Hamburger (1952), are illustrated in **2.63**. The anterior region of each ventrolateral (basal) lamina forms at first a continuous column of cells throughout the length of the developing cord. In many forms this soon develops into two columns (on each side)—one medially placed, concerned with innervation of axial musculature, and a lateral one innervating the limbs. At limb levels the latter column enlarges enormously but retrogresses at other levels.

Involved in transformations such as the foregoing, there is an interplay between a number of fundamental processes which vary in prominence at different times and at different levels—cell *proliferation, migration*, followed either by progressive cell *growth and differentiation* or, in complete contrast, by cell *degeneration and death*. In the example quoted, cell proliferation persists as a prominent feature at the levels concerned with limb innervation, whilst at thoracic levels a *dorsomedial* migration of neuroblasts occurs to lay the foundation of the visceral efferent column. Further, save at limb levels, massive cell degenerations occur in the lateral 'motor' columns, whereas the medial columns, which innervate axial musculature, persist throughout the cord. The phenomenon of cell death and removal on a large scale, balanced against local proliferation and migration rates, has only been

2.63 Diagrams illustrating the changing morphogenetic patterns in the developing neural tube of the *chick* seen in longitudinal section. Note the progression from A to C as the initial simple homogeneous columnar organization (A) is transformed into the definitive pattern (C). These changes follow variations in the turnover rate and differentiation rate of neuroblasts in different regions of the tube, combined with migration of neuroblasts in some regions, and cell death in others. For further description see the text. (From V Hamburger, with kind permission of the author and the New York Academy of Sciences.)

recognized relatively recently (p. 103) as a fundamental feature in many morphogenetic situations. For an excellent review of this field in relation to the developing nervous system, the interested reader should consult Hughes (1968, 1974).

Thus, as we have seen, some ventrolateral laminal neuroblasts differentiate into the ventral horn neurons from which both alpha, beta and gamma efferent fibres arise, and these are accompanied at thoracic, upper lumbar and mid-sacral levels by preganglionic autonomic efferents from neuroblasts of the developing lateral horn. However, additionally, numerous interneurons develop in both these situations (including the well-studied Renshaw cells), but it is uncertain how many of these differentiate directly from ventrolateral lamina neuroblasts and how many migrate to their final positions from the dorsolateral lamina.

In the human embryo, the definitive grouping of the ventral column cells which characterizes the mature cord occurs early, and by the fourteenth week (the 80 mm stage) all the major groups can be recognized (Romanes 1941, 1942, 1946, 1953, 1964).

As the anterior and lateral grey columns assume their final form the germinal cells in the ventral part of the ventricular zone gradually cease to proliferate and the layer becomes reduced in thickness until it ultimately forms the single-layered ependyma which lines the ventral part of the central canal of the spinal cord. The *posterior (dorsal) column* is somewhat later in its development and, as a result, its ventricular zone is for a time much thicker in the dorsolateral lamina than it is in the ventrolateral lamina (**2**.58).

While the columns of grey matter are being defined, the dorsal region of the central canal becomes narrow and slit-like and its walls come into apposition and fuse with each other (**2**.62B). In this way the central canal becomes relatively reduced in size and somewhat triangular in outline.

About the end of the fourth week advancing axonal sprouts invade the marginal zone. The first to develop are those destined to become short *intersegmental* fibres from the neuroblasts in the intermediate (mantle) zone, and also fibres of *dorsal roots* of spinal nerves which pass into the spinal cord from neuroblasts of the early spinal ganglia. The earlier dorsal root fibres that invade the dorsal marginal zone stem from *small* dorsal root ganglionic neuroblasts. By the sixth week the latter form a well-defined *oval bundle* near the peripheral part of the dorsolateral lamina (**2**.58, 62A); this bundle increases in size and, spreading towards the median plane, forms the *primitive posterior funiculus*; its constituent fibres are destined to be of fine calibre. Later, fibres derived from new populations of *large* dorsal root ganglionic neuroblasts join the dorsal root and invade the cord nearer the median plane; they are destined to become fibres of much larger calibre. As the posterior funiculi increase in thickness, their medial surfaces come into contact separated only by the *posterior median septum*, which is ependymal in origin, neuroglial in nature. A more detailed analysis of the temporal sequence of modifications of the dorsal lamina (roof plate), posterior median septum, and the lateral displacement of the *primitive posterior funiculus* with the later development of the fasciculus cuneatus followed by the fasciculus gracilis, based on a study of sectioned human embryos of 6–10 weeks and dissections of fetuses up to the end of the fourth month, has been provided by Hughes (1976). He proposed that the displaced primitive posterior funiculus may form the basis of the dorsolateral tract or fasciculus (of Lissauer), and also correlated the sequence, siting and calibre of the entrant dorsal root fibres with the changing size-distribution of the somata of the dorsal root ganglionic neuroblasts.

Long intersegmental fibres begin to appear about the third month and *corticospinal* fibres about the fifth month. All nerve fibres are at first without myelin sheaths and different groups *commence* to develop sheaths at different times, e.g. the ventral and dorsal nerve roots about the fifth month, the corticospinal fibres after the ninth month. In peripheral nerves the myelin is formed by Schwann cells; in the central nervous system oligodendrocytes are believed by the majority of workers to be concerned (p. 893). Myelination, of course, persists until overall growth of the central and peripheral nervous system has ceased. Thus, in many sites, slow growth continues for long periods, even into the postpubertal years.

The cervical and lumbar enlargements first appear simultaneously with the development of their respective limb buds.

In early embryonic life the spinal cord occupies the *entire length* of the vertebral canal and the spinal nerves pass at right angles to the cord. After the embryo has attained a length of 30 mm the vertebral column begins to grow more rapidly than the spinal cord, the caudal end of which gradually becomes more cranial in

the vertebral canal. Most of this relative rostral migration occurs during the *first half of* intrauterine life. By the twenty-fifth week the terminal ventricle of the spinal cord has altered in level from the second coccygeal vertebra to the third lumbar, a distance of nine segments, and there remain but two segments before the adult position is reached (Streeter 1919). As the change in level begins rostrally the caudal end of the terminal ventricle, which has become adherent to the overlying ectoderm, remains *in situ* and the walls of the intermediate part of the ventricle and its covering pia mater become drawn out to form a delicate filament, the *filum terminale*. The separated portion of the terminal ventricle persists for a time but it usually disappears before birth. It does, however, occasionally give rise to congenital cysts in the neighbourhood of the coccyx. In the definitive state, the upper cervical spinal nerves retain their position roughly at right angles to the cord; proceeding caudally, however, the nerve roots lengthen and are progressively more oblique.

THE SPINAL NERVES AND NEURAL CREST

Each spinal nerve is connected to the spinal cord by a ventral root and a dorsal root. The fibres of the ventral roots grow out from neuroblasts in the anterior and lateral parts of the intermediate zone; these pass through the overlying marginal zone and external limiting membrane to enter the *myotomes* of the mesodermal somites, or penetrate the latter, reaching the adjacent somatopleure, and in both sites ultimately form the alpha-, beta- and gamma-efferents. At appropriate levels these are accompanied by the outgrowing axons of preganglionic sympathetic neuroblasts (segments T1–L2), or preganglionic parasympathetic neuroblasts (S2–S4).

The fibres of the dorsal roots are developed from the cells of the spinal ganglia. Before the neural groove is closed to form the neural tube (p. 133) a ridge of neurectodermal cells, the *neural crest (ganglion ridge)*, appears along the prominent margin of each neural fold (**2**.27A–E). When the folds meet in the median plane the two neural crests fuse into a wedge-shaped mass along the line of closure of the tube. Opposite each primitive mesodermal segment the neural crest cells proliferate rapidly to form a bilateral series of oval-shaped *primordial spinal ganglia*, and these migrate for a short distance in a lateral and ventral direction. From the ventral *region* of each a small part separates to form *sympathochromaffin* cells (pp. 200, 1465), while the remainder becomes a *definitive* spinal ganglion. The spinal ganglia are arranged symmetrically at the sides of the neural tube and, except in the caudal region, are equal in number to the primitive segments. The cells of the ganglia, like the cells of the intermediate zone of the early neural tube, are glioblasts and neuroblasts. The glioblasts develop into the satellite cells, which become closely applied to the ganglionic nerve cell somata (perikarya), into Schwann cells, and possibly other cells. The neuroblasts, at first round or oval, soon become fusiform, with extremities gradually enlongating into central and peripheral processes. The central processes grow into the neural tube, as the fibres of dorsal nerve roots, while the peripheral processes grow ventrolaterally to mingle with the fibres of the ventral root thus forming a *mixed spinal nerve*. As development proceeds the original bipolar form of the cells in the spinal ganglia changes; the two processes become approximated until they ultimately arise from a single stem in a T-shaped manner, to form a unipolar cell (sometimes, less appropriately, termed pseudo-unipolar). The bipolar form is, however, retained in the retina and in the ganglia of the vestibulocochlear nerve. Some observers hold that the T-form is derived from the branching of a single process which grows out from the cell.

It should be noted that the position of the early neural crest as a wedge-shaped mass along the line of tube closure noted above, and the identification of ganglionic cells in various positions in the wall of the early neural tube, and even within the central canal (Humphrey 1944, 1947), is strongly reminiscent of the developmental history of the *Rohon-Beard cells* in fish and amphibia (Rohon 1884, Beard 1896), which are thought to be important in the emergence of primitive locomotor patterns (Hughes 1968). In this regard, other investigators have claimed that in primitive chordates (Cyclostomes and Euselachians) the neural crest develops as an *evagination* of the dorsal region of the dorsolateral lamina of the late neural folds and early neural tube (Conel 1942). For a review of the origin, widespread migration and differentiation of neural crest cells see, e.g. Weston (1970) Bellairs (1971) Leikola (1976) and p. 137.

For more than a century there have been many attempts to plan investigations which would aid an understanding of the *causal morphogenetic mechanisms* which operate during the development of the nervous system and to correlate the stage of development with emergent *behavioural patterns*. Whilst much has been established, answers to many fundamental questions still remain obscure. A review of this important and interesting area of biology lies outside the scope of the present volume and the reader should consult the pioneering works which have appeared over the intervening years. Consult references (His 1879, 1883, 1887, 1890, Ramón y Cajal 1928, 1955, Waldeyer 1891, Harrison 1906, 1907, 1910, 1914, 1924, Coghill 1929, Detwiler 1936, Spemann 1938, Weiss 1950, Hughes 1968, Gottlieb 1974).

Briefly, the nervous system is closely interlocked in terms of morphogenesis, with the 'periphery', i.e. surrounding non-nervous structures, and each is dependent upon the other for its effective structural and functional maturation.

Reference has already been made to the widely assumed initiating importance of a triggering system whereby the prechordal plate and chorda-mesoderm of the archenteron roof operate as a coordinated series of regional neural plate inducers—archencephalic, deuterencephalic and spinocaudal. (However, see discussions on pp. 107, 108–115 and consult Bellairs 1971.) Thereafter follows a period during which the main cell masses and subdivisions of the neural tube are established, and transplantation experiments have indicated that some of the earlier patterning is an expression of self-differentiation of the tube. (For a descriptive and experimental review of pattern formation in early neurogenesis in the chick consult Watterson 1965.) However, the polarization of ventrolateral lamina neuroblasts and those of the neural crest, and the formation of segmentally arranged ventral nerve roots and spinal ganglion primordia, is closely related to and dependent upon the orderly segmentation of the neighbouring mesodermal somites. Experimental removal or intercalation of somites results in corresponding disturbances of pattern in these nervous structures.

There are many other examples of the influence of peripheral structures on the development of the nervous system. Thus, if the normal peripheral innervation of the tetrapod limb is prevented there follows a gross disturbance in the balance between neuroblast proliferation, degeneration, migration and maturation in the relevant part of the neural tube and primitive spinal ganglia. Conversely, the denervated limb rudiment itself fails to complete its development in the absence of nerve-mediated influences. Other extensively investigated situations include the inductive influence of the optic vesicle on adjacent ectoderm with the formation of a lens vesicle (p. 202) and the reciprocal influences of the developing lens and peri-optic mesenchyme on the differentiation of the optic cup (p. 202); the profound influence of peripheral innervation on the regeneration of limbs in amphibia; the 'trophic' maintenance of striated muscle structure by peripheral nerves (p. 919); the dependence of regenerating peripheral nerves on the establishment of normal peripheral connections before a restoration of their structural and functional parameters ensues. Thus, whilst there are numerous experimentally demonstrable examples of the *interdependence* of the developing nervous system and the periphery, the precise causal mechanisms at work remain elusive. In this regard, however, mention should be made of a proposal (Prestige 1965, 1967, 1970) concerning the operation of *maintenance factors* thought to be produced by the tissues of developing tetrapod limbs, and which may enter the nervous system, perhaps to be stored in the cytoplasm of neurons, where their concentration influences the turnover of neuroblasts, i.e. the balance between the rate of proliferatration and degeneration. Similarly, other workers (Levi-Montalcini 1950, 1952, 1960, 1967, Levi-Montalcini & Chen 1971, Cohen 1958, Cohen & Levi-Montalcini 1956) have isolated various proteinaceous *nerve growth factors* from tissue and tumour extracts and snake venom which influence the in vitro form and

extent of nerve cell growth. Although the operation of such factors in normal ontogeny has not been claimed by these workers, others have demonstrated the presence of similar substances in homogenates of the axial structures of chick embryos during early neurogenesis.

One problem which has attracted neuroembryologists for many years concerns the manner in which growing nerve fibres reach and make functional contact with their appropriate end organs (neuromuscular endings, secretomotor terminals or synapses with other neurons), during which they often pursue complex courses between the parent cell body and the sites of termination. If the cells concerned had been in contact from the first, the problem would have reduced to one concerning mechanisms of relative displacement and migration of both, with simple elongation of the nerve cell process between them. However, during the outgrowth of axonal processes from, e.g. neuroblasts within the ventrolateral lamina to reach presumptive myoblasts in the limb buds, the earliest nerve fibres are known to cross appreciable distances occupied solely by loose general mesenchyme.

The growing tips of the neurites have been studied in tissue culture (Harrison 1910, Lewis 1945, Speidel 1932, 1933, 1935, Nakai 1960, Nakai & Kawasaki 1959, Pomerat et al 1967, and vide infra) and in the tail of larval amphibia (Speidel 1932, 1933, 1935). Classically, the tip has been described as expanded into a *growth cone* which is constantly active, changing shape, extending and withdrawing processes which apparently 'explore' the local environment for a suitable surface along which extension may occur (see 'cell motility' p. 49). One process then enlarges at the expense of others and expands into a new growth cone, the exploratory behaviour recommencing. However, it has been suggested that the very rapid surface activity of growth cones is associated more with the micropinocytotic imbibition of water and solutes (perhaps in relation to a peripheral undulating cytoplasmic veil, or ruffled border, as in macrophages), forming cytoplasmic vacuoles which migrate centrally along the neurite. On this view the tip of the main trunk of the neurite moves in a series of discontinuous directional thrusts. Earlier ultrastructural studies also emphasized the presence within growth cones of microvesicles in the general cytoplasm (Estable et al 1957) and vacuoles within the cisternae of the endoplasmic reticulum (Bellairs 1959, but vide infra). In this context it is also widely held that products important in the growth mechanisms and synthesized within the cell bodies are passed outwards by some form of proximodistal *axoplasmic flow* along the neurites. Bulk axoplasmic flow was first postulated following the experimental constriction of nerves (Weiss & Hiscoe 1948), and since that time many intricate analyses of rapid and slow components of *bidirectional flow systems* within axons have been made (Lubińska 1964, and see *Neurosciences Research Programme Bulletin* **4**, vol 5, 1968, also p. 881).

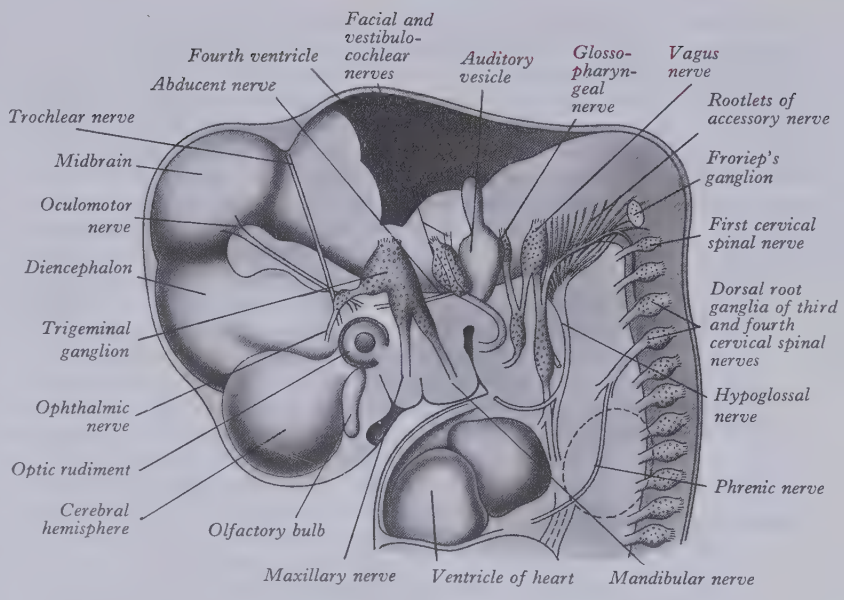
However, in a series of ultrastructural studies on the in vitro outgrowth of neurites from explants of chick *spinal cord*, a number of established views concerning their form, structure and surface contacts have been challenged (Grainger et al 1968, James & Tresman 1969, Grainger & James 1970). In addition to describing the formation of neuromuscular junctions and varieties of synapse under these experimental conditions, the authors have shown that the neurites usually grow out in bundles rather than as single processes. The neurites contain arrays of longitudinal microtubules which are probably interconnected, microfilaments, mitochondria, linear densities in the cytoplasm and populations of vesicles. The expanded tip of the neurite bundle is not an aggregation of simple 'growth cones' but usually the neurite terminals end in association with a 'glial' cell. The latter has a relatively dense cytoplasm containing an array of organelles enabling it to be distinguished from the neighbouring neurites. Further, the glial cell is complex in form. It sends a major cytoplasmic process back towards the parent explant; it presents surface projections which partly enfold the terminal neurites, and distally, beyond the neurites, cytoplasmic sheets or finger-like processes extend to come into intimate relationship with the culture substrate. Thus, the essential contacts appear to be between glial cell membrane and substrate, and between neurite membrane and glial cell membrane, posing the question whether the glial cell, rather than the tip of the neurite, is basically involved in determining the direction of outgrowth. Further investigations will be necessary to determine how far these appearances are reflected in the growth of both central and peripheral neurites in normal ontogeny, although strong supporting evidence has been adduced concerning the growth of *central* neuroblasts (Rakic 1971a,b, 1981, 1982). Further details cannot be pursued here, but an excellent review has appeared concerning the morphology, motility and directional growth of axons and their growth cones, including the in vitro establishment of synaptic contacts—for this consult James (1974). It should be pointed out that Rakic (1971a,b, 1981, 1982) suggested that within the central nervous system, the direction followed both by advancing neurites and by migrating neuroblast somata may stem from contact guidance (vide supra and pp. 115, 918) with previously established glioblast processes. On the other hand, studies of the growth cones of neurites from explanted dorsal root ganglia of the rat (including their endocytotic uptake and transport of horseradish peroxidase), using light, transmission and scanning electron microscopy, many surface features and ultrastructural details of the cones were provided; no 'leading' glial or Schwann cells were identified. For further discussion and bibliography consult Fischer (1977); and for a literature review concerning *dendritic* growth Berry (1974, 1982).

Over the years two principal theories emerged concerning the directional growth of nerve fibres—the *neurotropism* of Ramón y Cajal (1919) and the principle of *contact-guidance* of Weiss (1941). The former, based upon observations on the innervation of epithelia, proposed that growing fibres were guided by some form of attraction, presumably chemical, which emanated from the area to be innervated. The second view denied the existence of such attractive forces and, based upon many series of tissue culture experiments, held that pioneer neurites were guided to their destination by preferential growth along pathways provided by an orientation of the micellar substructure of the intercellular matrix in the intervening spaces. Despite the forceful arguments brought to bear on this question, it should be noted that in a critical review of this field (Hughes 1968), it was stated: 'Both contact guidance and neurotropism, however, associated or combined, are inadequate to explain the pattern of the peripheral nervous system and, *a fortiori*, of the enormously more intricate plan of the fully differentiated neural tube. No imaginable hypothesis is at present adequate to explain the phenomena of the regeneration of the optic nerve, which is the only central pathway which has so far been studied by experimental means. At present the only possible way of regarding the whole question is in terms of a succession of influences which operate in turn upon a growing nerve fibre, from its first emergence to its final link with an end organ. Such a sequence of controlling factors was postulated as far back as 1911.' Nevertheless, whilst few would disagree with the general tenets of these remarks, hypotheses abound, and there is currently a great upsurge of interest in neuroembryology. As an introduction to the extensive literature, the reader should consult, e.g. Sperry (1958, 1963, 1965), Schmitt et al (1970), Jacobson (1978), Gaze (1970), Gottlieb (1973, 1974), Mark (1974), Berry (1974, 1982), Rakic (1981, 1982). In addition to questions concerning the growth, guidance, and patterning of neurites and somata, the following kinds of problem confront neuroembryologists. What are the basic ontogenetic factors providing positional information (p. 109), controlling proliferative cycles, differentiating mitoses and the initial polarization and migration of neuroblasts? How much of the initial patterning is preprogrammed in the genome, and how much environmentally and functionally dependent? To what extent do regeneration experiments reflect ontogeny? Do neurons bear individually unique chemical markers? What are the structural bases of neuronal plasticity and the behavioural phenomena of instinct, learning and memory? Answers still elude us and we remain at the stage of attempting to plan meaningful experiments.

Development of the Brain

Prior to the closure of the neural tube the neural folds become expanded considerably in the head region as a first indication of a brain. Subsequent to the closure of the rostral neuropore

(p. 133) these regional expansions form the three *primary cerebral vesicles* (2.64, 67, 68). The customary use of the term 'vesicle', though followed here, is rather a misnomer as it suggests an exaggerated view of these localized accelerations of growth in the wall of the brain (O'Rahilly and Gardner 1971). In 'higher' vertebrates, and especially in primates, including mankind, the bulging is not initially marked, nor are the constrictions between them particularly narrow. The vesicles are more like gently fusiform tubes. The three regions are named (caudorostrally) the *rhombencephalon* or *hindbrain*, the *mesencephalon* or *midbrain* and the *prosencephalon* or *forebrain*—the first being continuous with the spinal cord. As a result of unequal growth of its different regions three flexures appear in the brain; two of these are concave ventrally and there are corresponding flexures of the head. The first is associated with the formation of the head fold and is a *midbrain flexure*; as a result the forebrain bends in a ventral direction around the cephalic end of the notochord and foregut and this progresses until its floor lies almost parallel with that of the hindbrain (2.64, 67, 68). The midbrain is thus, for a time, the most conspicuous part of the brain and underlies the marked *midbrain prominence* of the overlying ectoderm, seen to best advantage when viewed from the side. The second bend appears at the junction of the hindbrain and spinal cord, the *cervical* or *neck flexure* (2.64, 67, 68). This increases from the fifth to the end of the seventh week, by which time the hindbrain forms nearly a right angle with the spinal cord; after the seventh week, however, extension of the head takes place and the cervical flexure diminishes and eventually disappears. These bends are important factors in determining the shape of the cranial end of the embryo. The third bend, the *pontine flexure*, is at the level of the future pons. It differs from the other two in that its convexity is directed ventrally and it does not substantially affect the outline of the head. For more recent accounts of the early development of the brain consult Bartelmez & Dekaban (1962), Jacobson (1970), Gaze (1970), Eccles (1973), Gottlieb (1973, 1974), Mark (1974), Rakic (1981, 1982), Smart (1982, 1983).



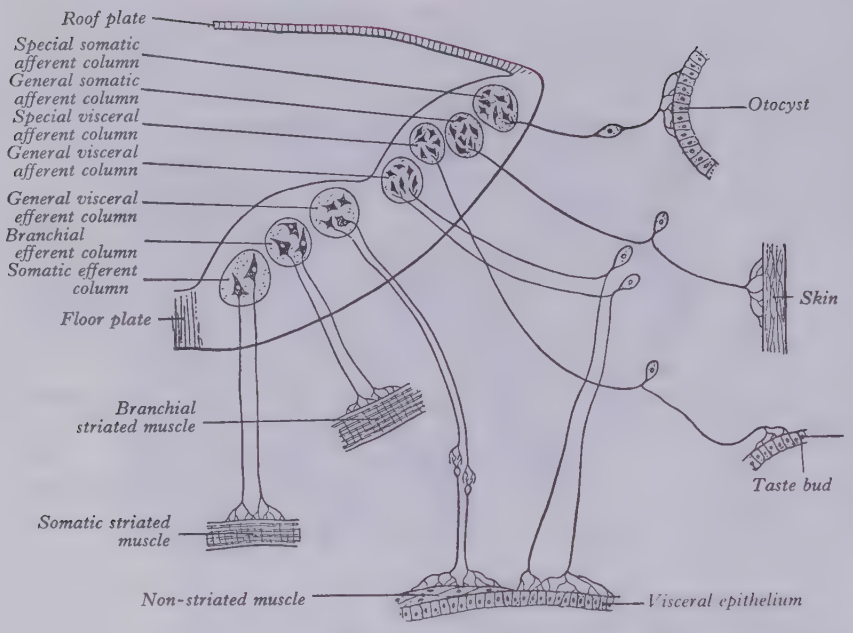
The lateral walls of the hindbrain and midbrain, like those of the spinal cord, are divided into *dorsolateral (alar)* and *ventrolateral (basal) laminae* by the upward continuation of the limiting sulci of the spinal cord.

THE RHOMBENCEPHALON

By the time the midbrain flexure appears, the hindbrain exceeds in length the combined extent of the other two brain vesicles. Cranially it exhibits a constriction, the *isthmus rhombencephali* (2.67B), best viewed from the dorsal aspect. Ventrally the hindbrain is separated from the dorsal wall of the primitive pharynx only by the notochord, the two dorsal aortae and a small amount of mesenchyme; on each side it is closely related to the dorsal ends of the visceral arches (2.49).

The pontine flexure appears to 'stretch' the thin, epithelial roof plate (dorsal lamina) which becomes widened, the greatest increase in width corresponding to the region of maximum convexity, so that the outline of the roof plate becomes rhomboidal. By the same change the lateral walls become separated, particularly dorsally, and the cavity of the hindbrain, subsequently the fourth ventricle, becomes flattened and somewhat triangular on cross-section. The pontine flexure becomes increasingly acute until, at the end of the second month, the laminae of its cranial (metencephalic) and caudal (myelencephalic) slopes are opposed to each other (2.66C) and, at the same time, the lateral angles of the cavity extend to form the lateral recesses of the fourth ventricle.

About the end of the fourth week, when the pontine flexure is first discernible, a series of six transverse *rhombic grooves* appears in the ventrolateral lamina of the hindbrain. Between the grooves, the intervening masses of neural tissue have, at this stage, been termed *rhombomeres (neuromeres)*. These are closely associated with the pattern of the underlying motor nuclei of certain of the cranial nerves. The first two overlie the trigeminal nucleus, the third the facial nucleus, the fourth that of the abducent nerve, the fifth that of the glossopharyngeal and the sixth that of the vagus. These grooves, though transient, are constant in appearance, but their significance is uncertain. Some regard them as evidence of a segmental (neuromeric) origin for brain and cord (Berquist 1952).



2.64 The brain and cranial nerves of a human embryo, 10.2 mm long. Note the midbrain, cervical and pontine flexures, and the expanding fourth ventricle. Note also the ganglia (stippled) associated with the trigeminal, facial vestibulocochlear, glossopharyngeal, vagus and spinal accessory nerves. Froriep's ganglion, an occipital dorsal root ganglion, is inconstant and soon disappears. (After His.)

The differentiation of the lateral walls of the hindbrain into ventrolateral and dorsolateral laminae has a similar significance to the corresponding differentiation in the lateral wall of the spinal cord (p. 181) and ventricular, intermediate and marginal zones are formed in the same way. Later extensive modifications occur.

The cells of the ventrolateral lamina are often, in elementary accounts, simply termed 'motor' (but vide infra), and they form *three* elongated, but interrupted, *columns*. The most ventral column is continuous with the anterior grey column of the spinal cord and will supply muscles considered 'myotomic' in origin. It is represented in the caudal part of the hindbrain by the hypoglossal nucleus, and it reappears at a higher level as the nuclei of the abducent, trochlear and oculomotor nerves, which are *somatic efferent nuclei*. The intermediate column is represented in the upper part of the spinal cord and caudal brain stem (medulla oblongata and pons) and is for the supply of branchial and postbranchial musculature. It is interrupted also, but the caudal brain-stem part, which gives fibres to the ninth, tenth and eleventh cranial nerves, forms the elongated *nucleus ambiguus*. The latter continues into the cervical spinal cord as the origin of the spinal accessory nerve. At higher levels parts of this column give origin to the motor nuclei of the facial and trigeminal nerves. These three nuclei are termed *branchial (special visceral) efferent nuclei*. The most dorsal column of the ventrolateral lamina (represented in the spinal cord by the lateral grey column) innervates viscera. It is interrupted also, its large caudal part forming some of the *dorsal nucleus of the vagus* and its cranial part the *salivatory nucleus*. These are termed *general visceral (general splanchnic) efferent nuclei* and their neurons give rise to preganglionic, parasympathetic nerve fibres.

It should be noted here that the neuroblasts of the ventrolateral (basal) lamina and their three columnar derivatives are only 'motor' in the sense that *some* of their number form either α, β or γ motor neurons, or preganglionic parasympathetic neurons. The remainder, which greatly outnumber the former, differentiate into functionally related interneurons and, in some loci, neuroendocrine cells.

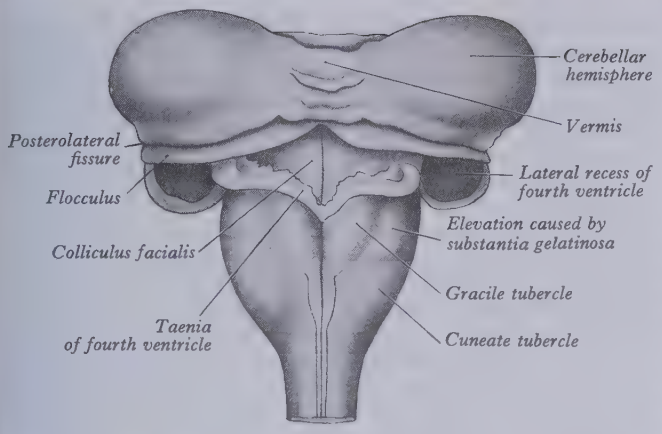
The cell columns of the dorsolateral lamina are also interrupted and give rise to *general visceral (general splanchnic) afferent, special visceral (special splanchnic) afferent, general somatic afferent* and *special somatic afferent* nuclei (their relative positions, in simplified transverse section, are shown in 2.65). The general

2.65 Diagram of a transverse section through the developing hindbrain of a human embryo *c.* 10.5 mm long, to show the relative positions of the columns of grey matter from which the nuclei associated with the different varieties of nerve components are derived. Note the postganglionic neurons associated with the general visceral efferent column, the bipolar neurons associated with the otocyst and the unipolar afferent neurons associated with the other alar lamina columns.

visceral afferent column is represented by a part of the dorsal nucleus of the vagus (see also p. 953), the special visceral afferent column by the nucleus of the tractus solitarius, the general somatic afferent column by the afferent nuclei of the trigeminal nerve (Brown 1974) and the special somatic afferent column by the nuclei of the vestibulocochlear nerve. (Again it should be noted here that the relatively simple functional independence of these afferent columns implied by the foregoing classification is, in the main, an aid to elementary learning. The emergent neurobiological mechanisms are in fact much more complex and less well understood—see p. 1121.) Although they tend to retain their primitive positions, some of these nuclei are later displaced by differential growth patterns and by the appearance and growth of neighbouring fibre tracts, and possibly by active migration. It has been suggested that a nerve cell tends to remain as near as possible to its predominant source of stimulation and that when the danger of separation arises, owing to the development of neighbouring structures, it will migrate in the direction from which the greatest density of stimuli come. This phenomenon was termed neurobiotaxis (Kappers 1921, 1934). Cells can migrate in this way only by lengthening of their axons, which therefore trace the route taken by the cells on their transit. The curious courses of the fibres arising from the facial nucleus (p. 1108) and nucleus ambiguus (pp. 956, 1114) have been held to illustrate this. In the 10 mm embryo the facial nucleus lies in the floor of the fourth ventricle, occupying the position of the special visceral efferent column and it is placed at a higher level than the abducent nucleus. As growth proceeds the facial nucleus migrates at first caudally and dorsally, relative to the sixth nerve nucleus, and then ventrally to reach its adult position. As it migrates, the axons to which its cells give rise elongate and their subsequent course is assumed to map out the pathway along which the facial nucleus has travelled. Similarly the nucleus ambiguus arises initially immediately deep to the ventricular floor, but in the adult it is more deeply placed and its efferent fibres first pass dorsally and *medially* before curving laterally to emerge at the surface of the medulla oblongata. Attractive as the concept of neurobiotaxis may seem, it must be added that it is supported by little direct evidence; further, many other parameters affecting pattern formation must be considered.

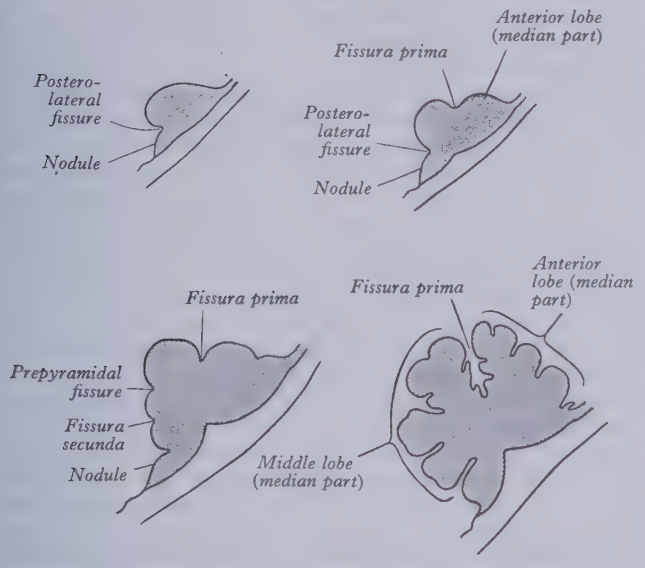
THE MYELENCEPHALON

The caudal slope of the embryonic hindbrain constitutes the *myelencephalon*, which develops into the medulla oblongata. The nuclei of the ninth, tenth, eleventh and twelfth cranial nerves develop in the situations already indicated and afferent fibres from the ganglia of the ninth and tenth nerves form an oval marginal bundle in the region overlying the dorsolateral (alar) lamina. The dorsal edge of this lamina throughout the rhombencephalon gives attachment to the thin expanded roof plate (dorsal lamina) and is termed the *rhombic lip*. (The *inferior rhombic lip* is confined to the myelencephalon; the *superior rhombic lip* to the metencephalon.) As the walls of the rhombencephalon spread outwards, the rhombic lip protrudes as a lateral edge which becomes folded over the adjoining area. According to this widely accepted view it later becomes adherent to this area, and the cells of the rhombic lip migrate actively into the marginal zone of the ventrolateral *lamina*. In this way the oval bundle which forms the *tractus solitarius* becomes buried. Dorsolateral lamina cells which migrate from the rhombic lip are believed to give origin to the olivary and arcuate nuclei and the scattered grey matter of the nuclei pontis. While this migration is in progress the thin floor plate (ventral lamina) is invaded by fibres which cross the median plane (accompanied by neuroblasts which cluster in and near this plane), and it becomes thickened to form the *median raphe*. Some of the migrating cells from the rhombic lip in this region do not reach the ventrolateral lamina and form an oblique ridge across the dorsolateral aspect of the inferior cerebellar peduncle; the *corpus pontobulbare (nucleus of the circumolivary bundle)*.



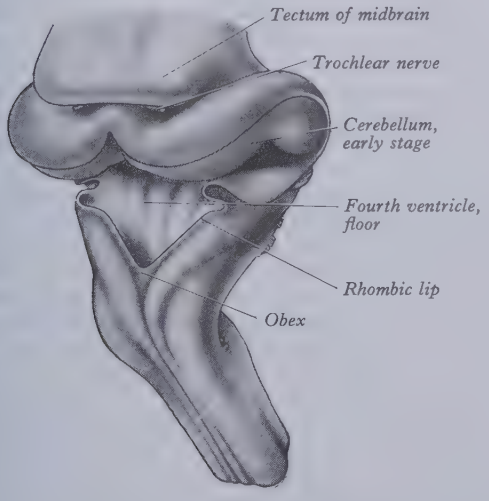
The lower (caudal half) part of the myelencephalon takes no part in the formation of the fourth ventricle and, in its development, it closely resembles the spinal cord. The nuclei, gracilis and cuneatus, and some reticular nuclei, are derived from the dorsolateral lamina, and their efferent arcuate fibres and interspersed neuroblasts play a large part in the formation of the median raphe.

About the fourth month the descending *corticospinal* fibres invade the ventral part of the medulla oblongata to initiate the pyramids whilst dorsally, ascending fibres from the spinal cord, with olivocerebellar and parolivocerebellar fibres, external arcuate fibres, together with two-way reticulocerebellar and vestibulocerebellar interconnections, form the inferior cerebellar peduncle. (The reticular nuclei of the lower medulla probably have a dual origin from both laminae.)



THE METENCEPHALON

The rostral slope of the embryonic hindbrain is the *metencephalon*, from which both cerebellum and pons develop. Prior to formation of the pontine flexure the dorsolateral laminae of the metencephalon are parallel with one another. Subsequent to its formation the roof plate of the hindbrain becomes rhomboidal and the dorsal laminae of the metencephalon lie obliquely, being close at the cranial end of the fourth ventricle but widely separated at the level of its lateral angles. Accentuation of the flexure approximates the cranial angle of the ventricle to the caudal, and the dorsolateral laminae of the metencephalon now lie almost horizontally.



It should be noted that, caudal to the developing cerebellum (vide infra), the roof of the fourth ventricle remains epithelial, covering an approximately triangular zone from the lateral angles of the rhomboid fossa to the median obex (p. 980). Over this region nervous tissue fails to develop and vascular pia mater is closely applied to the subjacent ependyma. At each lateral angle and in the midline caudally the membranes break through forming the lateral and median apertures of the roof of the fourth ventricle. Subsequently, these are the principal routes by which cerebrospinal fluid, produced in the ventricles, escapes into the subarachnoid space. The vascular pia mater (tela choroidea), in an inverted V formation cranial to the apertures, invaginates the ependyma to form vascular fringes—the vertical and horizontal parts of the choroid plexuses of the fourth ventricle (p. 979).

2.66C The dorsal aspect of the hindbrain of a human fetus about 3 months old. Viewed from behind and partly from the right side. (From a model by His.)

THE CEREBELLUM

While these changes are occurring the cells in the *superior rhombic lip* and adjacent dorsal part of the dorsolateral lamina of the metencephalon proliferate to form the *rudiment of the cerebellum*. Two rounded swellings are formed which at first project partly into the ventricle (2.66B,C), and they form the rudimentary cerebellar hemispheres. The most cranial part of the roof of the metencephalon originally separates the two swellings, but it becomes invaded by cells, which form the rudiment of the vermis. These cells were regarded as derivatives of both ventrolateral and dorsolateral laminae (Baxter 1953). At a later stage, *extroversion of the cerebellum* occurs, with reduction of its *intraventricular* projection and an increasing dorsal *extraventricular prominence*. The cerebellum now consists of a bilobar (dumb-bell shaped) swelling stretched across the rostral part of the fourth ventricle (2.66A), continuous rostrally with the anterior medullary velum, formed from the isthmus, and caudally with the epithelial roof of the myelencephalon. With growth a number of transverse grooves appear on the dorsal aspects of the cerebellar rudiment, as the precursors of the numerous fissures which characterize the surface of the mature cerebellum (2.66B, also p. 962).

The *posterolateral fissure*, in its lateral parts, appears first, demarcating the then most caudal area from the rest of the cerebellar rudiment, enabling the *flocculi* to be identified. The lateral parts of this fissure extend medially, meet in the median plane and demarcate the nodule. The *flocculonodular lobes* can now be recognized and are the most caudal part of the cerebellum at this stage but, owing to the growth of the adjoining areas, they progressively come to occupy the *anterior part* of the *inferior surface* in the adult. They are formed in close proximity to the line of attachment of the epithelial roof, i.e. to the rhombic lip (p. 963 and 2.66C).

At the end of the third month a transverse sulcus appears on the rostral slope of the cerebellar rudiment and deepens to form the *fissura prima*, which cuts into the vermis and both hemispheres, separating the most cranial region to form the anterior lobe.

About the same period two short transverse grooves appear on the inferior vermis; the first is the *fissura secunda*, which demarcates the uvula, and the second the *prepyramidal fissure*, demarcating the pyramid (2.66B). The whole cerebellum now grows dorsally and the caudoinferior aspects of the *hemispheres* expand much more than the inferior vermis, which therefore becomes buried at the bottom of a deep hollow—the *vallecula*. Meanwhile numerous additional fissures develop, which are approximately parallel to, and intervene between, the foregoing. They result in the relatively vast increase in surface area of the cerebellum which is occurring but their precise positions and systematic names have limited functional or morphological significance. The most extensive of these develops into the *horizontal fissure*.

In many mammals a part of the hemisphere immediately rostral to the posterolateral fissure becomes defined as an entity; in some it forms a very prominent part of the cerebellum, termed the *paraflocculus*, but the relationship is purely topographical and, in contrast to the flocculus, the paraflocculus receives afferent connections mainly, but not entirely, from the cerebral cortex. It is uncertain whether any homologue of the paraflocculus exists in the human cerebellum or whether, as has been proposed, it is represented by some small patches of grey matter which are frequently present on the inferior surface of the middle cerebellar peduncle (Larsell 1947).

The emergence of arrays of principal fissures ('fissuration') and folia ('foliation') has been studied experimentally, and with increasing refinement, morphometrically, by a number of workers. Pertinent results and bibliographies are given by Sievers et al (1981) and Allen et al (1981). It is apparent that *interactions* between developmental facets of many tissue components have an important bearing. These include changing spatio-temporal patterns of growth, migration and differentiation of the fibres constituting the central white core (p. 964), the Bergmann glioblasts, the neuroblasts of the external germinal layer, the pia/glial basal lamina and the pial fibroblasts. Selective experimental alteration of any of these elements alters or obliterates the folial pattern. (For these tissue components vide infra and pp. 968–972.)

Mammalian cerebellar histogenesis has been more completely described, both during normal ontogeny and after experimental intervention, than in any other part of the nervous system,

due in large measure to its precisely ordered geometry and highly distinctive cell types. The connectivity, synaptology and electrophysiology of the latter have also been intensively studied, and some knowledge of these aspects are a necessary prerequisite of any account of histogenesis. (For this consult pp. 968–972.) Particularly valuable in histogenetic investigations have been nuclear labelling with tritiated thymidine, the analysis of genetic variants and the changes following surgical deafferentation, exposure to biochemically active agents, X-irradiation and virus diseases. Most studies have been confined to mice and rats, and whilst it seems probable that *qualitatively* similar cell migrations and contacts occur, *quantitative* findings and ontogenetic *timings* cannot, of course, be extrapolated to the human cerebellum. Only the briefest introduction can be entertained in this volume, and the interested reader should enter the literature by consulting such key references as Miale & Sidman (1961), Fujita (1963), Fujita et al (1966), Kornguth et al (1966, 1968), Mugnaini (1970), Eccles (1970), Hámori (1972), Altman (1972a,b,c), Eccles (1973), Swarz (1976), Swarz & del Cerro (1975, 1977), Berry (1982); Berry et al (1980a,b,c,d).

The early cerebellar rudiment consists of a pseudostratified epithelium showing interkinetic migration (p. 178) which soon develops the three basic zones—ventricular, intermediate, and marginal—as elsewhere in the neural tube. Originating in the ventricular zone, *proliferation* of as yet *uncommitted germinal* (matrix) *cells* proceeds, however, in *two* quite distinct sites, which become increasingly separated as the rudiment expands and thickens. Germinal cells continue proliferating in the deep (subventricular) part of the intermediate zone forming what, for convenience, may be termed the *internal germinal layer*. Slightly later, spreading lateromedially from each side to meet centrally in a subpial position (i.e. the most superficial part of the marginal zone), similarly uncommitted germinal cells proliferate forming an *external germinal layer* (sometimes, less appropriately, called the external granular layer). Both germinal layers continue *proliferative mitoses*, giving clonal progeny, until they are several cells thick. This *proliferative phase* gradually diminishes with the onset of the *phase of neurogenesis*, and this, in its turn, overlaps and *merges* into a *phase of gliogenesis*. Following a precisely ordered time sequence, sets of *critical (quantal) mitoses* occur (p. 108), the progeny becoming *committed neuroblasts* which do not divide again. Each set is destined to become one of the specific neuronal varieties that characterize the deep cerebellar nuclei and cortex, and they *migrate* to their definitive positions, develop their neurites and synaptic contacts, and mature, again in finely patterned spatio-temporal *sequences*, the latter often exhibiting some degree of overlap (Altman & Bayer 1978, Berry et al 1980d). Similarly, as neurogenesis wanes, sets of quantal mitoses of some remaining germinal cells continue to give generations of *committed glioblasts* which, although less well documented than the neuroblasts, also migrate to and mature in their definitive positions. (The specialized, radially disposed *Bergmann glioblasts*, however, are amongst the *first* cells to be committed in the early neuroepithelium and may provide contact guidance morphogenetic paths for some varieties of neuroblast.) The fate of each germinal layer will now briefly be reviewed.

Quantal mitoses of the uncommitted cells of the *internal germinal layer* first result in the emergence of two types, followed somewhat later by a third type, of definitive neuroblasts. Initially, *primitive Purkinje neuroblasts* and *primitive nuclear neuroblasts* emerge in approximately equal numbers, but whether this follows a series of symmetrical or asymmetrical mitoses (p. 108) is unknown. The *nuclear neuroblasts* remain embedded in the developing future white matter adjacent to the roof of the rostral part of the fourth ventricle. The main mass of nuclear neuroblasts then slowly subdivides into the primordial fastigial, emboliform, globose and dentate deep cerebellar nuclei, and the individual neuroblasts differentiate into either small intranuclear interneurons or the larger projection neurons. The axons of the latter invade the early cerebellar peduncles and pursue complex paths to their multiple destinations. The *Purkinje neuroblasts*, in contrast, *migrate* superficially towards their definitive position in the expanding cortex, where they slowly mature into their highly characteristic form of somata and dendritic trees. As they migrate, the terminals of one neurite—the future axon—remain adjacent to, and ultimately in synaptic contact with, the nuclear neuroblasts, the remainder of the axon elongating as it 'trails' behind the advancing soma. The mature and developing Purkinje cell has been a favourite object for *quantitative* cytological and ultrastructural studies, both during normal ontogeny and after such experimental manipulations as suppression of granule cell (and therefore parallel fibre) development, or after prevention of climbing fibre growth (see e.g. Hámori 1972 and p. 971). Excellent illustrative examples of the maturation of normal rat cerebellar cortex are to be found in the writings of Altman (1972b), and after experimental manipulation, (Berry et al 1978, 1980a,b,c,d, Rakic 1981, 1982). When the formation of nuclear and Purkinje neuroblasts has proceeded for some time, a number of the remaining internal germinal cells give rise to generations of *Golgi neuroblasts* which also migrate superficially to gradually occupy, and mature in, their definitive position and morphology.

The first set of quantal mitoses in the *external germinal layer* gives generations of *basket neuroblasts* which migrate deeply to meet, and ultimately synapse with, the somata and preaxons of the ascending Purkinje neuroblasts, their axons passing transversely in the primordial cerebellar folia. Secondly, following intense and more prolonged proliferation of the external germinal cells, a second set of quantal mitoses results in vast numbers of *granule cell neuroblasts*. A widely held view is that these microneurons are at first bipolar, each presumptive axon growing in opposite directions along the long axis of the folium: bundles of such axons form the parallel fibres of the mature cortex (p. 971), and the more recently formed granule cell neuroblasts (with their parallel fibre axons) are placed in successive layers approaching the pial surface. The soma of the granule cell does not, however, remain bipolar and external to the Purkinje neuroblast layer. A neurite develops and grows deeply *through* the Purkinje layer, its tip ultimately dividing, meeting, and synapsing with the ingrowing mossy afferent terminals (p. 971), thus forming the primordial cerebellar glomeruli. As this centripetal neurite develops, the granule cell nucleus migrates along it to reach, and helps to form, the definitive granular layer of somata of the mature cortex. Rakic (1971a,b), however, reached a different conclusion from studies of migrating granule cell neuroblasts in the Rhesus monkey, holding that they migrated deeply by contact guidance along the surface of the long radial processes of the Bergmann glial cells (Mugnaini & Forstrønen 1967). He considered that the migrating soma 'trailed' behind it an elongating neurite which subsequently bifurcated to form the parallel fibre axons, whilst dividing neurites passing in advance of the soma met the mossy afferents to form cerebellar glomeruli.

The final generations of neuroblasts from the external germinal layer, relatively sparse and brief, occur whilst granule cell production is at its height; their progeny merely migrate locally and differentiate into outer stellate cells.

The origin of the cerebellar glial cells remains much more problematical and has been the subject of dispute for over a century. The view advanced by Obersteiner (1883) and Schaper (1897) was that the various macroglial cell varieties (Bergmann cells, astrocytes and oligodendrocytes) stemmed from final generations of germinal cells of *both* the internal and external germinal layers; this has received the more recent experimental support of such authorities as Fujita et al (1966), Fujita (1967), Meller et al (1969), Privat (1975). The second view proposed by Athias (1897), Ramón y Cajal (1911) held that the macroglia were formed exclusively from the internal germinal layer, and that the progeny of the external layer were solely the three varieties of neuroblast: this suggestion has been supported by the labelling studies of Swarz & del Cerro (1977). Clearly such diametrically opposed views must await further critical evaluation using alternative methods, sites and species. Further neither view embraces Rakic's analysis of the early emergence and possible roles of the pioneer mosaic of Bergmann glioblasts. All authorities seem agreed that the microglial elements are exogenous, invading the cerebellar rudiment from the surrounding mesenchyme.

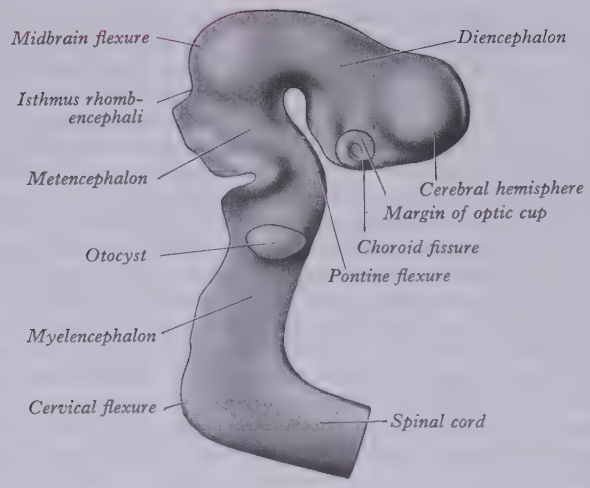
The remainder of the metencephalon becomes the pons, but

little is known of the individual stages in the transformation. Ventricular, intermediate and marginal zones are formed in the usual way, and the nuclei of the trigeminal, abducent and facial nerves develop in the mantle layer. It is possible that the grey matter of the formatio reticularis is derived from the ventrolateral lamina and that of the nuclei pontis from the dorsolateral lamina by the active migration of cells from the rhombic lip. However, about the fourth month the pons is invaded by corticopontine, corticobulbar and corticospinal fibres, becomes proportionately thicker, and takes on its adult appearance.

The region of the *isthmus rhombencephali* undergoes a series of changes notoriously difficult to interpret. As a result, however, the greater part of the region apparently becomes absorbed into the caudal end of the midbrain, only the roof plate (dorsal lamina), in which the anterior medullary velum is formed, and the dorsal parts of the dorsolateral laminae, which become invaded by converging fibres of the superior cerebellar peduncles, remaining as recognizable derivatives in the adult. Note that originally the decussation of the trochlear nerves was *caudal* to the isthmus, but as the growth changes occur it is displaced in a cranial direction until it reaches its adult position. These changes are also responsible (1) for the rostral movement of the trochlear nucleus, whereby it comes to lie in the midbrain, and (2) for the position of the mesencephalic nucleus of the trigeminal nerve, also a derivative of the isthmus (Frazer 1928).

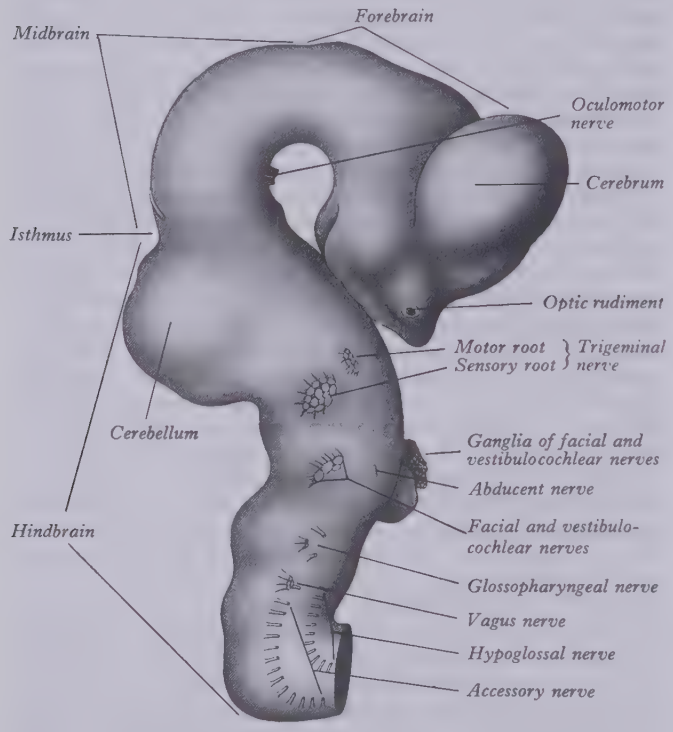
THE MESENCEPHALON

The mesencephalon or midbrain, derived from the intermediate primary cerebral vesicle, persists for a time as a thin-walled tube enclosing a cavity of some size, separated from that of the prosencephalon by a slight constriction and from the rhombencephalon by the isthmus rhombencephali. Later, its cavity becomes relatively reduced in diameter, and in the adult brain it forms the *cerebral aqueduct*. The ventrolateral laminae of the midbrain increase in thickness to form the *cerebral peduncles*, which are at first of small size, but enlarge rapidly after the fourth month, when their numerous fibre tracts begin to appear in the marginal zone (p. 917 et seq). The neuroblasts of the ventrolateral lamina give origin to the nuclei of the oculomotor nerve and some grey masses of the tegmentum, while the nucleus of the trochlear nerve, and also the mesencephalic nucleus of the trigeminal nerve, migrate rostrally into the midbrain owing to the developmental changes in the isthmus rhombencephali. It has been claimed (Chu-Wu & Wen-Kuei 1965) that some of the migrating neuroblasts of the mesencephalic nucleus reach the posterior commissure and its nucleus and also the interstitial nucleus. The cells of the dorsal part of the dorsolateral laminae proliferate and invade the roof plate, which therefore thickens and is later divided into corpora bigemina by a median groove. Caudally this groove becomes a median ridge, which persists in the adult as the frenulum veli. The corpora bigemina are later subdivided into the *superior* and *inferior colliculi* by a transverse furrow. The *red nucleus, substantia nigra* and *reticular nuclei* of the midbrain *tegmentum* may first be defined at the end of the third month. Their origins are probably mixed from neuroblasts of the ventrolateral and dorsolateral laminae.



The detailed histogenesis of the tectum, and its main derivatives, the colliculi, will not be followed here, but in general the principles outlined for the cerebellar cortex (p. 188) and the palaeopallium and neopallium (p. 195) also apply to this region. It may be noted, however, that there exists a high degree of geometric order in the developing retinotectal projection (p. 986), and also a precise somatotopy in tectospinal projection. These facts, coupled with the ability of the piscine and amphibian central nervous tracts to *regenerate* after severance, have led the retinotectal pathways to become classical sites for experimentation. A review of this field is beyond the scope of the present volume, but typical experiments included the electrophysiological and neuroanatomical mapping of the patterns of retinotectal connections that were established after, e.g. mere cutting of an optic nerve or, following nerve severance, the rotation of one or both eyes through 180°. Other experiments included bilateral optic nerve section together with median section of the optic chiasma; additionally the regeneration pattern was followed after deletion of different retinal sectors, or following various recombinations of half eye-cups. In general the results of such experiments led to the elaboration of a powerful theory of the *chemospecificity of neuroblasts*, the main proposition being that every neuroblast possessed a unique surface molecular configuration. It was further postulated that the growth pattern of a neurite followed a chemically coded path which led to a precise group of target cells bearing complementary surface configurations (see Sperry 1951a,b, 1958, 1963, 1965, 1971). While the *overall* results have received much subsequent experimental support, more detailed analyses of the re-established connectivity patterns, and in particular the *changing* patterns that occur with tectal growth (e.g. Chung et al 1972), and the modulation that occurs with altered environments, behaviour, experience and the phenomena of learning and memory, has cast doubt on the validity of a *rigid* theory of chemospecificity applying to *all* neuroblasts and neurons (e.g. see Szekely 1974, Hunt & Jacobson 1974, Mark 1974).

It may be pertinent to mention the interesting suggestion put forward by Jacobson (1969, 1970, 1974, 1978) that there are two principal classes of neuron (an elegant modern refinement of the old Golgi type I and type II varieties—see p. 976). Jacobson's *class I neurons* are phylogenetically ancient, develop early in ontogeny, possess prominent somata, long axons, specific target cells, and have invariant and unmodifiable connections and functions from their first establishment. It is presumed that their final form and activities are almost wholly encoded in the genome. In contrast, *class II neurons* are small, possessing a short (or no) axon (microneurons); they are phylogenetically recent and develop relatively late in ontogeny. They are considered to possess, initially, *multiple* functional potentialities that may persist for considerable intervals, and only become progressively restricted during subsequent fetal or post-natal growth, the microneuron *ultimately* becoming 'unipotential and unmodifiable'. It is also proposed that this restriction of functional potential occurs at varying times and rates in different locations in the developing nervous system. Such microneurons are, on this view, therefore regarded as one of the main structural bases of *plasticity* in nervous systems whereby structural/functional modifications result from environmental changes and the assessment of results of exploratory behaviour; they may thus be one of the sites where the elusive structural correlates of memory patterns should be sought (see essays by Young 1964, Gray 1974, Jacobson 1974).

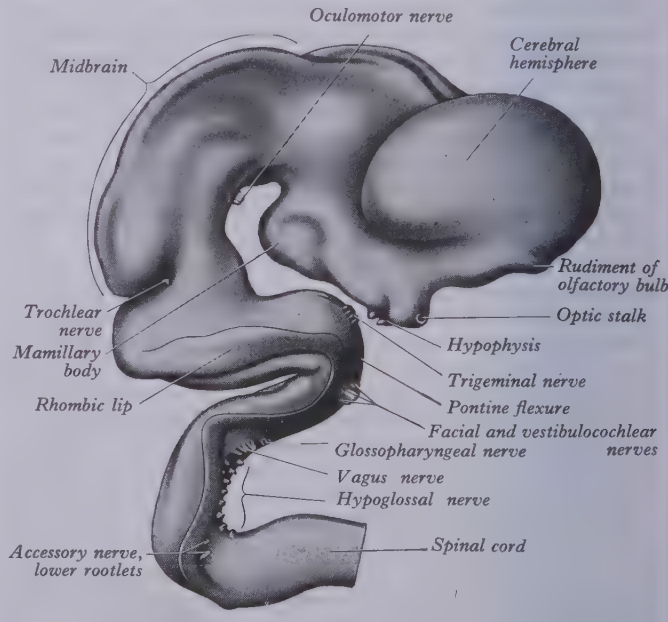


THE PROSENCEPHALON

At an early stage, a transverse section through the forebrain shows the same parts as are displayed in similar sections of the spinal cord and medulla oblongata—thick lateral walls connected by thin floor and roof plates. Moreover, each lateral wall is divided into a dorsal area and a ventral area separated internally by the *hypothalamic sulcus*. This sulcus ends anteriorly at the medial end of the optic stalk (vide infra and p. 202); in the fully developed brain, it persists as a slight groove extending from the interventricular foramen to the cerebral aqueduct. It is analogous to, if not the homologue of, the sulcus limitans. The thin roof plate remains epithelial, but invaginated by vascular mesenchyme, the tela choroidea of the choroid plexuses of the third ventricle. Later, the lateral margins of the tela undergo a similar invagination into the medial walls of the cerebral hemispheres (vide infra). The floor plate thickens, developing the nuclear masses of the hypothalamus and subthalamus.

At a very early period, before the closure of the rostral neuropore (p. 133), two lateral diverticula, the *optic vesicles*, appear, one on each side, about the level of the forebrain; for a time they communicate with its cavity by relatively wide openings. The distal parts of the optic vesicles expand, while the proximal parts become the tubular *optic stalks*. (Their further development is given on pp. 201–204.) The forebrain next grows, its tip curving ventrally, and two further diverticula rapidly expand from it, one on each side. These diverticula are rostrolateral to the optic stalks and subsequently form the *cerebral hemispheres*; their cavities are the rudiments of the lateral ventricles; they

2.67A The right side of the brain of a human embryo, 9 mm long. (Drawn from a model by His.)



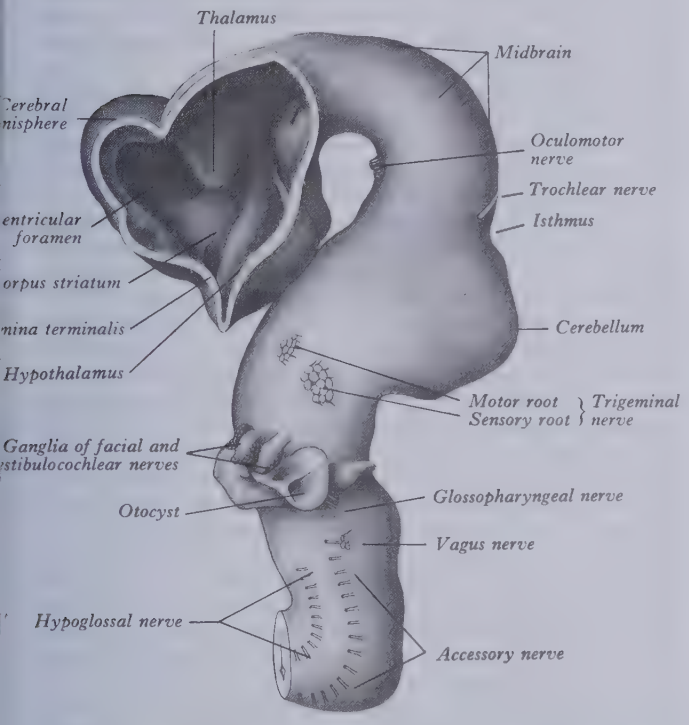
2.67B The brain of a human embryo about 10.2 mm long. Right lateral surface. (From a model by His.)

communicate with the median part of the forebrain cavity by relatively wide openings which ultimately become the interventricular foramina. The anterior limit of the median part of the forebrain consists of a thin sheet, the *lamina terminalis* (2.68A, B, C), which stretches from the interventricular foramina to the recess at the base of the optic stalks. The anterior part of the forebrain, including the rudiments of the cerebral hemispheres, is the *telencephalon (end-brain)*, and the posterior part the *diencephalon (between-brain)*; both contribute to the formation of the third ventricle, although the latter predominates. The fate of the lamina terminalis is detailed below.

The diencephalon is broadly divided by the hypothalamic sulcus into the *pars dorsalis diencephali* and *pars ventralis diencephali*; these, however, are composite, each contributing to diverse neural structures. The *pars dorsalis* develops into the (dorsal) thalamus and metathalamus along the immediate suprasulcal area of its lateral wall, whilst the highest dorsocaudal lateral wall and roof form the epithalamus. The *thalamus* (2.68A–C) begins as a thickening which involves the anterior part of the dorsal area (Cooper 1950). Caudal to the thalamus the lateral and medial geniculate bodies, or *metathalamus*, are recognizable at first as surface depressions on the internal aspect and as elevations on the external aspect of the lateral wall (Cooper 1945). As the thalami enlarge as smooth ovoid masses, they gradually narrow the wide interval between them into a vertically compressed cavity which forms the greater part of the third ventricle. After a time these medial surfaces may come into contact and become adherent over a variable area, the connection (single or multiple) constituting the *interthalamic adhesion*. The caudal growth of the thalamus excludes the geniculate bodies from the lateral wall of the third ventricle.

At first the lateral aspect of the developing thalamus is separated from the medial aspect of the cerebral hemisphere by a cleft, but with growth the cleft becomes obliterated (2.69) as the thalamus fuses with the part of the hemisphere in which the corpus striatum is developing. Later, with the development of the projection fibres (corticofugal and corticopetal) of the neocortex (p. 194), the thalamus becomes related to the internal capsule, which intervenes between it and the lateral part of the corpus striatum (lentiform nucleus). Ventral to the hypothalamic sulcus the lateral wall of the diencephalon, in addition to median derivatives of its floor plate, forms a large part of the hypothalamus and subthalamus.

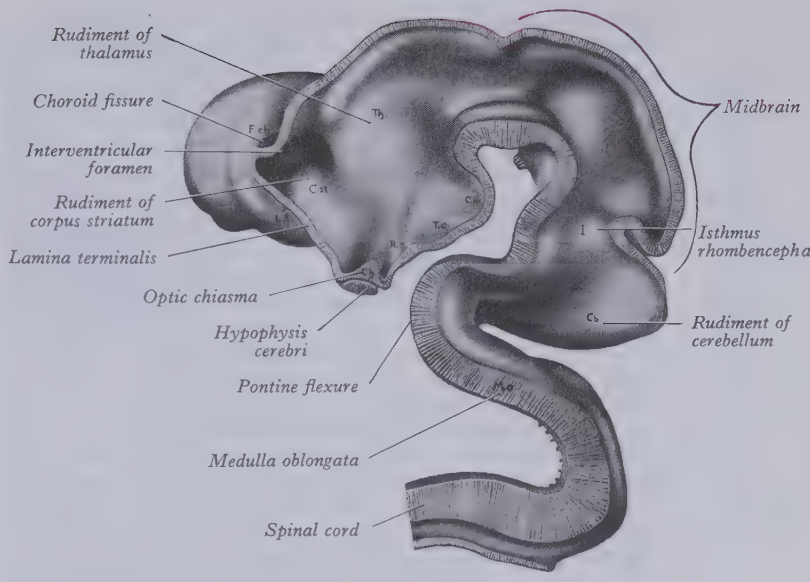
The *epithalamus*, which includes the pineal gland, the posterior and habenular commissures and the trigonum habenulae, develops in association with the caudal part of the roof plate and the adjoining regions of the lateral walls of the diencephalon. At an early period (12–20 mm CR length) the epithalamus in the lateral wall projects into the third ventricle as a smooth ellipsoid mass, larger than the adjacent mass of the (dorsal) thalamus and separated from it by a well defined *epithalamic sulcus*. In subsequent months growth of the thalamus rapidly overtakes that of the epithalamus; the intervening sulcus is obliterated. Thus, finally, structures of epithalamic origin are topographically relatively diminutive; in recent years, however, there has occurred a burgeoning of interest in, and understanding of their functional roles (p. 1457). The *pineal gland* arises as a hollow outgrowth from the roof plate, immediately adjoining the mesencephalon. Its distal part becomes solid by cellular proliferation, but its proximal stalk remains hollow, containing the pineal recess of the third ventricle. In many reptiles the pineal outgrowth is double. The anterior outgrowth (*parapineal organ*) develops into the pineal or parietal eye (p. 1456) while the posterior outgrowth is glandular in character. It is the *posterior*



2.67C The right side of the brain of a human embryo, 13.6 mm long. The roof of the hindbrain has been removed. Compare with 2.68B. (From a model by His.)

outgrowth which is homologous with the pineal gland in man. The anterior outgrowth also develops in the human embryo but soon disappears entirely.

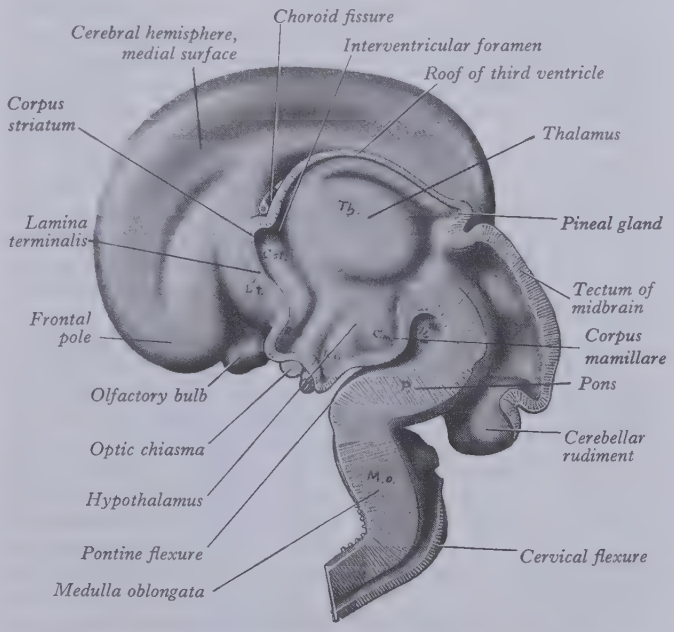
The *posterior commissure* is formed by fibres which invade the caudal wall of the pineal recess from both sides.



The *nucleus habenulae*, which is the most important constituent of the *trigonum habenulae*, is developed in the lateral wall of the diencephalon and is at first in close relationship with the geniculate bodies, from which it becomes separated by the dorsal growth of the thalamus. The *habenular commissure* develops in the cranial wall of the pineal recess.

It is the roof plate of the diencephalon, rostral to the pineal gland (and continuing over the median telencephalon), that remains thin and epithelial in character and is subsequently invaginated by the choroid plexuses of the third ventricle. Before the development of the corpus callosum and the fornix it lies at the bottom of the longitudinal fissure, between and reaching the two cerebral hemispheres, extending as far rostrally as the interventricular foramina and lamina terminalis. Here, and elsewhere, choroid plexuses develop by the close apposition of vascular pia

2.68A The brain of a human embryo, about 10.2 mm long. (From a model by His.)



mater and ependyma with no nervous tissue intervening. With development, the vascular layer is infolded into the ventricular cavity and develops a series of small villous (finger-like) projections, each covered by a cuboidal epithelium derived from the ependyma. The cuboidal cells carry numerous microvilli on their ventricular surfaces whilst basally their plasma membrane becomes complexly folded into the cell. The *early* choroid plexuses secrete a protein-rich cerebrospinal fluid into the ventricular system which may provide a nutritive medium for the primitive epithelial neural tissues. With increasing vascularity of the latter, however, the histochemical reactions of the cuboidal cells and the character of the fluid change to the adult type (Klosovskii 1963). It should also be noted that, in addition to choroid plexus formation, the remaining lining of the third ventricle does *not* simply form generalized ependymal cells. Many regions become highly specialized, developing concentrations of tanycytes or other modified cells, e.g. those of the *subfornical organ*, the *organum vasculosum (intercolumnar tubercle)* of the lamina terminalis, the *subcommissural organ* and those lining the *pineal, suprapineal*, and *infundibular recesses* (see Knigge et al 1975), collectively termed the *circumventricular organs*.

2.68B The brain of a human embryo, 13.6 mm long. Medial surface of right half. The roof of the hindbrain has been removed. (From a model by His.)

In addition to its subsulcal lateral walls, the floor of the pars ventralis diencephali takes part in the formation of the *hypothalamus*, including the mamillary bodies, the tuber cinereum and infundibulum of the hypophysis.

The *mamillary bodies* arise as a single thickening, which becomes divided by a median furrow during the third month. Anterior to them the *tuber cinereum* develops as a cellular proliferation which extends forwards as far as the infundibulum. In front of the tuber cinereum the floor of the diencephalon gives origin to a wide-mouthed diverticulum, which grows towards the stomatodeal roof and comes into contact with the posterior aspect of a dorsally directed ingrowth from the stomatodeum (Rathke's pouch, p. 229). These two diverticula together form the *hypophysis cerebri* (2.103). In the base of the neural outgrowth an extension of the third ventricle persists as the *infundibular recess*. The remaining caudolateral walls and floor of the ventral diencephalon are an extension of the midbrain tegmentum—the *subthalamus*. This forms the rostral limits of the red nucleus and

2.68C Medial surface of the right half of the brain of a human fetus, about 3 months old.

substantia nigra, numerous reticular nuclei and a wealth of interweaving nerve fibre bundles, ascending, descending and oblique, with many origins and destinations.

The optic vesicles, which are described with the development of the eye (p. 201), are derived from the lateral wall of the prosencephalon before the telencephalon can be identified. They are usually regarded as derivatives of the diencephalon and the optic chiasma is often regarded as the boundary between diencephalon and telencephalon.

The telencephalon (end-brain) consists of two lateral diverticula connected by a median region (the *telencephalon impar*). From the impar develops the anterior part of the cavity of the third ventricle, closed below and in front by the *lamina terminalis*. The lateral diverticula are outpouchings of the lateral walls of the telencephalon, which may correspond to the alar laminae, although this is uncertain; the cavities are the future lateral ventricles, and their walls the primordial nervous tissue of the *cerebral hemispheres*. The roof plate of the median part of the telencephalon remains thin and is, as noted, continuous behind with the roof plate of the diencephalon. In the floor plate and lateral walls of the prosencephalon, *ventral* to the primitive interventricular foramina, the *anterior* parts of the *hypothalamus* are developed; these include the optic chiasma, optic recess and related nuclei. The chiasma is formed by the meeting and partial decussation of the optic nerves in the ventral part of the lamina terminalis, and from it the optic tracts subsequently grow backwards to end in the diencephalon and midbrain.

The cerebral hemispheres arise as diverticula of the lateral walls of the telencephalon, with which they remain in continuity around the margins of the initially relatively large interventricular foramina, except caudally, where they are continuous with the anterior part of the lateral wall of the diencephalon (**2**.68A, B); as growth proceeds the hemisphere enlarges forwards, upwards and backwards and acquires an oval outline, with medial and superolateral walls and a floor. As a result the medial surfaces approach, but are separated from each other by a vascularized mesenchyme and pia mater that fills the median *longitudinal fissure*. At this stage the floor of the fissure is the epithelial roof plate of the telencephalon, which is directly continuous caudally with the epithelial roof plate of the diencephalon (**2**.68C), as already stated above.

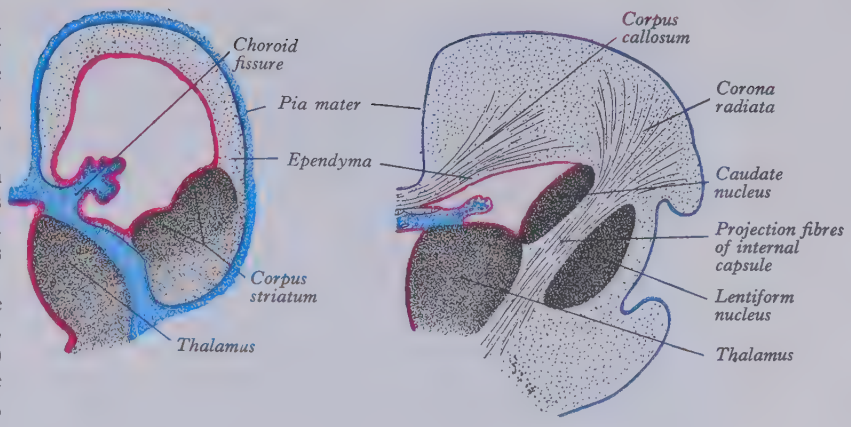
At the early oval stage of hemispheric development, regional names are given in accordance with their future principal derivatives. The rostromedial and ventral *floor* becomes linked with the forming olfactory apparatus and may be termed the primitive *olfactory lobe* (*see* below and pp. 1029, 1033, 1175). The floor (ventral wall, or base) of the larger remainder of the hemisphere forms the anlage of the primitive corpus striatum and amygdaloid complex: hence this, including its associated rim of lateral and medial walls is the *striate part of the hemisphere*. The rest of the hemisphere, the largest in surface area but initially possessing rather thin walls, medial, lateral, dorsal and caudal, is thus the *suprastriate part of the hemisphere*. The whole of the latter (except the interventricular foramen and its extension, the choroidal fissure) together with the superficial (subpial) zone of the striate part are the areas where histogenesis of named apparent variants of cerebral cortex (or pallium) occur. Further details, and comments on their plethora of terminologies and (often unsatisfactory) classifications, are furnished below and on p. 1021. (See comments on neocortical *uniformity* p. 1039).

The rostral end of the oval hemisphere becomes the definitive *frontal pole* but, as the hemisphere expands, its *original* posterior pole moves relatively in a caudoventral and lateral direction, curving thence towards the orbit in association with the growth of the caudate nucleus and numerous other structures to form the definitive *temporal pole*, and a *new* posterior part becomes evident which persists as the definitive *occipital pole* of the mature brain. The great expansion of the cerebral hemispheres is characteristic of mammals and especially of man, and in their subsequent growth they overlap, successively, the diencephalon and the mesencephalon and then meet the rostral surface the cerebellum; the temporal lobes embrace the flanks of the brainstem.

The early diverticulum or anlage of the cerebral hemisphere contains initially a simple spheroidal *lateral ventricle* which is continuous with the third ventricle via the interventricular foramen; the rim of the latter being, of course, the site of the original evagination. With expansion and the assumption of an oval outline by the hemisphere, the ventricle becomes firstly roughly ellipsoid and then a curved cylinder, convex dorsally. The ends of the cylinder expand towards (but do not reach) the frontal and (temporary) occipital poles—differentiating and thickening neural tissues separate the ventricular cavities and pial surfaces at all points, except along the line of the choroidal fissure (vide infra). Pronounced changes in ventricular form accompany the emergence of a temporal pole; the original caudal end of the curved cylinder expands within its substance. This temporal extension passes ventrolaterally to encircle its side of the upper brainstem (cf. choroidal fissure below). Finally, from the root of the temporal extension another may develop in the substance of the definitive occipital pole, passing caudomedially; this is quite variable in size, often asymmetrical on the two sides; one or both may be absent. Although a continuous system of cavities, specific parts of the lateral ventricle are now given regional names: the *central part (body)* extends from the interventricular foramen to the level of the posterior edge (splenium) of the corpus callosum. From the body three *cornua (horns)* diverge—*anterior* towards the frontal pole, *posterior* towards the occipital pole and *inferior* towards the temporal pole.

It may be noted that at these early stages of hemispheric development the term pole is preferred, in most instances, to lobe; the latter are defined by specific surface topographical features which will appear over several months, and differential growth patterns persist for a considerable period.

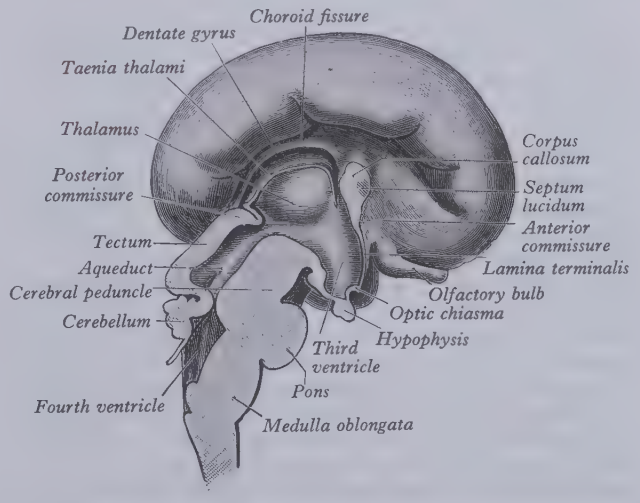
About the fifth week a longitudinal groove appears in the anteromedial part of the floor of each ventricle. This groove deepens and forms a hollow diverticulum continuous with the hemisphere by a short stalk. The diverticulum becomes connected on its ventral or inferior surface to the olfactory placode, the cells of which give rise to the afferent axons of its sensory cells. These terminate in the walls of the diverticulum. As the head increases in size the diverticulum grows forwards and, subsequently losing its cavity, becomes converted into the solid *olfactory bulb*. The forward growth of the bulb is accompanied by elongation of its stalk, which forms the *olfactory tract*, and the part of the floor of the hemisphere to which the tract is attached constitutes the *piriform area* (vide infra). For comments on the accessory olfactory bulb see p. 1033.



The pia mater which covers the epithelial roof of the third ventricle at this stage is itself covered with loosely arranged mesenchyme. In the meshes of this tissue numerous blood vessels develop and, as we have seen, on each side of the median plane these vessels subsequently invaginate the roof of the *third ventricle* to form its *choroid plexuses*. The lower part of the medial wall of the cerebral hemisphere, which immediately adjoins the epithelial roof of the interventricular foramen and the anterior extremity of the diencephalon, also remains epithelial, consisting of ependyma and pia mater, while elsewhere the walls of the hemisphere are thickening to form the *pallium*. The thin part of the medial wall of the hemisphere is invaginated by vascular tissue, continuous in front with the choroid plexus of the third ventricle and constituting the *choroid plexus* of the *lateral ventricle*. This invagination occurs along a line which arches upwards and backwards, parallel with and initially limited to the anterior and upper boundaries of the interventricular foramen; the curved indentation of the ventricular wall, where no nervous tissue develops between ependyma and pia mater, is termed the *choroid fissure* (**2**.68C,69A,B). The subsequent assumption of the complex, but exquisite, definitive form of the choroidal fissure naturally depends on related growth patterns in neighbouring structures: some are particularly relevant. These are the relatively slow growth of the interventricular foramen, the secondary 'fusion' between the lateral diencephalon and medial hemisphere walls, the encompassing of the upper brain stem by the forward growth of the temporal lobe and its pole towards the apex of the orbit and the massive expansion of two great commissures of the cerebrum—the fornix and corpus callosum. (Many of these features are detailed further below and in the Neurology section.) Nevertheless, the choroidal fissure is now clearly a caudal

extension of the (much reduced) interventricular foramen, which arches above the thalamus and in this region is only a few millimetres from the median plane. Near the caudal end of the thalamus it diverges ventrolaterally, its curve reaching and continuing in the medial wall of the temporal lobe over much of its length (i.e. to the tip of the inferior horn of the lateral ventricle). The upper part of the arch is overhung by the corpus callosum and, throughout its convexity is bordered by the fornix and its derivatives (vide infra and p. 1039). Thus, the extensive and helicoid disposition of the choroid plexus of the lateral ventricle is explained.

At first growth proceeds more actively in the floor and the adjoining part of the lateral wall of the developing hemisphere, and elevations formed by the rudimentary *corpus striatum* (2.68A) encroach on the cavity of the lateral ventricle (Cooper 1946). The head of the *caudate nucleus* appears as three successive parts, medial, lateral and intermediate, which produce elevations in the floor of the lateral ventricle. Caudally these merge to form the *tail* of the *caudate nucleus* and the *amygdaloid complex*. From the outset the latter are close to the temporal pole of the hemisphere and, when the occipital pole grows backwards and the general enlargement of the hemisphere carries the temporal pole downwards and forwards, the tail is continued from the *floor* of the central part (*body*) of the ventricle curving into the *roof* of its temporal extension, the future *inferior horn*, and the amygdaloid complex encapsulates its tip. Anteriorly the *head* of the *caudate nucleus* extends forwards to the floor of the interventricular foramen, where it is separated from the developing anterior end of the thalamus by a groove (2.68B); later, the head expands in the floor of the anterior horn of the lateral ventricle. The *lentiform nucleus* is developed from two laminae of cells, medial and lateral, which are continuous with both the medial and lateral parts of the caudate nucleus. The internal capsule appears first in the medial lamina and extends laterally through the outer lamina to the cortex. It divides the laminae into two, the internal parts joining the caudate nucleus and the external parts forming the lentiform nucleus. In the latter, which consists of two main parts, the remaining medial lamina cells give rise predominantly to the (medially placed) globus pallidus and the lateral to the (laterally placed) putamen. Subsequently the putamen expands concurrently with the intermediate part of the caudate nucleus (Hewitt 1958, 1961).



As the hemisphere enlarges, the caudal part of its medial surface overlaps and hides the lateral surface of the diencephalon (thalamic part), being separated from it by a narrow cleft occupied by vascular connective tissue. At this stage (about the end of the second month) a transverse section made caudal to the interventricular foramen passes from the third ventricular cavity successively through (1) the developing thalamus, (2) the narrow cleft just mentioned, (3) the thin medial wall of the hemisphere and (4) the cavity of the lateral ventricle, with the corpus striatum in its floor and lateral wall (2.69A). As the thalamus increases in extent it acquires a superior in addition to medial and lateral surfaces, and the lateral part of its superior surface fuses with the thin medial wall of the hemisphere so that, finally, this part of the thalamus is covered with the ependyma of the lateral ventricle immediately ventral to the choroid fissure (2.69B). As a result the corpus striatum is approximated to the thalamus and separated from it only by a deep groove which becomes obliterated by increased growth along the line of contact. The lateral aspect of the thalamus is now in continuity with the medial aspect of the corpus striatum so that a secondary union between the diencephalon and the telencephalon is effected over a wide area, providing a route for the subsequent passage of projection fibres to and from the cortex.

Throughout the brain stem, as in the spinal cord, the *migration* and differentiation of neuroblasts to form nuclei is either minimal or limited, their progeny remaining immediately extraependymal or, partially displaced towards the pial exterior, being arrested deeply embedded in the myelinated fibre 'white matter' of the region. As noted, however, the 'roofbrain' of part of the fore-, mid- and hindbrains develops following an additional, fundamental pattern which results in a superficial layer of *grey matter*. The latter consists of neuronal somata, dendrites, the terminations of incoming (afferent) axons, the stems of (or the whole of)

2.69 Diagrams illustrating transverse sections across the developing thalamus and cerebral hemisphere. Note that at the choroid fissure the vascular pia mater (blue) meets the ependyma (red) to form a choroid plexus. In A the lateral aspect of the thalamus is separated from the medial aspect of the hemisphere by an interval containing vascular mesenchyme. In B this interval has disappeared; the expanded upper surface of the thalamus is covered by the ependyma of the lateral ventricle, and the approximation of the thalamus and the corpus striatum has provided a pathway for the projection fibres of the internal capsule.

efferent axons, geometrically and functionally apposite glial cells and vasculature. Subsequent differentiation results in a highly organized subpial surface coat of grey matter termed the *cortex* (Latin–bark, e.g. of a tree) or *pallium* (Latin–pall, mantle or cloak). Pallium is used preferentially by neuroembryologists and some comparative zoologists; however, cortex is employed much more widely and (on occasion with its alternative in parenthesis) will be used here. It will be apparent that neither term is used (perhaps unfortunately) in the case of the mesencephalic tectum. In contrast cerebellar cortical transformations result in a virtually uniform neurohistogenesis, localized differences depending almost exclusively on its sources of 'input' and destinations of 'output' (pp. 967–968). In the cerebral hemisphere the superficial subpial regions of its wall, both striate and suprastriate (other than central areas of its medial wall, where secondary fusion with the diencephalon occurs and is encompassed by the lamina terminalis, interventricular foramen and curve of the choroid fissure), becomes invaded by migrating neuroblasts to form an elementary cerebral cortex. The cortical or pallial area which *borders* the lamina terminalis, the interventricular foramen, the convexity of the choroid fissure and continues into the diverging roots of the olfactory tract has been simply termed the *limbic lobe* (or bordering lobe), together with its numerous subdivisions and connections (p. 1028 et seq), the *limbic system*. Its cortical

2.70 The brain of a human fetus, 4 months old. Medial aspect of left half.

derivatives possessing, some regard, a relatively elementary structure, have been grouped as the *allocortex* (other cortex).

It is the first part of the cortex to initiate differentiation (vide infra) and at first it forms a continuous, almost circular strip on the medial and inferior aspects of the hemisphere. Below and in front, where the stalk of the olfactory tract is attached, it constitutes a part of the *piriform area (palaeocortex* or *palaeopallium*). The portion outside the curve of the choroid fissure (2.70) constitutes the *hippocampal formation* (*archaeocortex* or *archaeopallium*). In this region the neuroblasts of the developing cortex proliferate and migrate (vide infra), and the wall of the hemisphere thickens and produces an elevation which projects into the medial side of the ventricle. This elevation is the *hippocampus* (Humphrey 1964, 1967). It appears first on the medial wall of the hemisphere in the area above and in front of the lamina terminalis (*paraterminal area*) and gradually extends backwards, curving into the region of the temporal pole where it adjoins the piriform area. The marginal zone in the neighbourhood of the hippocampus is invaded by neuroblasts forming the *dentate gyrus*. Both extend from the paraterminal area (see precommissural septum and prehippocampal rudiment, p. 1035) backwards above the choroid fissure and follow its curve downwards and forwards towards the temporal pole, where they continue into the piriform area. A shallow surface depression (which has been termed the *hippocampal sulcus*) grooves the medial surface of the hemisphere throughout the hippocampal formation.

The efferent fibres from the cells of the hippocampus collect along its medial edge and run forwards immediately above the choroid fissure. Anteriorly they turn ventrally and enter the lateral part of the lamina terminalis to gain the hypothalamus, where they end in and around the mamillary body and neighbouring nuclei. These efferent hippocampal fibres form the *fimbria hippocampi* and the *fornix*. For the sources of afferent fibres to the hippocampus, hippocampal commissures and multiple subdivisions of the fornix see pp. 1036–1039.

The terms archaeocortex and palaeocortex as the two principal divisions of the *allocortex* focus on the acceptance by earlier neuroanatomists concerning the phylogenetically ancient nature of these regions. The remainder of the hemispheric surface, particularly in mammalia, with a relatively vast expansion in primates, developed what was regarded as a six-layered and (in this respect) equal *isocortex*, the young cortex, *neocortex* or *neopallium*. Isocortex seemed less appropriate, as all subregions showed fine structural differences. Aspects of *numerical uniformity* have been demonstrated (p. 1043), however. Furthermore, all three varieties of cortex are present simultaneously in an initial form in extant reptilia. Their relationship to piscine or amphibian ancestry remains controversial.

The development of the commissures effects a very profound alteration on the medial wall of the hemisphere. At the time of their appearance the two hemispheres are connected to each other by the median part of the telencephalon. The roof plate of this area remains epithelial, whilst its floor becomes invaded by the decussating fibres of the optic nerves and developing hypothalamic nuclei. These two routes are thus not available for the passage of commissural fibres passing from hemisphere to hemisphere across the median plane, and these fibres therefore pass through the anterior wall of the interventricular foramen, i.e. the *lamina terminalis*. The first commissures to develop are those associated with the *palaeocortex* and *archaeocortex*. Fibres of the olfactory tracts cross in the ventral or lower part of the lamina terminalis and, together with fibres from the piriform and prepiriform areas and the amygdaloid bodies, form the *anterior part* of the *anterior commissure*. In addition the two hippocampi become interconnected by transverse fibres which cross from fornix to fornix in the upper part of the lamina terminalis as the *commissure of the fornix*. Various other decussating fibre bundles (known as the *supra-optic commissures*, although they are not true commissures) develop in the lamina terminalis immediately dorsal to the optic chiasma, between it and the anterior commissure.

The commissures of the neocortex develop later and follow the pathways already established by the commissures of the limbic system. Fibres from the tentorial surface of the hemisphere join the *anterior commissure* and constitute its larger *posterior part*. All the other commissural fibres of the neocortex associate themselves closely with the commissure of the fornix and lie on its dorsal surface. These fibres increase enormously in number and the bundle rapidly outgrows its neighbours to form the corpus callosum (2.70).

The *corpus callosum* commences in a thick mass connecting the two cerebral hemispheres around and above the anterior commissure. (This site was, for a period, called the precommissural area. However, this ontogenetic use has been rejected here because of increasing use of the adjective precommissural to denote the position of parts of the limbic lobe—prehippocampal rudiment, septal areas and nuclei, strands of the fornix in relation to the anterior commissure of the mature brain.) The upper end of this neocortical commissural area extends backwards to form the trunk of the corpus callosum. The *rostrum* of the corpus callosum develops later and separates some of the rostral end of the limbic area from the remainder of the cerebral hemisphere. Further backward growth of the trunk of the corpus callosum then results in the entrapped part of the limbic area becoming stretched out to form the bilateral septum pellucidum (Hewitt 1962). As the corpus callosum grows backwards it extends *above* the choroid fissure, carrying the commissure of the fornix on its under surface. In this way a new floor is formed for the longitudinal fissure, and additional structures come to lie above the epithelial roof of the third ventricle. In its backward growth the corpus callosum invades the area hitherto occupied by the *upper* part of the archaeocortical hippocampal formation, and the corresponding parts of the dentate gyrus (2.70) and hippocampus are reduced to vestiges—the *indusium griseum* and the *longitudinal striae*. However, the *posteroinferior* (temporal) archaeocortical regions of both dentate gyrus and hippocampus persist and *enlarge* because, with the forward growth of the temporal lobes, the brain stem presents a complete barrier to further extension of the corpus callosum in the median plane.

The growth of the *neocortex* and its enormous expansion are associated with the initial appearance of projection fibres (corticofugal and corticopetal) during the latter part of the third month. These fibres follow the pathway provided by the apposition of the lateral aspect of the thalamus with the medial aspect of the corpus striatum, and, as they do so, they (the *internal capsule*) divide the latter, almost completely, into a lateral part, the lentiform nucleus, and a medial part, the caudate nucleus, these two nuclei remaining confluent only in their antero-inferior regions. The corticospinal tracts begin to develop in the ninth week of fetal life and have reached their caudal limits by the twenty-ninth week. The fibres destined for the cervical and upper thoracic regions and implicated in the innervation of the upper limb are in advance of those concerned with the lower limbs, which in turn are in advance of those concerned with the face. The appearance of reflexes in these three parts of the body shows a comparable sequence (Humphrey 1960). For further analysis of the development of the projection fibres and corpus striatum see Hewitt (1961, 1962).

The preceding emphasis on corticospinal projection fibres is a reflexion of the limited information available to the earlier neuroanatomists. It should be emphasized, however, that the majority of subcortical nuclear masses receive terminals from descending fibres of cortical origin. Furthermore, the foregoing are joined by thalamocortical, hypothalamocortical and other afferent ascending bundles, the whole complex constituting the internal capsule that divides the early corpus striatum. It should also be noted that the internal capsular fibres pass *lateral* to the head and body of the caudate nucleus, the anterior cornu and central part of the lateral ventricle, the rostroventral extensions and body of the fornix, the dorsal thalamus and dorsal choroidal fissure; at similar levels they pass *medial* to the lentiform nucleus. With temporal lobe formation, the capsular fibres also lie *medial* to the inferior cornu of the lateral ventricle which has the amygdaloid complex capping its tip, the tail of the caudate nucleus in its roof, the hippocampus, dentate gyrus and fimbria of fornix in its floor, and temporal extension of the choroidal fissure in its medial wall.

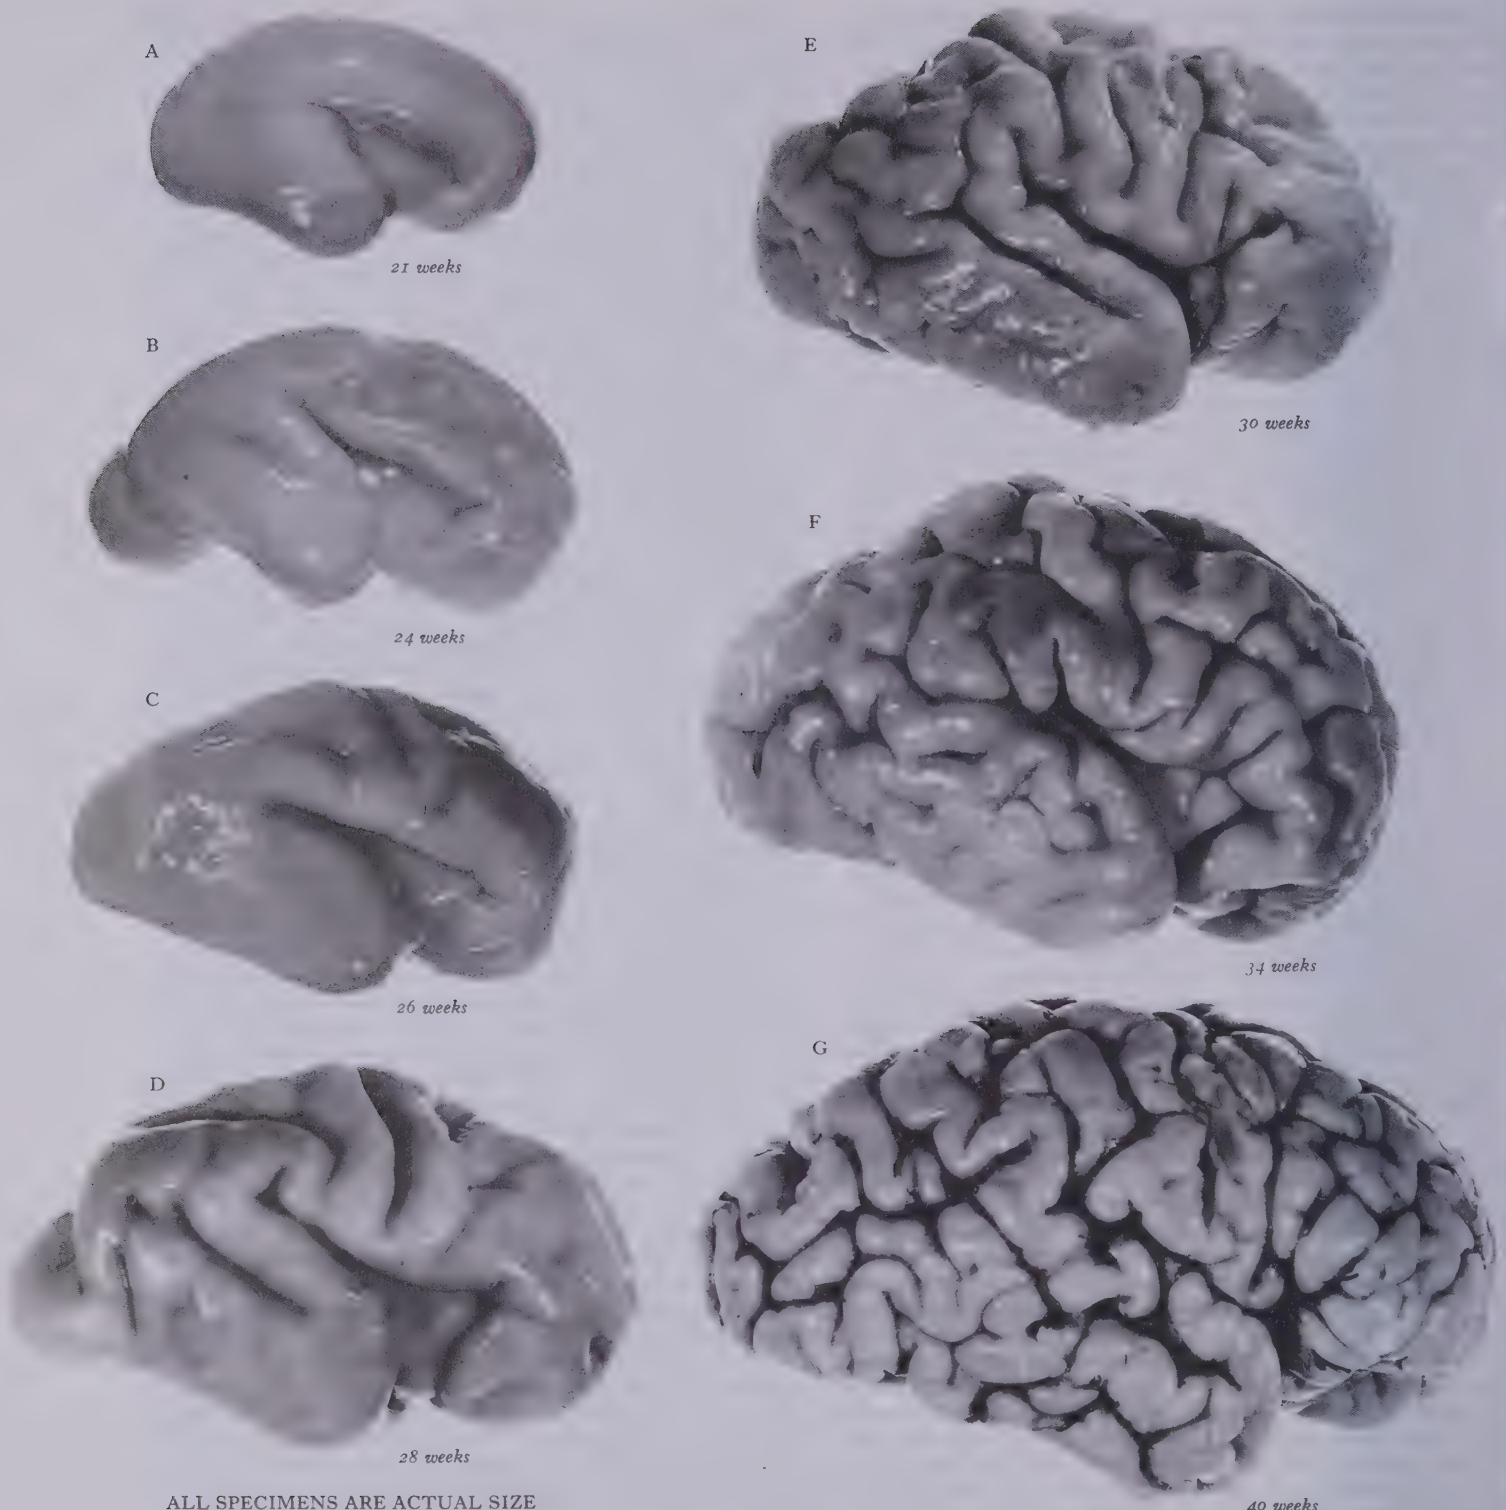
At the end of the third month the superolateral surface of the cerebral hemisphere shows a slight depression anterosuperior to the temporal pole. This corresponds to the site of the corpus

striatum in the floor and lateral wall of the ventricle, and its presence is due to the more rapid growth of the adjoining cortical regions. This *lateral cerebral fossa* gradually becomes overlapped and submerged, and is converted into the *lateral cerebral sulcus*; its floor becomes the *insula* (**2**.71A–G). The process, however, is not completed in its most anterior part until after birth. The presumptive neocortical areas that overlap the insula are termed the frontal, parietal and temporal *opercula*. The lentiform nucleus (lateral part of the corpus striatum) remains deep to and coextensive with the insula, the superficial zones of the latter transforming into varieties of cortex. Posteriorly the insula develops granular neocortex and an intermediate area forms agranular neocortex; finally the rostroventral area becomes similar to and continuous with the palaeocortex of the piriform area.

The growth changes in the temporal lobe which help to submerge the insula produce important changes in the olfactory and other neighbouring limbic areas. The olfactory tract, as it approaches the hemispheric floor, diverges into *lateral, medial* and (variable) *intermediate striae*. The medial stria is clothed with a thin archaeocortical *medial olfactory gyrus*; this curves up into further archaeocortical areas anterior to the lamina terminalis (paraterminal gyrus, prehippocampal rudiment, parolfactory gyrus, septal nuclei) and these continue into the indusium griseum. The lateral stria, clothed by the *lateral olfactory gyrus*, and, when present, the intermediate stria, terminate in the rostral parts of the *piriform area*. In brief, this includes the olfactory trigone and tubercle, anterior perforated substance and the uncus (hook) and entorhinal area of the anterior part of the future parahippocampal gyrus. Its lateral limit is indicated by the *rhinal sulcus*. (For details of the numerous subdivisions and putative interconnections of these areas, see p. 1029 et seq and 7.148–151.) The forward growth of the temporal pole and the general expansion of the neopallium cause the lateral olfactory gyrus to bend laterally, the summit of the convexity lying at the antero-inferior corner of the developing insula (**2**.71A–G). During the fourth and fifth months much of the *piriform area* becomes submerged by the adjoining neopallium and in the adult only a part of it remains visible on the inferior aspect of the cerebrum.

Apart from the shallow hippocampal sulcus and the lateral cerebral fossa the surfaces of the hemisphere remain smooth and uninterrupted until early in the fourth month (**2**.71A–G). The parieto-occipital sulcus also appears about that time on the *medial* aspect of the hemisphere and its appearance seems associated with the increase in the splenial fibres of the corpus callosum. Over the same period the posterior part of the *calcarine sulcus* appears as a shallow groove extending forwards from a region near the occipital pole. It is a true infolding of the cortex in the long axis of the *striate area*, producing an elevation, the *calcar avis*, on the medial wall of the posterior horn of the ventricle.

During the fifth month the *sulcus cinguli* appears on the medial aspect of the hemisphere, but not until the sixth month do sulci appear on the inferior and superolateral aspects. The *central, precentral* and *postcentral sulci* appear, each in two parts, upper and lower, which usually coalesce shortly afterwards although they may remain discontinuous. The *superior* and *inferior frontal*, the *intraparietal, occipital, superior* and *inferior temporal*, the *occipitotemporal, collateral* and *rhinal sulci* make their appearance during the same period, and by the end of the eighth month all the important sulci can be recognized (**2**.71A–G).



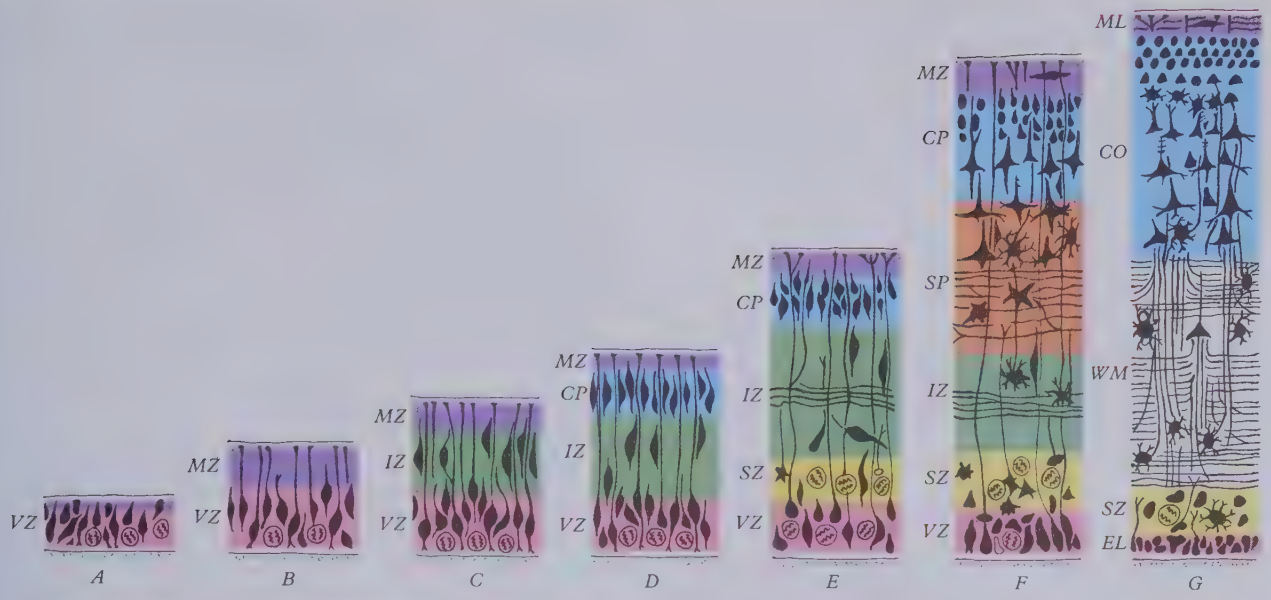
Histogenesis of the cortical (pallial) wall of the cerebral hemisphere has generated an impressive literature since the early 1930s. Nevertheless, because of the immense complexity, multiplicity of cell types and structural heterogeneity in different locations, descriptive and experimental analyses are less well understood and documented than those appertaining to the cerebellum, with its regular, geometrically ordered microstructure (p. 969). Only the briefest review of some basic principles, together with a few introductory key references, can be encompassed in this volume and the interested reader will find it apposite to constantly cross-refer to the sections devoted to mature neuronal and cortical architecture (pp. 1039–1043).

The wall of the earliest cerebral hemisphere, as elsewhere in the neural tube, consists of a pseudostratified epithelium, its cells exhibiting interkinetic migration (p. 178) as they proliferate to form clones of, it was assumed, as yet uncommitted germinal cells. The columnar cells elongate and (following the initial nomenclature proposed by the Boulder Committee, *Anat. Rec.*, 1970 and **2**.60) their non-nucleated peripheral processes now constitute a *marginal zone*, whilst their nucleated, paraluminal and mitosing regions constitute the *ventricular zone*. Some of the mitotic progeny now leave the ventricular zone and migrate to occupy an *intermediate zone*. This *proliferative phase* continues for a considerable period of fetal (and in some species post-natal) life, but, as in the case of the cerebellar cortex, after a period, groups of germinal cells undergo quantal mitoses forming, at first, generations of *definitive neuroblasts* and, later, *definitive glioblasts*, which migrate to and mature in their final positions (see below for variant views). It must be appreciated, however, that these phases of proliferation, migration, differentiation and maturation are not precisely sequential for each cell variety but overlap each other in space and time. (While the foregoing was widely accepted, and was apposite in the 36th edition of this volume, there has been a burgeoning of investigation and publication on these topics; both prominent literature sources and classifications will receive brief mention.)

The earliest migration of definitive neuroblasts from the ventricular and intermediate zones occurs radially until they approach, but do not reach, the pial surface, their somata becoming arranged as a transient *cortical plate*. Subsequently, proliferation wanes in the ventricular zone but for considerable periods persists in the immediately subjacent *subventricular zone*. From the pial surface inwards, therefore, there may now be defined the following zones: *marginal, cortical plate, subplate, intermediate, subventricular* and *ventricular*. Briefly, whilst the foregoing *terminology* is relatively recent it has for long been accepted that the *marginal zone* forms the outermost layer of the cerebral cortex, the neuroblasts of the *cortical plate* and *subplate* form the neurons of the remaining cortical laminae (the complexity, of course, varying in different locations and with further additions of neuroblasts from the deeper zones), whilst the intermediate zone gradually transforms into the white matter of the hemisphere. Meanwhile other deep germinal cells have been producing generations of glioblasts which also migrate into the more superficial layers. As proliferation wanes and finally ceases in the ventricular and subventricular zones their remaining cells differentiate into general or specialized ependymal cells, tanycytes or subependymal glial cells. Illustration **2**.72A–F summarizes the modifications of the Boulder Committee original proposals, suggested by Rakic (1982) in the light of more recent investigations.

As mentioned above, the phases of proliferation, neurogenesis and gliogenesis are by no means sequential as first envisaged but vary spatiotemporally with location and cell type. Further, the gliogenesis referred to was related to the (numerically largest) astrocyte and oligodendrocyte population of the mature tissue. However, as noted (p. 180), immunohistochemical studies of glial fibrillary acid protein (GFA) distribution showed a patterned array of GFA-positive columnar cells in the earliest pseudostratified neuroepithelium of the neural tube including the walls of the rudimentary cerebral hemisphere. The positive cellular elements are interspersed with GFA-negative columnar cells, both undergoing interkinetic migration or proliferation. The GFA-positive elements are presumptive glial cells which stretch radially across the full thickness of the wall of the telencephalon and provide contact guidance paths for the subsequent peripheral migration of groups of functionally related neuroblasts—the foundation of the cortical *columns* or *modules* of neurobiology. The first groups of neuroblasts to migrate are destined for the deep part of the column, later groups passing through them to more superficial regions (see below). The *subplate zone*, a transient feature most prominent during mid-gestation, contains neuroblasts surrounded by a dense neuropil: the neuroblasts appear to await the arrival of thalamocortical afferents before migrating to disperse in most cortical layers. The subplate neuropil is the site of the most intense *synaptogenesis* in the cortex.

Thus, with growth, both radial and tangential, there occurs a great increase in cortical thickness and a vast increase in surface area. Accordingly, the glial contact guidance paths, originally having a simple radial ventriculo-pial disposition, become



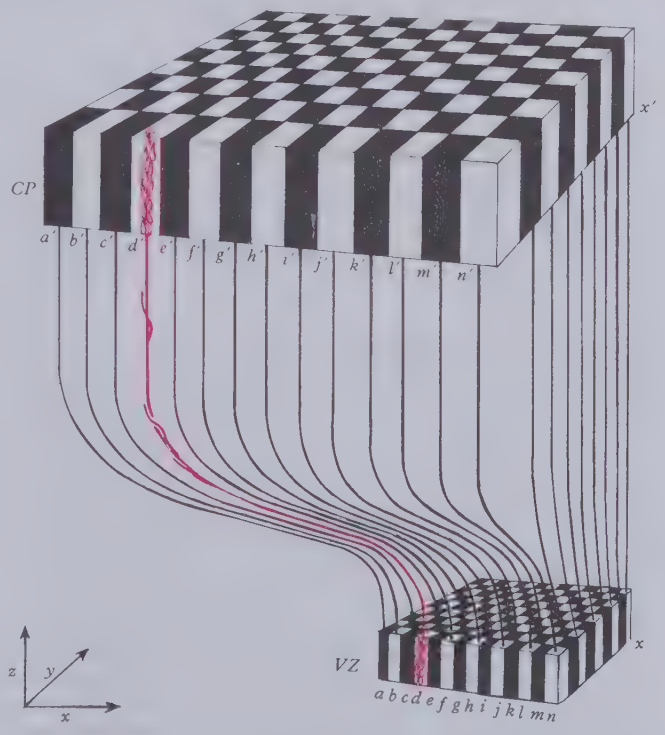
ALL SPECIMENS ARE ACTUAL SIZE

2.71 Series showing the superolateral surfaces of human fetal cerebral hemispheres at the ages indicated, demonstrating the changes in size, profile and the emerging pattern of cerebral sulci with increasing maturation. Note the changing prominence and relative positions of the frontal, occipital and particularly the temporal pole of the hemisphere. At the earliest stage (A) the lateral cerebral fossa is already obvious—its floor covers the developing corpus striatum in the depths of the hemisphere and progressively matures into the cortex of the insula. The fossa is bounded by overgrowing cortical regions, the frontal, temporal and parietal opercula, which gradually converge to bury the insula; their approximation forms the lateral cerebral sulcus. By the sixth month the central, pre- and post-central, superior temporal, intraparietal and parieto-occipital sulci are all clearly visible. In the subsequent stages shown all the remaining principal and subsidiary sulci rapidly appear and by 40 weeks all the features which characterize the adult hemisphere in terms of surface topography are already present in miniature.

The photographs were kindly supplied by Dr Sabina Strick of the Maudsley Hospital, London.

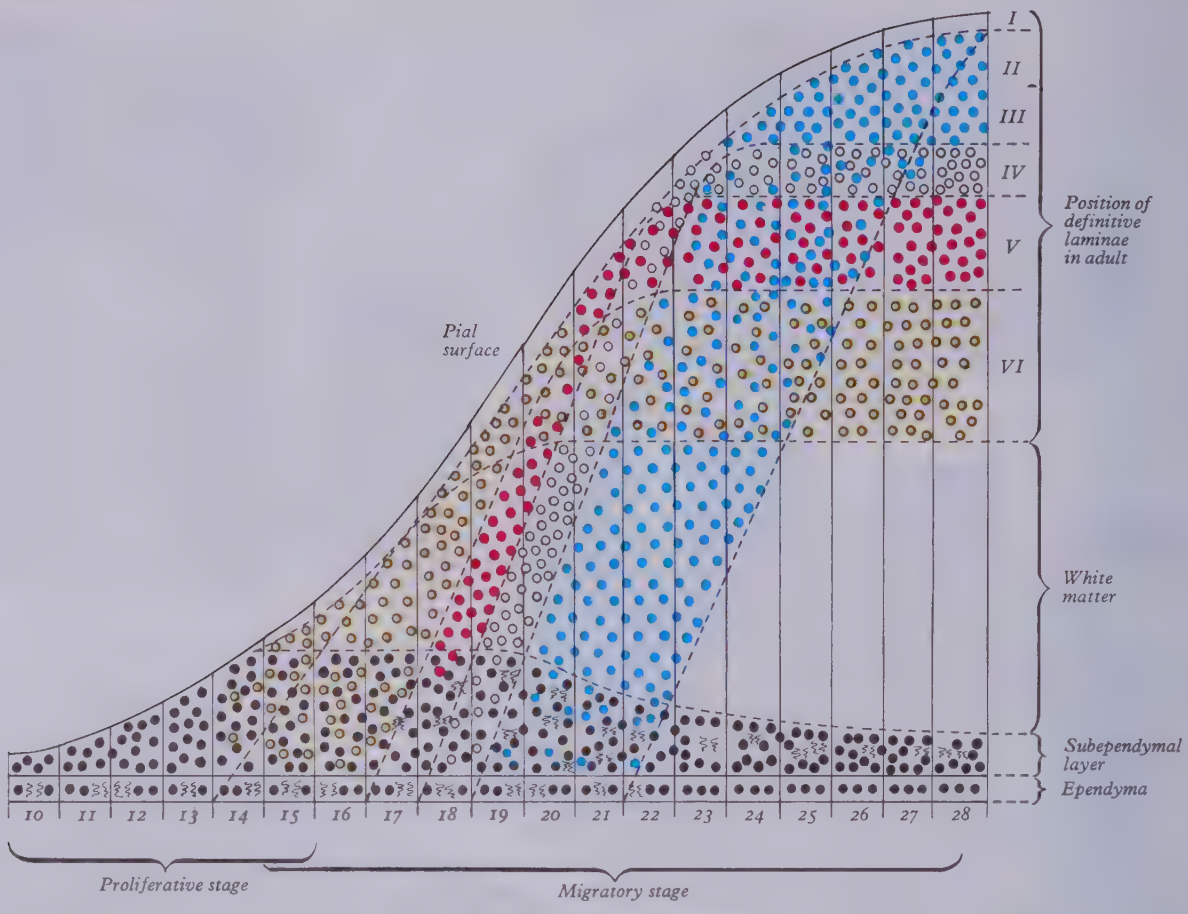
systematically deformed (**2.73**). Nevertheless, it is held that the *overall pattern* in the ventricular zone of the early hemisphere, which is probably genetically preprogrammed in the genome, is maintained in the array of definitive structural/functional cortical columns (modules).

Although the short account just given of the *general* histogenetic history of the cortex gained, and maintains, wide acceptance, it is of the greatest interest that, with the advent of modern nuclear labelling techniques, there has been a fundamental reappraisal of the *sequences* involved in the migratory patterns of the



2.72 Formalized diagram of the laminar development of cerebral neocortex. The original proposals of the Boulder Committee (1970) have been revised, in the light of subsequent research, by Rakic (1982), with further additions and modifications in preparation for the present volume. See text for further comment. VZ — ventricular zone; MZ — marginal zone; IZ — intermediate zone; CP — cortical plate; SZ — subventricular zone; SP — subplate zone; CO — definitive neocortex; WM — white matter; EL — ependymal layer; ML — molecular layer.

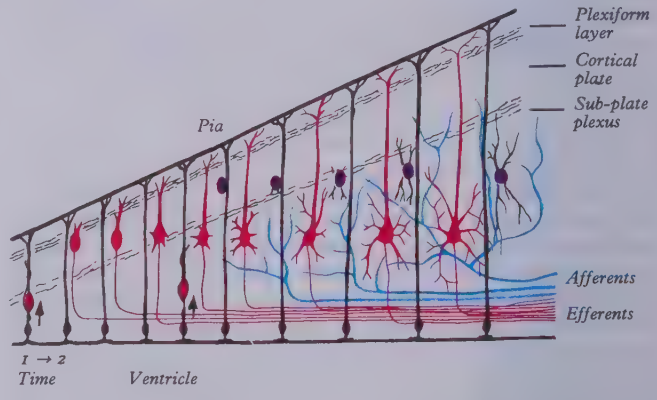
neuroblasts, with consequently considerable ontogenetic and phylogenetic implications.



Pioneering studies into neuroblast migration in the developing mammalian *neocortex* were made by Tilney (1933), the technique available to him at this time being analysis of sections of Nissl stained tissue. Whilst it was clear that the subpial (marginal) zone formed the plexiform lamina (I), he considered that the remaining laminae stemmed from *three* quite distinct and *separate migrations* of neuroblasts up to the cortical plate. The first migration he thought differentiated into the external granular lamina (II) and the pyramidal lamina (III); the second migration forming the internal granular lamina IV; the third migration he held formed the ganglionic lamina V and the multiform lamina VI. On this view, therefore, the *outermost* layers were the *earliest* to be formed, with progressively deeper layers at successively later times.

The possibility that precisely the *reverse* sequence, progressing from *deep to superficial*, was first implied by the results of X-irradiation studies by Hicks et al (1959). Further irradiation studies (Berry & Eayrs 1966), and autoradiographic nuclear labelling studies (Berry & Rogers 1965, Berry 1974 and **2.74**) supported this contention. These seminal investigations have, in the subsequent years, been amply confirmed in the rat (**2.75, 76**), mouse, opossum and golden hamster. (The individual references are too numerous to quote in this volume, but for an excellent overview of this and many other problems appertaining to cortical histogenesis the reader should refer to Berry 1974, 1982; see also comments and bibliographies in: Smart 1982, 1983, Rakic & Goldman-Rakic 1982, editors and contributors.) Thus in these various mammals, apart from the pre-existing anlage of Lamina I, the first laminae to be populated are VI and V, followed sequentially by laminae IV to II. Clearly, whilst the ontogenetic timings of migrations from these experimental sources are not directly appropriate to a volume on *human* anatomy, it is assumed from comparison of purely descriptive material that similar *patterns* of migration and elaboration occur in the human cortex. It should also be noted that, as yet only in the human cortex, a thin subpial lamina of densely staining cells, of unknown origin or destination, has been identified (Rabinowicz 1964, 1967, Brun 1965): they are not a prominent feature of cortical histogenesis but an analogy with the external germinal layer of the cerebellum has been suggested.

No attempt will be made here further to discuss neuroblast and glioblast differentiation, migration and maturation with the establishment of intercellular contacts; for these the reader is



2.73 Development of the cerebral neocortex. Diagram of the spatial three dimensional (and implied temporal fourth-dimensional) relationship between a defined region of the proliferative ventricular zone (VZ) and its subsequent derivative, an enlarged subpial block of cortical plate (CP). The micro-architecture of each is represented as a chequer-board pattern on its upper surface each square extending as a miniature column, or module, through the full thickness of the lamina. The lines joining homologous modules are vertical distally but increasingly sigmoid proximally; they represent changes in the disposition of the primitive radial glial cell processes (contact guidance paths for generations of neuroblasts). Thus the tangential patterning of modules in the cortical plate reflects that already present in the ventricular zone. Vertical patterns of neuroblasts within a module, however, reflect the time of onset and rate of migration along a particular path. The first (i.e. oldest) to migrate reach and mature in the deeper part of the cortical plate; succeeding generations bypass these and occupy successively more superficial parts, the whole finally integrating into a radial functional cell column. (After Rakic 1982.)

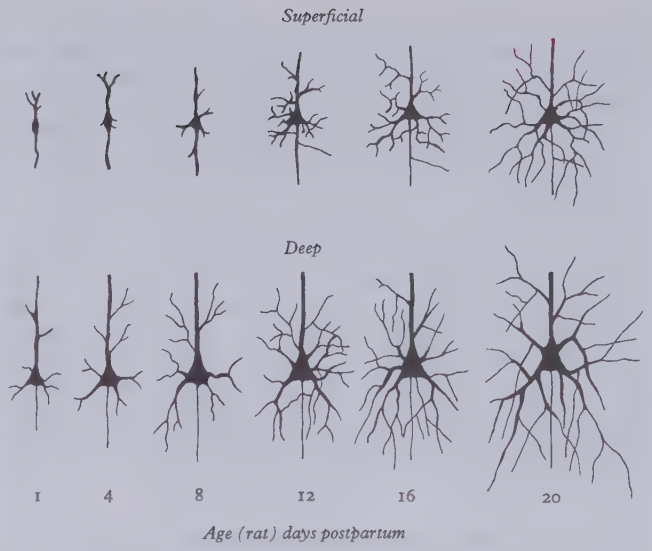
2.74 Schematic representation of the dynamics of neuroblast migrations during transformation of the early cranial neural tube to form the cerebral neocortex of the rat through days 10 to 28. Note the successive waves of migration. Coding: symbolic metaphase chromosomes—mitotic cells; *full black* discs—ventricular and subventricular zone neuroblasts; *full yellow discs*—infragranular neuroblasts destined for lamina VI; full *magenta discs* —infragranular neuroblasts destined for lamina V; *open black circles*—granular neuroblasts destined for lamina IV; *full blue discs*—supragranular neuroblasts destined for laminae III and II. (Redrawn and colour coded by kind permission from data provided by Professor M Berry (1974) of the Anatomy Department, Birmingham University, now Guy's Hospital Medical School, London.)

referred to pp. 178–180, 188, 197 (see also Molliver et al 1973, Kostović & Molliver 1974). However, some general hypotheses may be mentioned, involving a comparison of ontogeny and phylogeny. Firstly, all parts of the neural tube, from the presumptive spinal cord to presumptive neocortex, pass through the stage of a pseudostratified epithelium and a proliferative phase, followed by differentiation sets, with the emergence of ventricular, intermediate and marginal zones. Neuroblast migration, target cell contact and maturation (or, in some locations, *degeneration* and *cell death*), whilst *still confined to* the deeper reaches of the intermediate zone, are the principal events in spinal cord development. Throughout the encephalon, however, the primary difference is the *continued migration* of neuroblasts and their ultimate maturation far *beyond* the confines of the intermediate zone, forming either nuclear masses, variously displaced from the ventricular and aqueductual channels, or, in the 'roof-brain' regions, reaching the subpial marginal zones forming, initially, a simple cortical plate of neuroblasts. The latter then differentiates into subzones, showing a tangential *laminar* organization, whilst in some locations there emerges a well-defined *columnar (modular)* radial organization. Such cortical dispositions are evident in the hemispheric forebrain, tectal midbrain and cerebellar hindbrain. In the pallial walls of the mammalian cerebral hemisphere, the phylogenetically *oldest regions* and the *first* to differentiate during ontogeny are those that *border* the interventricular foramen, and its extension the choroidal fissure, the lamina terminalis and piriform lobe. There exists an increasingly complex level of organization from three to six tangential laminae, passing from the dentate gyrus and cornu ammonis through the subiculum until the general neocortex is reached. (It may be noted that many investigators find the simple progression from three to six major laminae a gross oversimplification, and numerous subdivisions have been proposed, e.g. see cornu ammonis p. 1037, and neocortex p. 1039.) The *deepest* and phylogenetically oldest *tangential laminae* are the first to be populated by migrating neuroblasts, more superficial layers being added in sequence, their neuroblasts migrating *through* the older layers; the number of superadded laminae depending upon the location with respect to the choroidal fissure. These broad

2.75 Diagram to show the manner of the initial stages of formation of apical and basal dendrites of pyramidal neurons, also of stellate neuron dendrites in the cortical plate. Note radial glial cells (black) extending from internal to external limiting membrane; these provide contact guidance paths for neuroblasts. 1. Migration of a presumptive pyramidal neuron (magenta). 2. Migration of a presumptive stellate neuron (purple). Time increments from left to right. (After Berry 1982.)

patterns have been demonstrated by nuclear labelling studies, not only in the neocortex but, with modifications, also in the dentate gyrus and hippocampus (see, e.g. Angevine 1975, Altman & Bayer 1975, Smart 1982).

The state of differentiation at birth and at various postnatal stages, as seen in Golgi (metal impregnation) preparations, has been described in considerable detail elsewhere (Conel—a series of publications 1939–1959). However, the *mechanisms* whereby variation in cell type, number, dendritic patterns and connectivity arise continue under intense investigation. Nevertheless, gross nutritional deficiencies, selective neural ablation, endocrine imbalances, sensory deprivation, neurotropic viruses, vascular abnormalities and perinatal anoxia may all disturb the normal pattern. (See bibliographies in Rakic & Goldman-Rakic 1982.)



At birth the volume of the brain is approximately 25% of its volume in adult life. The greater part of the increase occurs during the *first year*, at the end of which the volume of the brain has increased to 75% of its adult volume. The growth can be accounted for partly by increase in the size of nerve cell somata, the profusion and dimensions of their dendritic trees, axons and their collaterals and by growth of the neuroglial cells and cerebral blood vessels, but it is the acquisition of myelin sheaths by the axons which is principally responsible for it. The great sensory pathways, visual, auditory and somatic, myelinate first, the motor fibres later. During the second and subsequent years, growth proceeds much more slowly; the brain attains adult size by the seventeenth or eighteenth year. This is largely due to continued myelination of various groups of nerve fibres.

A summary of the parts derived from the cerebral vesicles is as follows:

Rhombencephalon (or hindbrain)	1. Myelencephalon	Medulla oblongata Caudal part of the 4th ventricle Inferior cerebellar peduncles
	2. Metencephalon	Pons Cerebellum Middle part of the 4th ventricle Middle cerebellar peduncles
	3. Isthmus rhombencephali	Anterior medullary velum Superior cerebellar peduncles Rostral part of the 4th ventricle
Mesencephalon (or midbrain)		Cerebral peduncles Tegmentum Tectum Aqueduct
Prosencephalon (or forebrain)	1. Diencephalon	Thalamus Metathalamus Subthalamus Epithalamus Caudal part of the hypothalamus Caudal part of the 3rd ventricle
	2. Telencephalon	Rostral part of the hypothalamus Rostral part of the 3rd ventricle Cerebral hemispheres Lateral ventricles Cortex (archaeocortex, palaeocortex, neocortex) Corpus striatum

THE CRANIAL NERVES AND THE NEURAL CREST

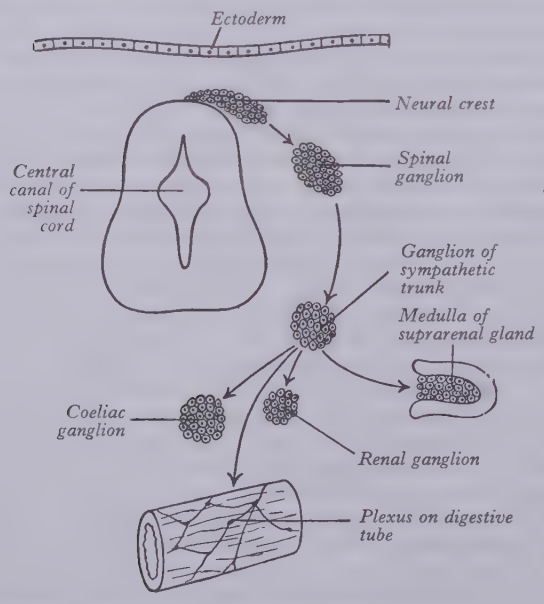
With the exception of the olfactory and optic nerves, which will be considered separately, the cranial nerves are developed in a manner similar in some respects to components of the spinal nerves.

2.76 The temporal sequence of the initial appearance, growth and maturation, of basal and oblique dendrites by pyramidal neurons in the superficial and deep neocortical laminae of the rat. In the first postpartum week the deep neurons are well differentiated relative to the superficial neurons; the latter have only recently terminated their migration from the ventricular zone. Maturation of the superficial neurons relatively hastens in the second and third weeks, and by the 20th postpartum day the degree of maturation of superficial and deep pyramidal neurons is the same. (After Berry 1982.)

The motor fibres of the cranial nerves to striated muscle are the axons of cells in the 'ventrolateral' lamina of the midbrain and hindbrain which grow outwards to their muscle fibres of distribution, but whereas the motor fibres of the spinal nerves form a single series, those of the cranial nerves form two, which are derived from the medial and intermediate parts of the ventrolateral lamina respectively. The first series (*somatic efferent*) comprises the oculomotor, trochlear, abducent and hypoglossal nerves, supplying somite-derived muscles or their homologues; the second (*branchial efferent*) comprises the accessory nerve and the motor parts of the trigeminal, facial, glossopharyngeal and vagus nerves, all of which supply the *striated* muscles derived from the branchial arches, or from post-branchial 'visceral' mesoderm. (It should be recalled, however, that some authorities regard the mesoderm of the branchial arches and immediate post-branchial region as neither somatic nor visceral but *mixed*, being *unsplit lateral plate* since it is devoid of a coelomic cavity; it also receives accessions from the cranial neural crest and varieties of 'head' placodes.) The dorsolateral part of the ventrolateral lamina contributes a variety of neuroblasts, both pre- and post-ganglionic during autonomic neurogenesis (vide infra and p. 200).

As the lips of the neural groove fuse in the region of the hindbrain and midbrain, a *neural crest* is formed which is homologous with the neural crest of the trunk, flanking the spinal cord (p. 137). (For a review of the origin, migration and differentiation of neural crest cells, consult Weston 1970, Bellairs 1971, Leikola 1976, Fujita 1976, Pearse 1977.) The ganglia of the vagal, glossopharyngeal, vestibulocochlear (in part), facial and trigeminal nerves are derived from the neural crest, but they migrate ventrally and soon lie on the ventrolateral aspect of the hindbrain. The vestibulocochlear nerve ganglion is believed to receive contributions from the otocyst (otic placode initially). There is also descriptive and experimental evidence, mainly from lower vertebrates, that overlying ectodermal thickenings or *placodes* (epibranchial, dorsolateral and suprabranchial) contribute to the ganglia of the trigeminal, facial, vestibulocochlear, vagus and glossopharyngeal nerves. It is claimed that these contributions give rise, in the main, to the *special somatic afferent* (acoustic and lateral line) and the *special visceral afferent* (chiefly gustatory) components of these nerves. The development of these cranial nerve ganglia and the role of the ectodermal placodes in the *human* embryo, however,

still need clarifying (see p. 138). Caudal to the ganglion of the vagal nerve the occipital region of the neural crest is concerned with the ganglia of the accessory and hypoglossal nerves. Rudimentary ganglion cells may occur along the hypoglossal nerve in the human embryo; they undergo regression later. Ganglion cells are also found on the developing spinal root of the accessory nerve and these are believed to persist in the adult. The central processes of the cells of these various ganglia, where they persist, form some sensory roots of the cranial nerves and enter the dorsolateral lamina of the hindbrain; their peripheral processes join the efferent components of the nerve to be distributed to the various tissues innervated. Some incoming fibres from the facial, glossopharyngeal and vagal nerves collect to form an oval bundle, the *tractus solitarius* (p. 954), on the lateral aspect of the myelencephalon. This bundle is the homologue of the oval bundle of the spinal cord, but in the hindbrain it becomes more deeply placed by the overgrowth, folding and subsequent fusion of tissue derived from the rhombic lip on the external aspect of the bundle.



THE AUTONOMIC NERVOUS SYSTEM

The ganglion cells of the *sympathetic system* are derived from the neural crest through the medium of the *primitive spinal ganglia* (p. 183). Some cells in the ventral parts of the latter migrate towards the sides of the aorta, where they subsequently form the *ganglia of the sympathetic trunks* and certain other associated cells (vide infra). Others migrate still further and eventually form the subsidiary sympathetic ganglia such as the coeliac and renal (2.77). The original migration is limited to the thoracic and upper lumbar regions. Thereafter the chain grows rostrally and caudally until the whole trunk is laid down. The view has also been advanced that the sympathetic ganglion cells are, at least in part, derived from cells which migrate from the *ventrolateral lamina* along the ventral nerve roots. The results of destruction of the neural crest in chick embryos and excision of the neural crest and portions of the neural tube in frog embryos have been somewhat contradictory in the hands of different investigators. On the whole the balance of the evidence favours the earlier view. For experimental analysis of the neural crest regional mosaic of ganglionic neuroblast sources in quail-chick chimeras see Le Douarin (1980, 1981).

The ganglion cells of the cranial part of the *parasympathetic system* are probably derived from the neural crest through the medium of the primitive ganglia of the oculomotor, trigeminal, facial, glossopharyngeal and vagus nerves. The *ciliary ganglion* is formed by cells which migrate from the trigeminal ganglion along the ophthalmic nerve, but it is almost certainly reinforced by cells migrating from the nucleus of the oculomotor nerve along which a few scattered cells are always demonstrable in post-natal life. The *pterygopalatine ganglion* receives contributions from the ganglia of the trigeminal and facial nerves, the *otic* from that of the glossopharyngeal and the *submandibular* from that of the facial cranial nerve.

The origin of the enteric ganglia in the walls of the gastrointestinal tract has been disputed, but a critical review of the available evidence (Andrew 1971), suggested that both the vagal neural crest and that of the trunk may provide sources. Further evidence was awaited. Le Douarin and Teillet (1974) studying explants of quail neural crest into the chick confirmed that avian enteric neuroblasts have both a vagal and lumbo-sacral neural crest origin. The sacral derivatives join the vagal and colonize 'postumbilical' hindgut (Le Douarin 1980).

Since the foregoing publications there has been a surge of interest in autonomic neurogenesis; e.g. in relation to neuroeffector junctions, the events occurring at 'prerecognition', 'recognition' and 'postrecognition' stages have been characterized. In general, cell sources, critical mitoses, migrations, neurochemical differentiation (cholinergic, noradrenergic, serotonergic, purinergic and an array of other peptidergic neuroblasts) have gained acceptance, together with numerous other facets. For details and extensive bibliographies see Burnstock (1981, editor and contributor). See also p. 891.

2.77 Diagram showing some derivatives of the neural crest.

THE NEUROGLIA

The glial cells are partly neurectodermal and partly mesodermal in origin. The ventricular zone lining the early central canal of the spinal cord and the cavities of the brain give rise, as we have seen, to at least two types of cell (GFA positive and negative, see pp. 180, 188, 195); many of their proliferative progeny migrate into the intermediate zone. The negative cells form neuroblasts which differentiate into neurons, and the positive cells glioblasts which differentiate first into form *primitive radial* varieties, and then generations of *astroblasts* and *oligodendroblasts*; the latter mature into astrocytes and oligodendrocytes (for their mature morphology and hypothesized functional roles, see p. 892). The earliest glioblasts' radial processes extend both outwards to form the outer limiting membrane deep to the pia mater and inwards forming the inner limiting membrane around the central cavity. Their cell geometry may provide contact guidance paths for subsequent cell migrations, both neuroblastic and glioblastic. As the glioblasts differentiate into primitive neuroglia some lose their connections with both inner and outer limiting membranes. They may partially clothe the somata (between presumptive synaptic contacts) of neighbouring developing neuroblasts, or similarly enwrap intersynaptic surfaces of their neurites. (When many varieties of axon are involved, the encircling glial processes form internodal segments of myelin.) Further glial processes expand around intraneural capillaries as perivascular end-feet. Other glioblasts retain an attachment (or form new expansions) applied as pial end-feet to the innermost stratum of the meninges (pia mater)—this is the *pia intima* of some neurocytologists. Both strata may be termed *pia-glia*. Still other glioblasts remain lining the central canal and cavities of the brain as generalized or specialized ependymal cells, including tanycytes, but lose their peripheral attachments. In some situations, as in the anterior median fissure of the spinal cord, the ependymal cells retain their attachments to both the inner and outer limiting membranes. Thus, in addition to functioning as perineuronal satellites, the glia provide cellular channels interconnecting extracerebral and intraventricular cerebrospinal fluid, the cerebral vascular bed, the intercellular crevices of the neuropil and the cytoplasm of all neural cell varieties. (For further comments see pp. 892-896.)

In contrast to astrocytes and oligodendrocytes which are ectodermal in origin, the microglia are mesodermal derivatives. They appear in the central nervous system after this has been penetrated by blood vessels and invade it in large numbers from certain restricted regions, whence they spread in what have picturesquely been called 'fountains of microglia', to extend deeply

amongst the nervous elements. Their origin has been variously ascribed to perivascular mesenchyme cells, vascular endothelial cells, and even to blood-borne leucocytes. See comments in Neurology, Section 7, p. 895.

THE MENINGES

The meninges may be divided in development into the *pachymeninx* (dura mater) and *leptomeninges* (arachnoid and pia mater). Experimental work in lower vertebrates indicates that the dura mater is mesodermal in origin (derived, at least in part, from the sclerotomes), whilst the arachnoid and pia mater are closely associated, being ectodermal in origin and largely derived from neural crest cells (Harvey & Burr 1926, Hörstadius 1950, Leikola 1976). However, morphological studies on the *spinal* meninges of human embryos suggest that all three membranes are initially derived from the loose mesenchyme of sclerotomic origin surrounding the spinal cord, hence termed the *meninx primitiva*. Neural crest cells mingle with this mesenchyme and, as mentioned above, appear to be predominantly involved in the formation of the pia and arachnoid (Sensenig 1951, Weston 1970, Leikola 1976). In the head, the mesoderm from which the *cranial* dura mater develops is closely associated at first with the mesenchyme which is chondrified and ossified, or ossified directly, to form the skull, and these layers are only clearly differentiated as the venous sinuses develop. For an interesting study of pre- and postnatal growth of the tentorium cerebelli, with a mathematical analysis, see Klintworth (1967).

The Chromaffin Organs

The tissue from which the sympathetic ganglia are formed is, at first, a mass of relatively undifferentiated *sympatho-chromaffin cells* but later, a number of cell varieties which may be roughly grouped into *small* and *intermediate-sized neuroblasts (sympathoblasts)* and *large*, initially rounded *phaeochromocytoblasts*. The intermediate-sized neuroblasts differentiate into the typical multipolar post-ganglionic sympathetic neurons (which secrete noradrenalin at their terminals) of classic autonomic neuroanatomy. The small 'neuroblasts' have only come into prominence relatively recently; they are currently the subject of intense scrutiny and they will unquestionably cause a radical reappraisal of autonomic terminology and views concerning ganglionic transmission. Ultrastructural and specialized light-microscopic fluorescence techniques led them to be termed, firstly small granulated cells and, latterly, *small intensely fluorescent* (SIF) cells, type I and II. Both have been shown (at least in some species and sites) to be dopamine-storing and secreting cells. It is postulated that type I function as true interneurons, synapsing with the principal post-ganglionic neurons. Type II are thought to operate as *local neuroendocrine cells*, secreting dopamine into the ganglionic microcirculation. Both types of SIF cells probably modulate the principal preganglionic/post-ganglionic synaptic transmission. The *large* cells differentiate into masses of columnar or polyhedral *phaeochromocytes* ('classic' chromaffin cells) which secrete either adrenalin or noradrenalin. These cell masses are termed *paraganglia* and may be situated near, on the surface of, or embedded in the capsules of the ganglia of the sympathetic chain, or in some of the large autonomic plexuses (see p. 1465 and 8.235). The largest members of the latter are the *para-aortic bodies* which lie along the sides of the abdominal aorta in relation to the inferior mesenteric artery. During childhood the para-aortic bodies and the paraganglia of the sympathetic chain partly degenerate and can no longer be isolated by gross dissection, but even in the adult chromaffin tissue can still be recognized microscopically in these various sites (p. 1472). It may be noted here that both the phaeochromocytes and the SIF cells, using a wider and more recent classification, are regarded as chromaffin; they belong to the APUD series of cells and are paraneuronal in nature (see further discussions on pp. 136, 138, 1466, and Burnstock 1981, editor).

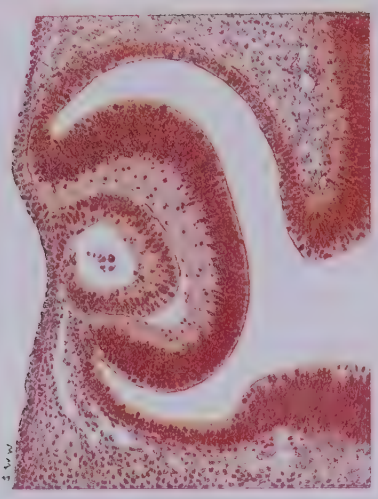
THE SUPRARENAL GLANDS

Each suprarenal gland consists of a cortex of mesodermal origin and a medulla of neurectodermal origin. The cortex is initiated during the second month as a proliferation of coelomic mesothelium into the underlying mesenchyme between the root of the dorsal mesogastrium and the mesonephros (Keene & Hewer 1927, Crowder 1957). (An older view that two separate proliferations form at first a fetal cortex before the definitive cortex has not been corroborated.) The proliferating tissue extends from the level of the sixth to the twelfth thoracic segments. It is soon disorganized dorsomedially by invasion by sympathochromaffin tissue from adjacent sympathetic ganglionic masses to form the medulla and also by the development of venous sinusoids. The latter are joined by capillaries which arise from adjacent mesonephric arteries and penetrate the cortex in a radial manner. When proliferation of the coelomic epithelium ceases the cortex is enveloped ventrally, later dorsally, by a mesodermal capsule derived from the mesonephros. The subcapsular nests of cortical cells are the rudiment of the *zona glomerulosa*. These nests proliferate cords of cells which pass deeply between the capillaries and sinusoids. The cells in these cords degenerate in an erratic fashion as they pass towards the medulla, becoming granular, eosinophilic and ultimately autolysed. These cords of degenerating cells constitute the *fetal cortex*, which undergoes a rapid degeneration during the first two weeks after birth with marked shrinkage of the gland. The *fascicular* and *reticular* zones of the adult cortex are proliferated from the glomerular zone after birth and are only fully differentiated by about the twelfth year.

Development of Special Sense Organs

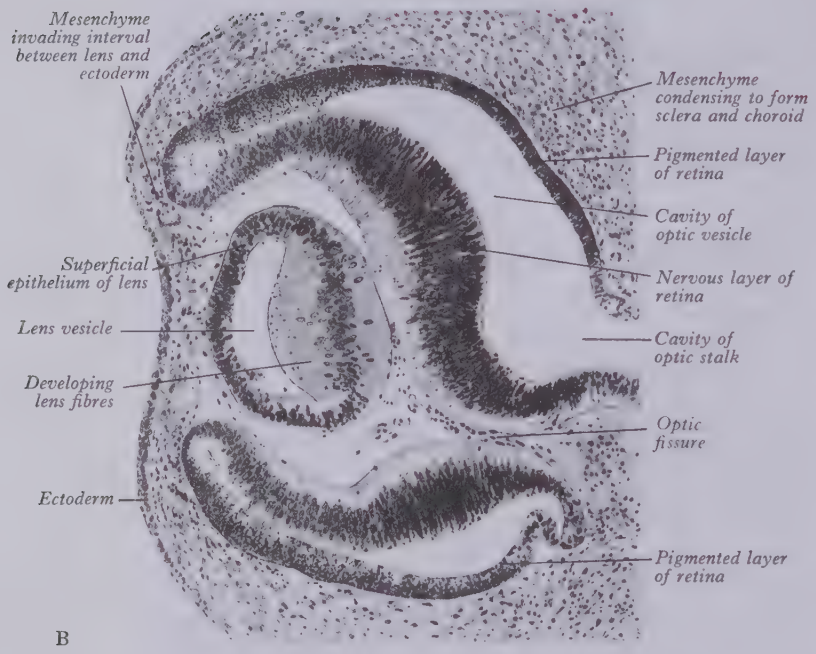
THE NOSE

The early development of the olfactory placodes, external nose and nasal cavities have already been considered (pp. 166 et seq.).



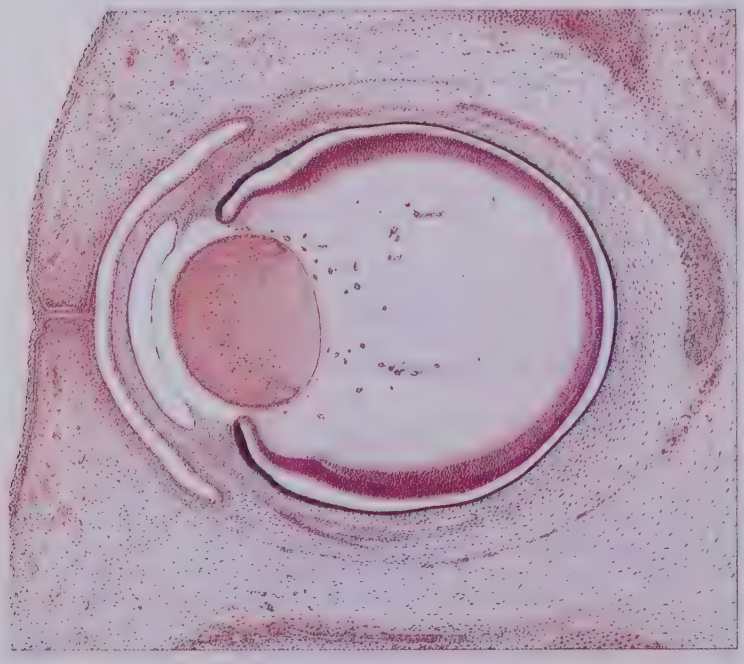
The *olfactory nerve fibre bundles (fila olfactoria)* are developed from a proportion of the placodal cells which line the olfactory pits; these cells proliferate and give rise to *olfactory receptor cells*. Their central processes grow into the overlying olfactory bulb and thus form the axons of the olfactory nerves. It was claimed that the olfactory cells are from the first connected with the overlying brain by bridges of cytoplasm, within which the olfactory nerve fibres develop (Smith 1908, Ballantyne 1925). More recent accounts, however, suggest that the earliest pioneer neurites are naked cytoplasmic processes which cross a mesenchyme-filled gap between the placode and the superjacent brain. Later these and subsequent generations of centrally directed neurites become enclothed in Schwann cell processes, presumably derived from the rostral neural crest (Pearson 1941, Van Campenhout 1956, Dejean et al 1958). Within the olfactory bulb the terminals of the olfactory axons divide repeatedly, and establish complex synaptic contacts with a number of neuroblast types in rudimentary *olfactory glomeruli* (p. 1031). The single dendrite extends towards the nasal cavity surface of the olfactory epithelium where, in most regions, slight expansion with surface specializations occurs (p. 1173).

The remaining placodal cells, with probable accessions from neighbouring rostral neural crest and mixed head mesenchyme, differentiate into columnar *supporting (sustentacular) cells*, rounded *basal cells* and, by invagination, the flattened *duct-lining* and polyhedral *acinar cells* of the glands of Bowman. Later, basal infiltration by lymphocytes occurs.



For further details and references consult p. 1175.

THE EYES



The rudiments of the eyeballs appear as two hollow evaginations from the lateral aspects of the forebrain (Mann 1964, Duke-Elder 1963, O'Rahilly 1966, 1975). These rudiments are visible some time before the closure of the rostral neuropore; after its closure they are known as the *optic diverticula*. Their formation is dependent on the organizing influence of the mesoderm of prechordal

A

B

C

plate origin which underlies this part of the neural tube. They project *laterally* towards the sides of the head, and the distal part of each expands as an *optic vesicle (vesicula optica)* while the proximal part remains narrow as the *optic stalk* (**2.78**A, B). Each contains, initially, a correspondingly shaped part of the original diverticular *optic cavity*. Under the inductive influence of the subjacent optic vesicle the ectoderm overlying it becomes thickened and depressed in its centre. (The classical experiments of Spemann in this field were largely responsible for initiation of the concept of embryonic induction—see p. 107.) This *lens pit* deepens and its edges come together and fuse to enclose a hollow *lens vesicle (cupula optica)* (**2.78**A) which soon loses its connection with the surface ectoderm—the rudiment of the lens. The lateral, paralental wall of the optic vesicle increases in thickness and undergoes invagination into the optic cavity to form the *optic cup*, its wall consisting of two strata of cells (**2.78**A,B). These two strata are continuous with each other at the cup's margin, which grows forwards at the end of the third month, overlapping first the rim then the front of the lens, and finally converging to form the edge of the future pupil. The invagination is not limited to the lateral wall of the vesicle, but involves also its caudal surface and extends as a *groove* some distance along the optic stalk. Thus, for a time, a wide hiatus, the *optic* or *choroidal fissure and groove*, exists in the caudal part of the cup and distal stalk respectively. Through the groove and fissure mesenchyme extends into the optic stalk and cup, carrying the *hyaloid artery* with it; as growth proceeds, the edges of the groove and fissure become approximated and they close during the seventh week, including the artery in the distal part of the stalk. Failure of the optic fissure to close is a rare anomaly and there is always a corresponding deficiency in the choroid and the iris (*congenital coloboma*). It may be noted, however, that localized deficiencies of the choroid and iris can occur independently, and in such cases the retina is normal (Lopashov & Stroeva 1961). Although the cavity of the optic vesicle is largely obliterated by the invagination to form a cup, a potential space does persist, at the microscopic level, as the interval between rod and cone processes and the apical microvilli of the pigmented cells of the most external layer of the retina (p. 1194). The 'space' is of course originally continuous with that of the cerebral vesicle of the forebrain. It is also the site of pathological detachment of the retina.

At the stage of growth briefly described above, a few pertinent terminological points may be noted. Each eye has passed through the phases of a prosencephalon-derived optic diverticulum, conversion into a pedunculated vesicle which induces lens vesicle formation, invagination forming a partially incomplete optic cup and stalk and completion of these deficiencies. The walls of the cup, as mentioned, are two cellular strata thick—the *laminae externa et interna cupulae* separated by a rapidly diminishing *intraretinal space*; the strata are confluent at the margin of the future pupil. The cavity of the cup (*cavitas cupularis*), with growth of the cup rim, comes to engulf the developing lens, internal to which is the site of formation of the vitreous body and the fibro-elastic and membranous structures associated with these. Anteriorly develops the diminutive posterior chamber of the aqueous space. Because of the event of invagination, substrata and fine cellular zones derived from the *inner lamina* have become *reversed* with respect to their original position in the unaltered wall of the neural tube. Many structures in the ocular tunics are named in relation to their radial distance from the centre of the *mature eyeball*. Note in particular the plethora of names for

2.78 A Section through the developing eye of a human embryo. 8 mm CR length. The thick nervous and the thinner pigmented layers of the retina and the developing lens are shown. Stained with haematoxylin and eosin. Magnification × *c.* 114. (From material loaned by Professor R J Harrison.) B Section through the developing eye of a human embryo, 13.2 mm long. (Streeter 1948.) C Section through the eye of a human embryo. 40 mm CR length. Note the layers of the retina, developing lens, pupillary membrane, cornea, conjunctival sac, anterior and posterior aqueous chambers, the developing vitreous body, and condensing circumoptic mesenchyme, and the fused eyelids. Stained with haematoxylin and eosin. Magnification × *c.* 62.

sublayers of the neural retina and compare them with the line of the early (ventricular) intraretinal space. Another group of terms, occasionally causing confusion but approved by a number of developmental biologists, is, with qualification, to dub as 'retinal' (retinae, retinaris) almost *all* derivatives of the optic cup. Thus true photoreceptors and associated neuroblasts form in the internal lamina from a scalloped line a little posterior to the lens's rim (*ora serrata*) throughout the deeply placed remainder of the globe. This, with its associated external lamina, constitutes the *pars optica retinae*. The forward continuation of the (now non-nervous) double strata ends at the pupil's rim, the whole being termed the *pars caeca retinae*. Regionally this forms the columnar to cuboidal cells of the *pars ciliaris retinae* (p. 1186) and similar cells of the *pars iridica retinae* (p. 1194); double epithelia result in both sites.

The neural retina, as indicated, develops from the *pars optica* of the cup (**2**.78B,C). Its two strata are at first equipotential and mutually interchangeable. Depending on contact with surrounding mesoderm, however, the external stratum of the cup remains a single layer of cells, which assume a flattened to cuboidal shape, acquire pigment and form the *pigmented epithelium of the retina*, the pigment first appearing in the cells near the edge of the cup. The majority of the cells have a regular geometry, rectangular in radial section, hexagonal in tangential section. (For further structural details see p. 1195.) Under the influence of the lens the cells of the internal stratum proliferate and form a layer of considerable thickness from which are developed the nervous elements and the elongate sustentacular cells of the retina, together with a portion of the vitreous body.

The cells of the inner layer of the cup proliferate and form an outer *nuclear zone* and an inner *marginal zone*, devoid of nuclei. At 12 mm the cells of the nuclear zone invade the marginal zone, and at 17 mm the nervous stratum of the retina consists of inner and outer *neuroblastic layers*. The inner neuroblastic layer gives origin to the ganglion cells, the amacrine cells and the somata of the 'fibrous' sustentacular cells (of Muller); the outer neuroblastic layer is the source of the horizontal and rod- and cone-bipolar neurons and probably the rod and cone cells, which first appear in the central part of the retina. By the eighth month all the named layers of the retina can be identified. For bibliographies on retinal development, including ultrastructural studies, consult Spira & Hollenberg (1973), Fisher & Linberg (1975), Warwick et al (in press).

The deepest part of the optic fissure is at the centre of the floor of the optic cup. In this situation, which later is the site of the *optic disc*, the inner (neural) cell layer of the cup is continuous with the corresponding invaginated cell layer of the optic stalk and, as a result, the developing nerve fibres of the ganglion cells pass directly into the wall of the stalk, converting it into the *optic nerve*. The fibres of the optic nerve begin to acquire their myelin sheaths shortly before birth, but the process is not completed until some time after birth. The *optic chiasma* is formed by the meeting and partial decussation of the fibres of the two optic nerves in the ventral part of the lamina terminalis and it marks the junction of the telencephalon with the diencephalon in the floor of the third ventricle. Beyond the chiasma the fibres are continued backwards as the optic tracts principally to the lateral geniculate bodies and to the superior tectum.

The lens is developed from the lens vesicle (**2**.78A), which is overlapped by the margin of the cup and becomes separated from the overlying ectoderm by mesenchyme. The cells forming the posterior wall of the vesicle lengthen greatly and, although retaining their nuclei for many years, are usually described as converting into so-called lens fibres, which grow into and fill its cavity (**2**.78B,C). The cells forming the anterior wall retain their cellular character and form the epithelium on the anterior surface of the fully developed lens; at the equator of the lens the gradual transition of the cells into elongate lens fibres can be observed; lens fibre differentiation and growth continues throughout life. Characteristic ultrastructural changes have been described (Wulle & Lerche 1967). (For further structural, dimensional and age changes, see p. 1207.) By the second month the lens is invested by a vascular mesenchymal condensation, the *vascular capsule* of the lens, the ventral part of which is named the *pupillary membrane*; the blood vessels supplying the dorsal part of this capsule are derived from the *hyaloid artery*, those for the ventral part from the *anterior ciliary arteries*. By the sixth month all the vessels of the capsule are atrophied except the hyaloid artery, which becomes occluded during the eighth month of intrauterine life. Prior to this, during the fourth month, the hyaloid artery gives off retinal branches and its proximal part persists in the adult as the *central artery of the retina*, (together with its accompanying *central vein*). The *hyaloid canal*, which carries the vessels through the vitreous, persists after the vessels have become occluded. In the newly born child it extends more or less horizontally from the optic disc to the posterior aspect of the lens but when the adult eye is examined with a slit-lamp it can be seen to follow a wavy, curved course, sagging downwards as it passes forwards to the lens (Mann 1927). With the loss of its blood vessels the vascular capsule of the lens disappears, but sometimes the pupillary membrane persists at birth, giving rise to *congenital atresia of the pupil*.

The vitreous body is developed between the lens and the optic cup. The lens rudiment and the optic vesicle are at first in contact, but after closure of the lens vesicle and formation of the optic cup the former is withdrawn from the retinal layer of the cup; the two, however, remain connected by a network of delicate cytoplasmic processes. This network, derived partly from the cells of the lens and partly from those of the retinal layer of the cup, is the *primitive vitreous body*. At first these cytoplasmic processes spring from the whole of the neuroretinal area of the cup, but later are limited to the ciliary region where, by a process of condensation, they form the basis of the *ciliary zonule*. The mesenchyme which enters the cup through the choroidal fissure and around the equator of the lens becomes intimately united with this reticular tissue and also contributes to the formation of the vitreous body, which is therefore derived partly from the ectoderm and partly from the mesoderm. Considerable controversy regarding the precise derivation of the vitreous still persists. There are probably three sources: the local *mesenchyme*, the lens (*ectoderm*) and the retina (*neurectoderm*). The mesodermal component is probably represented only by the juxtazonular vitreous and the vitreous immediately adjacent to the hyaloid vestiges.

The aqueous chamber of the eye initially appears as a cleft in that part of the mesenchyme which intervenes between the lens and the ectoderm. The mesenchyme superifical to the cleft forms the *substantia propria* of the cornea that deep to the cleft the mesenchymal stroma of the *iris* and the *pupillary membrane*. Tangentially, this early cleft extends as far as the *iridocorneal angle* where communications are established with the sinus venosus sclerae. The cornea is induced by the lens and optic cup. The corneal epithelium is formed from the surface ectoderm and the endothelium of the anterior chamber from mesenchyme (O'Rahilly & Meyer 1959, Coulombre 1964). When the pupillary membrane disappears cavitation continues between the double epithelium on the deep surface of the iris and the anterior part of the lens capsule, until zonular lental suspensory fibres and ciliary processes are reached. Thus the aqueous chamber is now divided by the iris into *anterior* and *posterior chambers*, communicating through the pupil. Their walls furnish the sites of production, channels of circulation and reabsorption of the aqueous humour (p. 1190).

The sclera and choroid are derived from the mesenchyme surrounding the optic cup, and the anterior part of the choroid is modified to form the *ciliary body* and *ciliary processes*. The fibres of the *ciliary muscle* are derived from the mesoderm, but those of the *sphincter* and *dilatator pupillae* are unusual being of neurectodermal origin, developed from the cells of the pupillary part of the optic cup, as is the double epithelium on the posterior (lenticular) aspect of the iris.

The eyelids are formed as small cutaneous folds (**2**.78C). About the middle of the third month their edges come together and unite over the cornea; they are usually said to remain united until about the end of the sixth month. In a more recent study, however, it was concluded that the separation is slow but completed a month earlier (5.1 months, 155 mm stage). The same observers, from examination of 20 human embryos and fetuses, also stated that the tarsal plates and glands begin to develop respectively at 55 mm and 75 mm stages. For the chronology of

development of the human eye at embryonic and fetal stages consult O'Rahilly (1966, 1975).

THE LACRIMAL APPARATUS

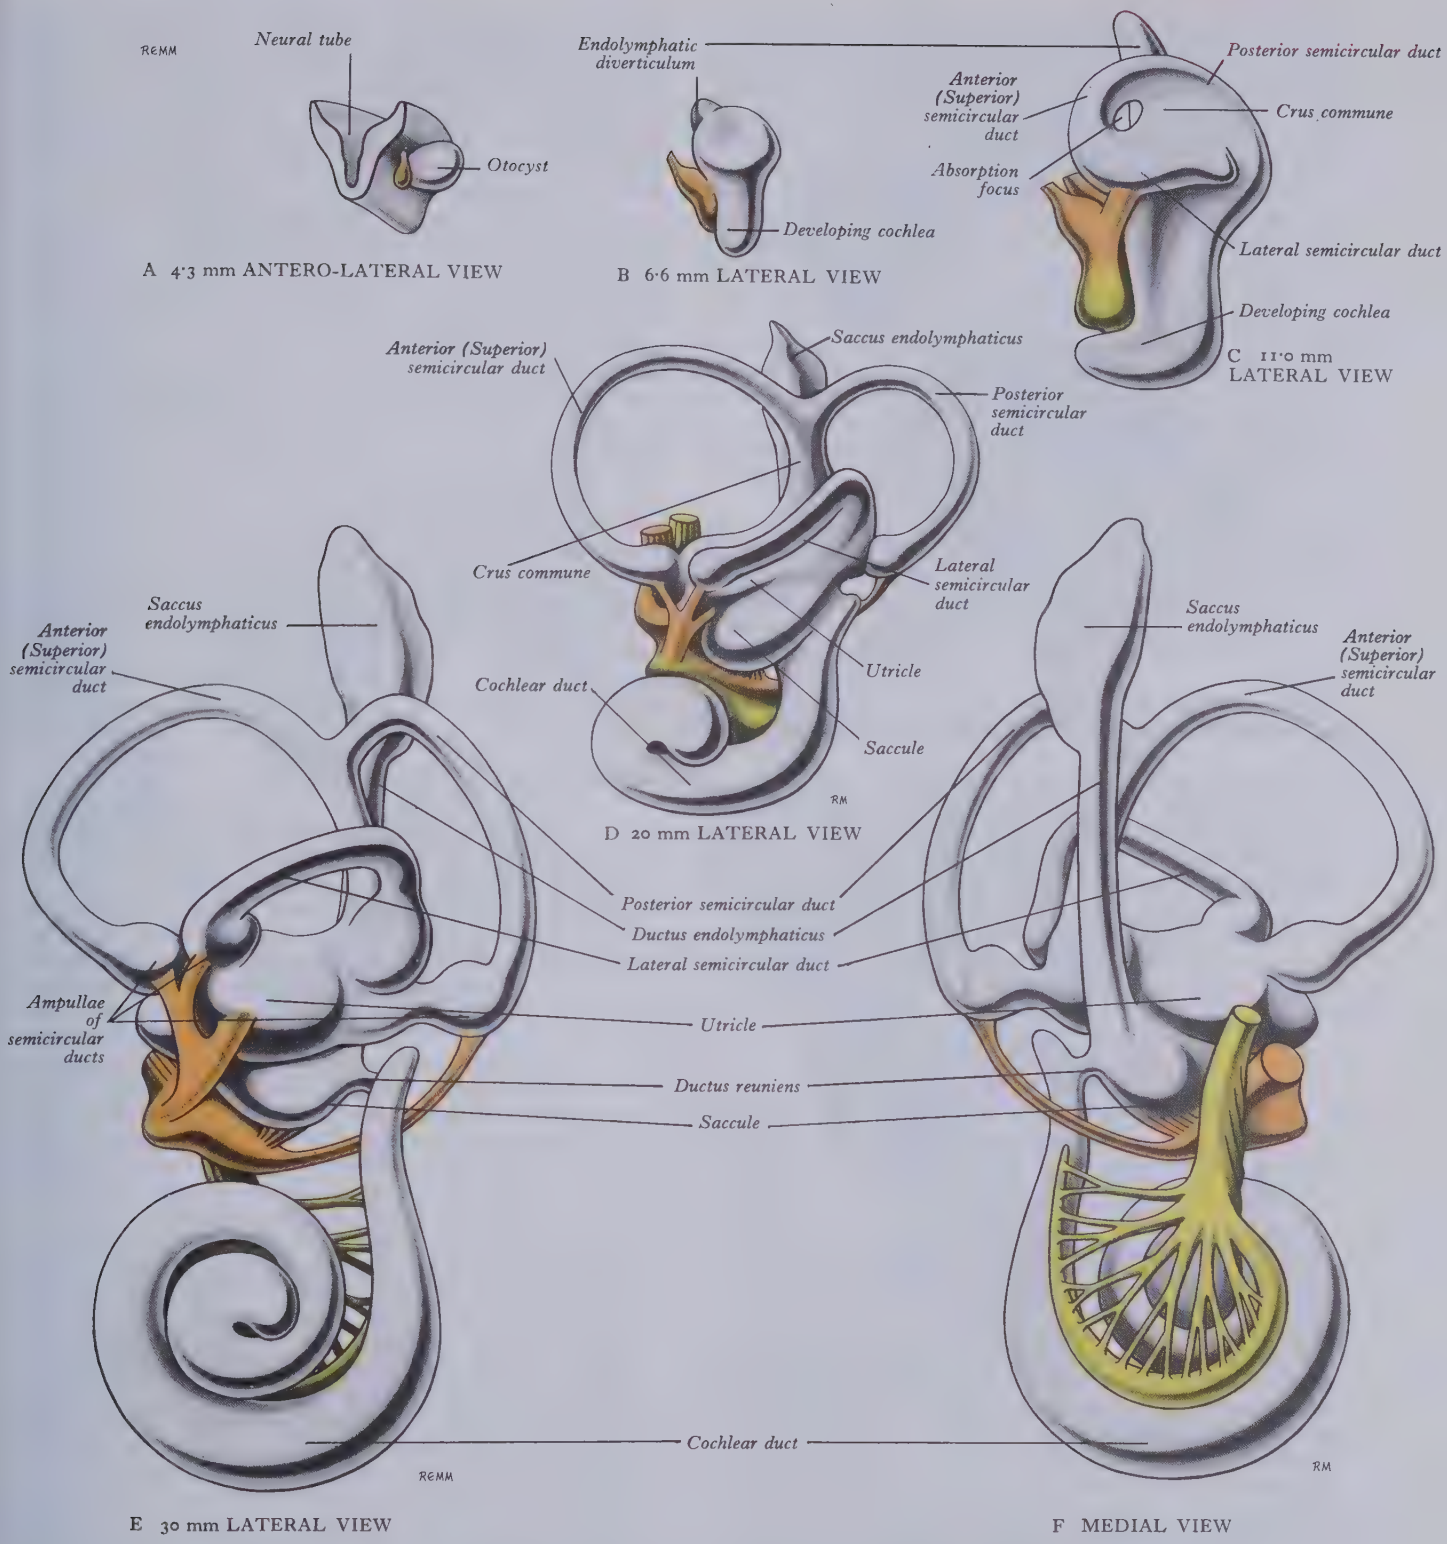
The epithelium of the alveoli and ducts of the *lacrimal gland* arise as a series of tubular buds from the ectoderm of the superior conjunctival fornix; these buds are arranged in two groups; one forming the gland proper, and the other its palpebral process. The *lacrimal sac* and *nasolacrimal duct* are considered to be derived from the ectoderm in the nasomaxillary groove between the lateral nasal prominence and the maxillary prominence (p. 1219). This thickens to form a solid cord of cells which sinks into the mesenchyme; during the third month the central cells of the cord break down and a lumen is acquired. In this way the *nasolacrimal duct* is established. The lacrimal canaliculi arise as buds from the upper part of the cord of cells and secondarily establish openings (*punctua lacrimalia*) on the margins of the lids; the inferior canaliculus cuts off a small part of the lower eyelid to form the *lacrimal caruncle* and *plica semilunaris*. The epithelium of the cornea and conjunctiva is of ectodermal origin, as are also the eyelashes and the lining cells of the tarsal, ciliary and other glands which open on the margins of the eyelids.

For general accounts of ocular developmental abnormalities consult Dejean et al (1958) and Mann (1964).

The Ears

The rudiments of the **internal ears** appear shortly after those of the eyes as two patches of thickened, surface epithelium, *otic placodes*, lateral to the hindbrain. These patches, though surrounded by general skin ectoderm, are probably neurectodermal in character. Each placode invaginates as an *otic pit* (**2**.125A). The mouth of the pit then closes and an *otocyst (auditory* or *otic vesicle*) is formed (**2**.79A), initially piriform in shape, and from it the epithelial lining of the *membranous labyrinth* is derived (**2**.79A-F). A vertical infolding of its wall progressively marks off a tubular diverticulum on the medial side, which differentiates into the *ductus* and *saccus endolymphaticus*, and they communicate via the ductus with the remainder of the vesicle—the *utriculosaccular chamber*—which is placed laterally. From the dorsal part of this chamber three compressed diverticula appear as disc-like evaginations; the central parts of the walls of the discs coalesce and disappear while the peripheral portions of the discs persist as *semicircular ducts*; the anterior duct is completed first, and the lateral last. From the ventral part of the utriculosaccular chamber arises a medially directed evagination which progressively coils as the *cochlear duct;* its proximal extremity constricts as the *ductus reuniens*. The central part of the chamber now represents the membranous vestibule, divided into a smaller ventral *saccule* and a larger *utricle* mainly by horizontal infolding which extends from the lateral wall towards the opening of the ductus endolymphaticus, leaving only a narrow *ultriculo-saccular duct* between its divisions. This duct becomes acutely bent on itself, its apex being continuous with the ductus endolymphaticus (7.355). During this period the membranous labyrinth undergoes a rotation so that the long axis, originally vertical, becomes more or less horizontal (Bast & Anson 1949). Subsequently, otocyst derived cells (having contributed placodal cells to the vestibulocochlear ganglion) differentiate into the specialized paraneuronal hair cells of the utricle, saccule, ampullae of the semicircular ducts, and organ of Corti; they also differentiate into various specialized sustentacular cells and the unique epithelia of the stria vascularis and endolymphatic sac. The remainder form the general epithelial lining of the rest of the membranous labyrinth. (For structural details consult p. 1231 et seq.)

The mesenchyme surrounding the various parts of the epithelial labyrinth is converted into a *cartilaginous otic capsule*, and this is finally ossified to form most of the *bony labyrinth* of the internal ear. (Exceptions are the modiolus and osseous spiral lamina—vide infra.) For a time the cartilaginous capsule is incomplete and the cochlear, vestibular and facial ganglia are situated in the gap between its canalicular and cochlear parts. These ganglia are soon covered by an outgrowth of cartilage and at the same time the facial nerve is covered in by a growth of cartilage from the cochlear to the canalicular part of the capsule. In the embryonic connective tissue between the cartilaginous capsule and the epithelial wall of the labyrinth the perilymphatic spaces are developed. The rudiment of the *periotic cistern* or vestibular perilymphatic space can be seen in an embryo of from 30 to 40 mm in length in the reticulum between the saccule and the fenestra vestibuli. The scala tympani is next developed and begins opposite the fenestra cochleae; the scala vestibuli is the last to appear (Streeter 1917). The two scalae gradually extend along each side of the ductus cochlearis, and when they reach the tip of the ductus a communication, the *helicotrema*, is developed between them. The modiolus and the osseous spiral lamina of the cochlea are not preformed in cartilage but ossified directly from connective tissue.



The auditory tube and tympanic cavity are developed from a hollow, termed the *tubotympanic recess* (Frazer 1914), between the first and third branchial arches, the floor of the recess consisting of the second arch and its limiting pouches. By the forward growth of the third arch the inner part of the recess is narrowed to form the tubal region, and the inner part of the second arch is excluded from this portion of the floor. The more lateral part of the recess subsequently develops into the *tympanic cavity* and the floor of this part forms the lateral wall of the tympanic cavity up to about the level of the chorda tympani nerve. From this it will be seen that the lateral wall of the tympanic cavity contains first and second arch elements, the first arch being limited to the part in front of the anterior process of the malleus. The second arch forms the outer wall behind this and turns on to the back wall to take in the tympanohyal region. Some observations, however, indicate that the tympanic cavity is derived wholly from the first pouch (Kanagasuntheram 1967). The tubotympanic recess is at first inferolateral to the cartilaginous otic capsule, but as the latter enlarges the relations become altered and the tympanic cavity becomes anterolateral. A cartilaginous process grows from the lateral part of the capsule to form the tegmen tympani and it curves caudally to form the lateral wall of the auditory tube. In this way, subsequent to ossification, the tympanic cavity and the proximal part of the auditory tube become included in the petrous region of the temporal bone. During the sixth or seventh month the mastoid antrum appears as a dorsal expansion of the tympanic cavity. Much of the cavity's basic development thus occurs during *fetal* life (Bok 1966). A study of the posterior part of the tympanic cavity and in particular of the sinus tympani, a recess between the promontory and pyramid (p. 1225), emphasizes the late fetal development of this region (Bollobas & Hajdu 1975).

The opinion long held as to the development of the auditory ossicles was that the *malleus* derived from the dorsal end of the ventral mandibular (Meckel's) cartilage (**2**.53) and the *incus* from the dorsal cartilage, probably corresponding to the quadrate bone of birds and reptiles. The *stapes* stems mainly from the dorsal end of the cartilage of the second (hyoid) arch, first as a ring (*annulus stapedis*) encircling the small stapedial artery (p. 214). The primordium of the stapedius muscle appears close to the artery and facial nerve at the end of the second month, and at almost the same time the tensor tympani begins to appear near the extremity of the tubotympanic recess (Candiollo & Levi 1969). Detailed analysis of early embryos concerning the *mesenchymal* origins of the blastemal ossicles, however, differs from the foregoing. Each ossicle has at least *two* distinct sources (see p. 172 and Hanson et al 1962).

At first the ossicles are embedded in the mesenchymal roof of the tympanic cavity and their extraneous origin is indicated in the adult by the covering which they receive from its mucous lining.

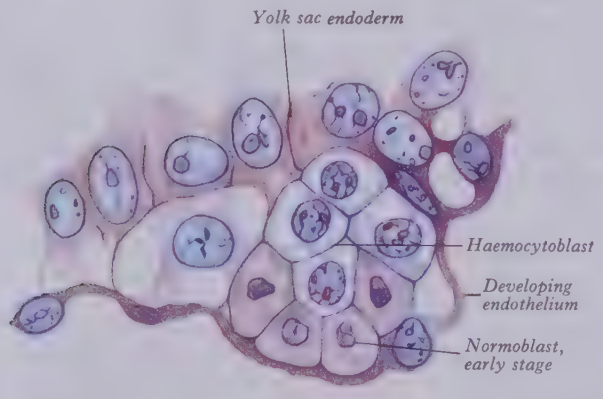
THE EXTERNAL EAR

The external acoustic meatus is developed from the dorsal end of the hyomandibular or first branchial groove. Close to its dorsal extremity this groove extends inwards as a funnel-shaped *primary meatus* from which the cartilaginous part and a small area of the roof of the osseous meatus are developed. From this funnel-

2.79 A series of diagrams showing the stages in the development of the membranous labyrinth from the otocyst, at the embryonic stages and viewed from the aspects indicated. Note also the relationship of the vestibular (orange) and cochlear (yellow) parts of the vestibulocochlear nerve. (From a series of models prepared by His.)

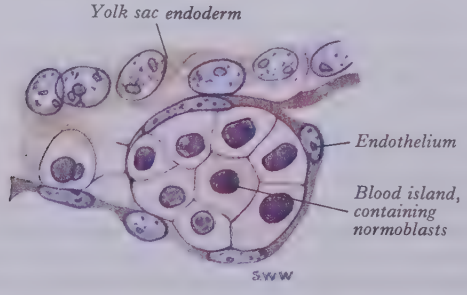
shaped tube a solid epidermal plug extends inwards along the floor of the tubotympanic recess; by the breaking down of the central cells of this plug the inner part of the meatus (*secondary meatus*) is produced, while its deepest ectodermal cells form the epidermal stratum of the *tympanic membrane*. The fibrous stratum of the membrane is formed from the mesenchyme between the meatal plate and the endodermal floor of the tubotympanic recess.

The development of the *auricle* is initiated by the appearance of six hillocks which form round the margins of the dorsal portion of the hyomandibular groove. Of the six, three are on the caudal edge of the mandibular arch and three on the cranial edge of the hyoid arch (**2**.125F). These hillocks appear at the 4 mm stage, but they tend to become obscured as development proceeds and of those on the mandibular arch only the most ventral, which subsequently forms the *tragus*, can be identified throughout (**2**.50). The remainder of the auricle follows proliferation of the mesenchyme of the hyoid arch (Streeter 1922), which extends forwards round the dorsal end of the



remains of the hyomandibular groove, forming a keel-like elevation—the forerunner of the *helix*. The contribution made by the mandibular arch to the auricle is greatest at the end of the second month; as growth continues, it is relatively reduced; eventually the area of skin supplied by the mandibular nerve extends little above the tragus (7.340). The lobule is the last part of the auricle to develop.

The rudiment of the eighth nerve appears in the fourth week as the *vestibulocochlear ganglion*, which lies between the otocyst and the wall of the hindbrain. At first it is fused with the ganglion of the facial nerve (*acousticofacial ganglion*) but later the two separate. The cells of the vestibulocochlear ganglion are mainly derived from the neural crest, but with accessions from the neurectoderm of the otocyst; the ganglion divides into *vestibular* and *cochlear* parts, each associated with the corresponding division of the eighth nerve. The cells of these ganglia remain bipolar throughout life, each sending a proximal fibre into the brainstem, and a peripheral fibre to the internal ear. These neurons are also unusual in that many of their *somata* become enveloped in thin *myelin sheaths*.



The ganglionic fibres just described provide, of course, the afferent, sensory innervation of the labyrinthine hair cells. The latter soon become associated with the *outgrowing* axons from cells of the superior olivary complexes of the pons which provide an efferent innervation, the *olivocochlear bundle* (pp. 1112, 1241). Development details are, however, lacking in mankind.

Development of the Vascular System

The earliest blood vessels are derived from *angioblastic tissue*, which differentiates from extra-embryonic mesenchyme in three regions: (*a*) in splanchnopleure of the yolk sac; (*b*) in the body stalk (allantoic); and (*c*) somatopleure of the chorion (Hertig 1935, Bloom & Bartelmez 1940). In the yolk sac and *base* of the body stalk small, more or less spherical groups of cells are found early in the third week, termed *blood islands* (2.80A,B). Stages of transformation of islands into blood-containing *vessels* are controversial in detail, but it is widely believed that peripheral cells of the islands flatten as the vascular endothelium, while the central cells transform into primitive red blood corpuscles (2.80B). Later these small blood-containing spaces merge forming a continuous network of fine vessels. In the chorionic end of the body stalk and mesoderm lining the chorion typical blood islands are not found, but some mesodermal cells give rise to solid strands of angioblasts. Each strand contains two or three rod- shaped nuclei arranged in a single row, which soon develops a space occupied by one or more nucleated haemoglobin-containing cells. These spaces coalesce to form blood vessels which are lined by endothelial derivatives of the mesoderm; the precise source of their contained blood cells is uncertain. The earliest vessels, therefore, are formed at several separate centres; from the walls of these vessels buds grow out and become canalized, thus converted into new vessels which join with those of neighbouring areas to form a close meshwork. The heart and the blood vessels of the embryo arise from angioblastic tissue differentiated from the *intra-embryonic* mesoderm. Prior to the establishment of the circulation (p. 141), such new vessels (e.g. endothelial heart tubes, dorsal aortae, umbilical and early vitelline vessels) develop in situ, but thereafter they all take origin as outgrowths from pre-existing vessels. (Early vascular patterns are described on pp. 213 et seq. and 219 et seq., see also 2.88-97 and 2.87A,B.) The subsequent development of the blood corpuscles is described on p. 675.

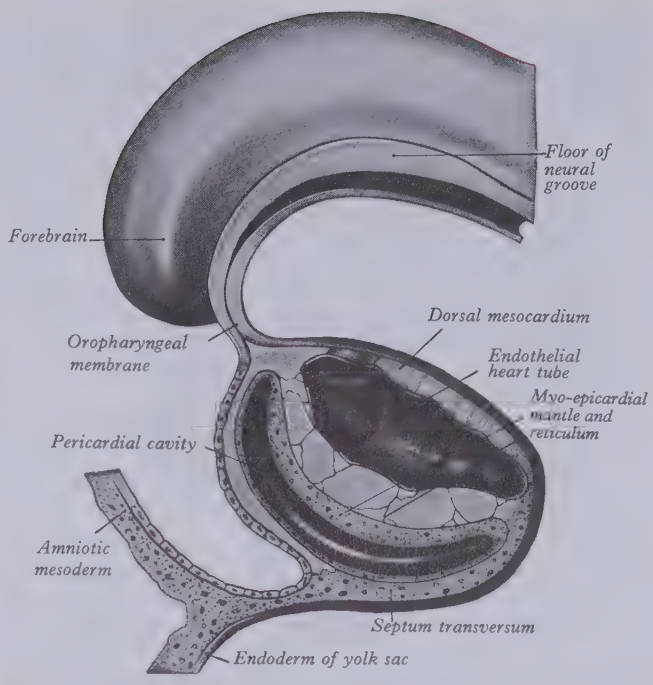
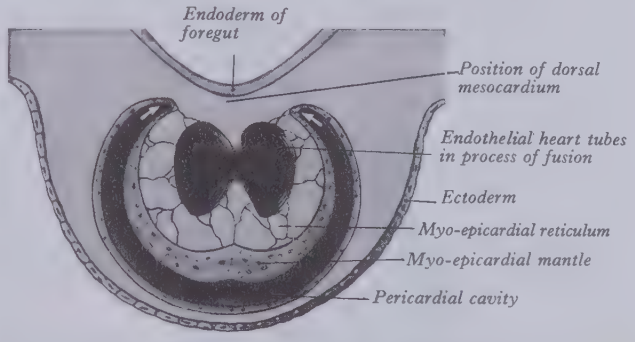
Development of the Heart

The precocious development of the heart has already been mentioned (p. 141). In placental vertebrates it is the earliest major organ to function; for obvious nutritive reasons it must not only accommodate a stream of blood but also begin to propel it. These early *functional* demands on the heart represent an important factor in the dynamics of its development. The early appearance of cardiac activity in the tubular hearts of chick and rat embryos was noted many years ago (e.g. Sabin 1920 et seq., Goss 1942). First manifested by arrhythmic and sporadic ventricular contractions, these are rapidly superseded by regular peristaltic activity propagated directionally along the atrioventricular tube. Earlier observers also described the emergence of valvular function by the accumulation, subjacent to the endothelium, of *cardiac jelly* or *subendocardial reticulum*. This occupies a large space between the primitive endocardium and myoepicardial mantle (vide infra and 2.81C,D). These rapid and critical early events in cardiac morphogenesis have been re-examined with improved techniques, including electron microscopy, especially in the mouse (Challice & Viragh 1973). As the simple heart tube elongates and develops an asymmetrical twist, a succession of cavities, joined by more constricted regions, begin to define the sinus venosus, atrium, ventricle and bulbus cordis. Initially somewhat cylindrical, they rapidly become more spherical (within 24 hours in the mouse). Coincidentally, myoblastic strands invade the subendocardial reticulum from the cells of the myoepicardial mantle and form a complex network of intercommunicating *trabeculae*, external to but ultimately indenting and becoming clothed by endocardium. In many vertebrate groups the myocardium remains predominantly trabecular, but in birds and mammals compact layers of cardiac muscle develop external to the trabeculae. The latter also persist, however, but constitute a lesser volume of the propulsive tissue (vide infra).



These early events in cardiac development provide an approximate parallel between phylogeny and ontogeny. The evolution from a 'trabecular' heart to an organ with rounder chambers and a largely compacted myocardium is likely to be an expression of increased efficiency. An attempt to demonstrate this by mathematical analysis (Challice & Viragh 1973 et seq.) provides some corroboration and also an explanation for the persistence of the internal trabeculation in the mammalian heart. In the account which follows, attention is necessarily concentrated upon the complex changes which transform a tube into



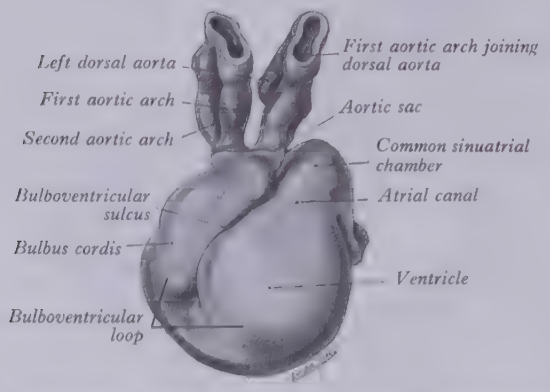
2.81A Median section through the cranial end of an early human embryo to show the position of the pericardium before the formation of the head fold. A few scattered angioblasts are seen between the cardiogenic plate and the yolk sac; they will ultimately form the endothelial heart tubes. (After C L Davis.)

2.81B Median section through the cranial end of a young human embryo, showing the head fold in process of formation and its reversal effect on the position of the pericardium and endothelial heart; also intervening reticulum and myo-epicardium.

2.81C Median section through the cranial end of a young human embryo, after completion of the head fold and reversal of the pericardium.

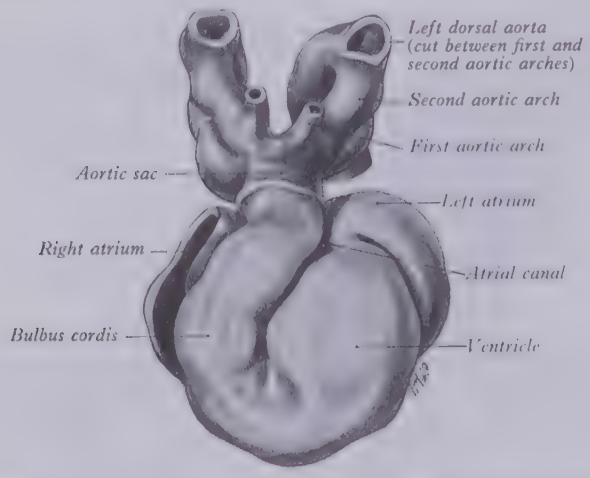
2.81D Horizontal section through the pericardium and developing heart of the embryo shown in 2.81C. The arrows indicate the directions in which the dorsolateral recesses of the pericardium deepen so as to define the transient dorsal mesocardium. (After C L Davis.)

a chambered septate human heart. It is also necessary to keep in mind that at every stage the heart must be an effective circulatory pump.



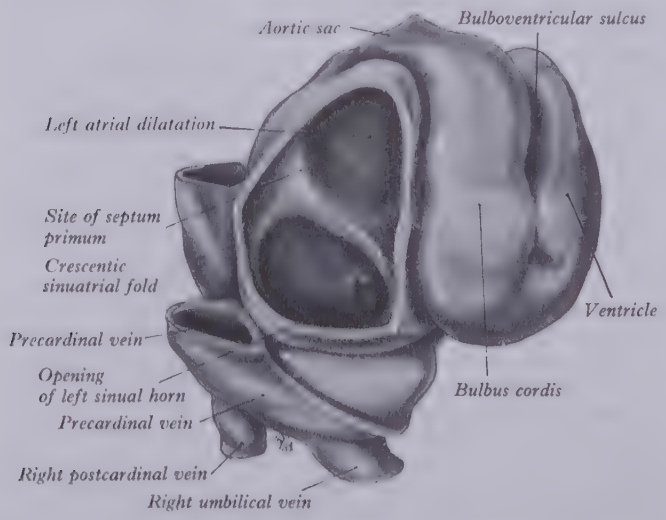
The human heart, as in all vertebrates, is formed by the fusion of two symmetrically developing tubes (2.81D), but the fusion is progressive, commencing at the bulbar or arterial end and extending to the venous end (Tandler 1912, Davis 1927).

The pericardial cavity can be identified before the head fold is formed or during its early formation, when the embryo possesses only two somites. The heart is then represented by groups of angioblasts derived from the splanchnopleuric mesenchyme which lies between the pericardial cavity and the endoderm of the yolk sac (2.81A). At this stage the *ventral* (or yolk sac) pericardial wall, which will form both the epicardium and the myocardium, is thicker than the dorsal wall and is termed a *myo-epicardial mantle*. When the head fold is formed, the mantle becomes the *dorsal* wall of the pericardial *cavity* and lies *ventral* to the foregut. While this reversal of the pericardium is taking place (2.81B,C), the *cardiogenic mesenchyme* gives rise to two paramedian endothelial tubes which rapidly fuse to form a tubular heart. Except at its venous end the *tubular endothelial heart* is separated from the myo-epicardial mantle by a substantial accumulation of *cardiac jelly (gelatinoreticulum)*.



The proximity of the presumptive cardiac mesoderm and yolk sac endoderm at this stage of development is suggestive; in chick embryos, at least, experimental studies indicate that movements, determination of polarity and regional differentiation of the cardiac mesoderm are in some way dependent upon the adjacent endoderm, and perhaps also ectoderm. For discussions and bibliographies concerning such experimental studies, and the importance of haemodynamic influences on regional cardiac morphogenesis, consult Stalsberg & De Haan (1968), Bellairs (1971), Balinsky (1981), Orts-Llorca et al (1982). Thus, in addition to such fundamental phenomena common to all organs, including genomic encoding and differentiation with pattern formation, discussed elsewhere, other aspects have received particular emphasis in cardiogenesis. As indicated the endothelial cardiac tube is separated from the proliferating myo-epicardial mantle by elastically deformable gelatinoreticulum. The latter is invaded by waves of mantle-derived fasicles of differentiating cardiac myoblasts and fibroblasts, whilst interiorly its endothelial lining receives the impact of changing directions of blood flow and pressure profiles. With the emergence of early cardiac chambers the interchamber protrusions of jelly provide a primitive valvular system. With development, these processes contribute to the sculpturing, not only of the subendocardial trabeculae, but also the papillary muscles, chordae tendinae and valve leaflets, the septal complexes between the heart chambers, the complex spiral bulbotruncal ridges and septum, and the fibrous 'skeleton' of the heart (vide infra, and pp. 696 et seq.).

The dorsal aortae arise in situ as paired endothelial vessels. They extend caudally into the body stalk, establishing continuity



with the umbilical arteries, which precede them in time of appearance. At their cranial ends the dorsal aortae curve ventrally round the sides of the foregut to reach the pericardium and become continuous with the cranial end of the endothelial heart tube, thus forming the first pair of aortic arches (2.82A). In all vertebrates in which the heart and aortae are laid down *before* the formation of the head fold, the arteries communicate with the *caudal* end of the heart. When the head fold forms, as noted, the ends of the heart are *reversed* and the cranial ends of the dorsal aortae are curved forwards round the sides of the foregut as the first aortic arches.

2.82A The heart of a 0.95 mm rabbit embryo, viewed from the ventral side. (Drawn from a model by G Born.)

2.82B The heart of a 1.7 mm rabbit embryo, viewed from the ventral side. (Drawn from a model by G Born.)

2.82C The heart shown in 2.82B, viewed from the right side and slightly from the ventral aspect. The right wall of the common sinuatrial chamber has been removed to show the interior. (Drawn from a model by G Born.)

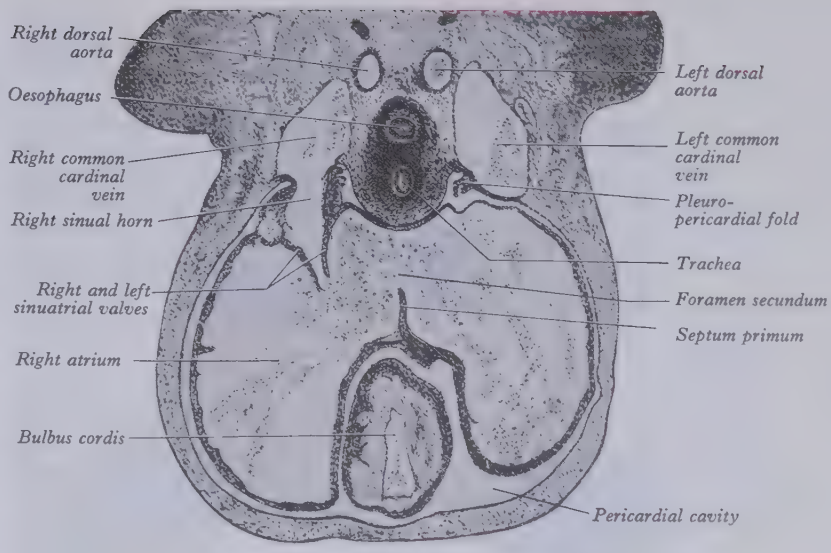
A transverse groove appears on the surface of the heart tube about its middle, the junction of the *bulbus cordis* with the *ventricle*. The bulbus is cranial to the groove and continues as the first pair of aortic arches. The ventricle shows a second groove at its caudal end where it opens into a *common atrium*, which, initially, is embedded in the floor of the pericardium (the future *septum transversum*) and the chamber is disposed transversely. On each side the common atrium is joined caudally by a short venous trunk, formed by the union of the corresponding umbilical vein with veins issuing from the *vitelline* (yolk sac) *plexus*. These trunks represent the right and left *horns* of the *sinus venosus (sinual horns)* so that the common atrium may justifiably be termed a *common sinuatrial chamber*. The umbilical and vitelline radicles of each sinual horn are soon joined laterally by a *common cardinal vein* (each the confluence of a *precardinal* and *postcardinal vein* —p. 223).

Early in the fourth week the heart tube undergoes a striking change. Hitherto the pericardium increased in length proportionately with the heart, but now the heart tube grows more rapidly than the pericardium and the bulboventricular tube bulges ventrally and caudally, forming a U-shaped loop; the bulb is the right limb and the ventricle the left. The loop is conspicuous throughout the fourth and fifth weeks, and seen as a deep *bulboventricular sulcus* externally (2.82A) and a corresponding *bulboventricular ridge* projects internally. Other factors often considered operative in determining the disposition of the loop are modifications in the tubular heart flow patterns, and co-ordinated ciliary action of the coelomic epithelium (Afzelius 1979).

The dorsolateral recesses of the pericardium deepen and approach one another (2.81D); their opposed walls fuse, completing the myo-epicardial covering of the heart thus converting its early broad dorsal attachment into a thinning cardiac mesentery. This *dorsal mesocardium* is transient breaking down early in the fourth week and establishing a passage across the pericardial cavity from side to side dorsal to the heart. This persists as the *transverse sinus* of the pericardium. While these bulboventricular changes are occurring, the atrial part is also affected; the atrioventricular opening moves cranially and to the left, and both parts of the common atrial or sinuatrial chamber 'rise' or emerge from the mesoderm of the septum transversum to grow cranially into the pericardial cavity dorsal to the ventricle. Owing to these changes the atrioventricular canal for a time connects the *left* part of the atrium to the ventricle and venous blood from the right side has to pass through both parts of the atrium.

At this stage (2.87A), about the middle of the fourth week, the bulbus cordis communicates with the dorsal aortae through the first pair of aortic arches, and both are connected with the capillary plexus associated with the developing cerebral vesicles. From this plexus the primitive head vein passes caudally, but ends blindly before it reaches the heart. The intersegmental arteries begin to grow out from the dorsal aorta on each side but have not yet established connections with their corresponding veins; and the postcardinal veins, which later drain the body wall caudal to the heart, are only in process of development. The umbilical arteries and veins are defined and, early in the fourth week, their terminals and radicles, respectively, link up with the capillaries which have developed in the chorionic villous stems, establishing the chorionic part of the circulation. Despite the fact that the channels for the remainder of the circulation are only partially established there is good ground for assuming, from observations made on living embryos by a variety of techniques, that the heart begins to contract about this time. Under the prevailing conditions, the effect can only be of an 'ebb and flow' nature, but this also serves to effect some movement in the nutritive fluid filling the pericardial cavity, coelomic ducts and exocoelom (p. 141), on which the embryo is still heavily dependent.

Towards the end of the fourth week the connection between the bulbus cordis and the first pair of aortic arches lengthens to form the *truncus arteriosus*, and the cranial end of this vessel becomes connected to the dorsal aortae by the remaining five pairs of aortic arches. By this time the *venous drainage* of the body wall and neural tube has been established. On each side a *precardinal vein*,



from the cranial end of the embryo, unites with a *postcardinal vein* from the caudal region to form the *common cardinal vein (duct of Cuvier)*; the latter vessel opens close to the umbilical and vitelline veins into the dorsocaudal part of the common sinuatrial chamber (the three vessels forming the right or left *sinual horn*).

As the chorionic circulation already exists the embryo can now exchange materials with the maternal blood in the intervillous space. This is not effected suddenly; initially the blood volume and its cellular content in the heart and vessels of the embryo is insufficient to enable it to take full advantage of this new source of nourishment, and until this is rectified, the embryo continues to draw upon the coelomic fluid.

The separation of a definitive *sinus venosus* from the *common atrium* completes the definition of the primitive chambers of the heart. A crescentic groove appears on the left wall of the sinuatrial chamber and rapidly deepens to the right. Hence the left horn of the sinus venosus loses its connection with the left part of the atrium and becomes linked to the right sinual horn by separation of the caudal part of the sinuatrial chamber; the latter now constitutes the *body of the sinus venosus*. At the same time the right sinual horn becomes more clearly demarcated from the right part of the atrium by a shallow groove, and its wide connection with the atrium (2.82C) becomes relatively smaller (Foxon 1955). The right and left parts of the atrium grow cranially to occupy the dorsal part of the pericardial cavity, and later they bulge forwards, embracing the sides of the bulb (2.83A).

The embryo has now reached a length of nearly 4 mm (2.87B). It possesses 28 somites and has almost completed the fourth week of development. From this stage onwards it is more convenient to deal with the individual chambers with only occasional reference to the development of the heart as a whole.

It must be noted that the above account of early cardiogenesis, though widely subscribed to, is not without its critics. In considering the many factors governing cardiac development—phylogenetic, ontogenetic, and physiological— the last is usually underestimated and the first is perhaps stated too dogmatically (Foxon 1955). Ontogenetic mechanisms must conform to the early demand for a functioning heart, and cardiogenesis is not necessarily a mere repetition of phylogenetic steps, which are themselves uncertain, however plausible they may seem (De Vries & Saunders 1962).

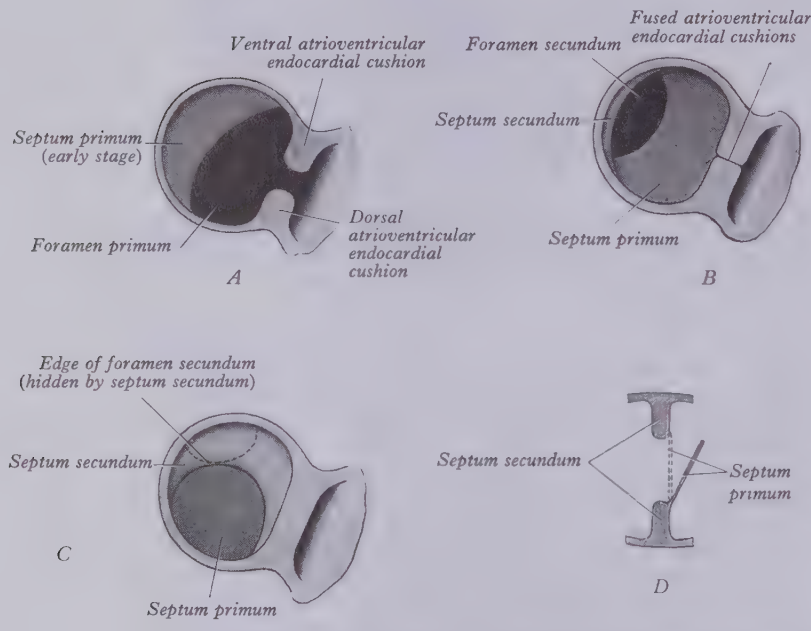
2.83A Transverse section of a human embryo, 8 mm long. Observe how the atria bulge forwards on each side of the bulbus cordis. The septum primum has broken down in its dorsal region and the two atria communicate through the ostium secundum or foramen ovale.

THE SINUS VENOSUS

The right sinual horn increases rapidly in size at the expense of the left, due to the changes already outlined and to those occurring in the originally symmetrical arrangement of the umbilical and vitelline veins by the development of the liver (2.93-95, p. 219). As a result the vitello-umbilical blood flow enters the right horn through a wide but short vessel, the *common hepatic vein*, which becomes the cranial end of the inferior vena cava. In addition, the right horn receives the right common cardinal vein (from the body wall of the right side) and the body of the sinus, which conveys the blood from the left horn and left common cardinal vein. Later, when *transverse connections* are established between the cardinal veins (2.96–98), the blood from the body wall of the left side reaches the heart via the veins of the *right* side. The left common cardinal vein then becomes much reduced in size and forms the oblique vein of the left atrium and the fold of the left caval vein, while the left horn and the body of the sinus venosus persist as the *coronary sinus* (2.97).

The right sinual horn opens into the right atrium through its dorsal and caudal walls. The orifice, elongated and often slit-like, is guarded by two muscular folds, the *right* and *left sinuatrial (venous) valves (valvules)* (2.83A). These two valves meet cranially and become continuous with a fold which projects into the atrium from its roof, the *septum spurium*. Caudally the valves meet and fuse with the dorsal endocardial cushion of the atrial canal. The cranial part of the right sinuatrial valve loses its fold-like form, but its position is indicated in the adult heart by the crista terminalis of the right atrium; its caudal part forms the valve of the coronary sinus and most of the valve of the inferior vena cava. The medial (or left) end of the valve of the inferior vena cava is formed by a small fold continuous with the dorsal wall of the sinus venosus, the *sinus septum*. The latter intervenes between the orifice of the common hepatic vein and the opening of the body of the sinus. (In the mature heart see the *tendon of Tondaro* and *triangle of Koch* pp. 703, 720.)

The left venous valve blends with the right side of the atrial septum and usually no trace of it can be seen in the adult heart.



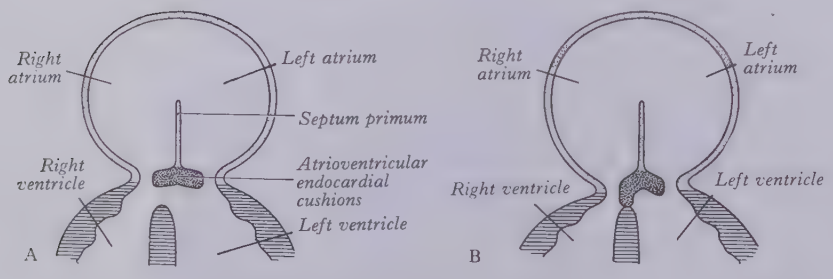
As the sinuatrial valves undergo these changes the right sinual horn becomes incorporated in the right atrium and expands to form its smooth dorsal wall, medial to the crista terminalis. This part of the adult atrium is termed the *sinus venarum*, the receiving chamber of the large venous orifices. The right half of the primitive atrium forms the internally ridged, more muscular, wall anterior to the crista terminalis and the right auricular appendage.

THE RIGHT AND LEFT ATRIA

As stated, the common atrium is derived from the cranial part of the sinuatrial chamber. It receives the opening of the sinus venosus dorsocaudally and to the right of the median plane, while it communicates ventrally with the ventricle through the atrioventricular canal, which has resumed its median position by the middle of the fifth week, thus permitting both right and left parts of the atrium to communicate with the common ventricular cavity. Dorsal and ventral swellings appear in the walls of the atrioventricular canal between the endothelial tube and the myo-epicardial mantle. These, the *atrioventricular endocardial cushions*, consist of a core of gelatinoreticular mesenchyme. They encroach on the canal and eventually fuse, leaving a relatively small orifice on each side. The fused tissue constitutes the *septum intermedium* (of His), which separates the two, small, right and left atrioventricular orifices and canals.

Internal separation into right and left atria is mainly effected by sequential growth of two septa (but with additional, less prominent structures). First the *septum primum* grows from the dorsocranial atrial wall as a crescentic fold (2.83B,*A*), separated from the left sinuatrial valve by the *interseptovalvular space*. The ventral horn of the crescent reaches the ventral atrioventricular cushion, the dorsal horn the dorsal cushion. Ventral and dorsal refer to the positions of the cushions after the atrium repositions to lie dorsal to the bulbus cordis. Strictly the cushions are ventrocranial and dorsocaudal in position, but ventral and dorsal are in general use and will be retained here. Ventral and caudal to the advancing edge of the septum the two atria communicate through the *foramen primum* (2.83B,*A*). Free passage of blood from right to left atrium is essential throughout fetal life, as oxygenated blood from the placenta reaches the heart

via the inferior vena cava (p. 723); therefore, as the foramen primum diminishes, the septum primum breaks down dorsally and a new right-left shunt, the *foramen secundum*, is formed before the end of the fifth week. The foramen primum is finally occluded by fusion of the edge of the septum primum with the fused atrioventricular cushions, in the median plane. The foramen secundum enlarges, allowing sufficient free passage of blood from right to left atrium (**2**.83B), and it persists throughout intrauterine life as *part* of the valvular *foramen ovale* in the progressively changing *interatrial septal complex* (vide infra). At first the foramen secundum is sited craniodorsally in the septum primum but it becomes modified until it is cranioventral.



2.83B Diagrams representing three stages in the development of the atrial septum, viewed from the right side. The heart has been divided in its long axis to the right of its median plane and only the atria and the adjoining part of the ventricular cavity are depicted.

A The septum primum has not yet obliterated the original communication between the two atria and the atrioventricular endocardial cushions have not yet fused.

B The atrioventricular endocardial cushions have fused with each other and with the septum primum, which has broken down in its dorsal part. The foramen secundum, thus formed, subsequently moves to the position shown in C.

C The septum secundum has formed and hides the foramen secundum, the margins of which are indicated by the curved, dotted line.

D Section to show the valve-like character of the foramen secundum. When the pressure in the right atrium exceeds that in the left atrium, blood passes from the right to the left side of the heart, but when the two pressures are equal the septum primum assumes the position indicated by the dotted outline.

2.83C Diagram to show two stages in the formation of the adult ventricular septum. In A the right and left ventricles communicate with each other, but in B the interventricular communication has been closed by the fusion of the ventricular septum with the enlarged right extremity of the fused a.v. cushions. Note the position of the septum primum relative to the fused a.v. cushions, and observe that in B cushion tissue intervenes between the two ventricles (membranous part of ventricular septum), and also between the *right* atrium and the *left* ventricle (atrioventricular septum).

Towards the end of the second month the muscular wall of the atrium becomes invaginated as another crescentic septum on the right side of the septum primum (**2**.83B,*B*,*C*). This, the *septum secundum*, involves more than the whole width of the interseptovalvular space; thus the dorsal attachments of the septum primum and the left sinuatrial valve are carried into the interior of the atrium on its left and right surfaces respectively. The superior (ventrocranial) and inferior (dorsocaudal) horns of the septum secundum at first grow ventrally; the superior horn grows much more rapidly and fuses first with the septum intermedium; it is then continuous with the *sinus septum* (vide supra). Thus the free edge of the septum secundum (*crista dividens*) is at first directed caudoventrally and later caudally alone; it overlaps the foramen secundum (**2**.83B,*C*,*D*); thus the septum primum acts as a flap valve. Since the blood pressure is greater in the right atrium than in the left, the blood flows from right to left, but not conversely. The right-left flow occurs through the 'true', but somewhat misnamed *foramen ovale*, proceeding from the right atrium under the crescentic free border of the septum secundum, thence through the oblique cleft between the (parted) secondary and primary septal surfaces, to finally enter the left atrium through the foramen secundum. After birth the intra-atrial pressures are equalized and the free edge of the septum primum is therefore kept in contact with the left side of the septum secundum and fusion occurs. Not infrequently the fusion is incomplete, but the remaining cleft is usually small, valvular and has no functional significance. The initially free, crescentic margin of the septum secundum forms, after fusion, the *limbus fossae ovalis* and the septum primum the floor of the *fossa ovalis* of the adult heart. An alternative derivation of the septum secundum from a ridge developing to the right of the line of fusion between the confluent endocardial cushions and the septum primum has been advanced (Odgers 1934). The dorsal horn of the septum secundum is said to incorporate tissue derived from part of the left sinuatrial valve; its contribution, however, remains uncertain; sometimes, small vestigial remnants persist to maturity. Another view embodies the above suggestion, but regards the valve as of minor importance in this connection, describing, however, yet another ridge—the *septum accessorium*, contributing to the lower part of the dorsal border of the limbus (Christie 1963).

Early in the development of the septum primum a single, common pulmonary vein of controversial origin opens into the caudodorsal wall of the left atrium close to the septum. It is the union of a right and a left pulmonary vein, each formed by two small veins issuing in turn from each developing lung bud. Subsequently the common trunk and the two veins forming it expand and are incorporated in the left atrium to make up the greater part of its cavity. This expansion usually continues as far as the orifices of the four veins, which thus open separately into the left atrium; variations, however, are quite common. The left half of the primitive atrium is progressively restricted to the mature auricular appendage.

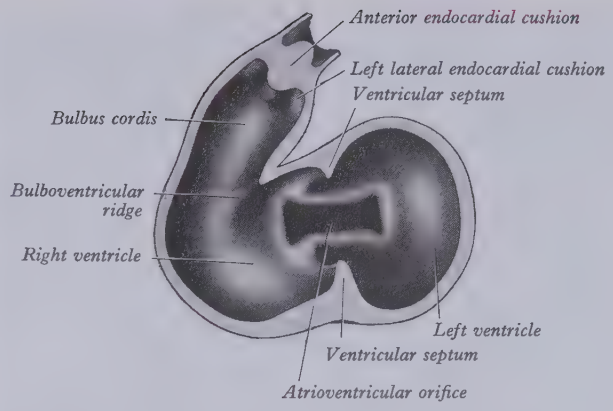
During the second month the two atria bulge ventrally one on each side of the bulbus cordis, which lies in a groove on their ventral surface (**2**.82B,83A). These projecting parts of the atria form the auricular appendages of the adult heart.

THE VENTRICLES BULBUS CORDIS AND THE TRUNCUS ARTERIOSUS

The process of separation of the ventricles is intimately related to that of the aortic and pulmonary orifices at the distal end of the bulbus (**2**.84A-C) and also to the division of the truncus arteriosus into pulmonary and aortic channels. Their interdependence is such that the history of the truncus arteriosus is dealt with here, although strictly it takes no part in the formation of the heart itself. Bulbotruncal separation is conveniently considered before final interventricular septation and valve modelling. As intimated these complex events are the result of mutual *interaction* between factors controlling pattern formation, differential growth and the continuously changing blood-flow paths, volumes and pressures. This interplay moulds the grooves, ridges, outpouchings, valve complexes and varying myocardial thickness and architecture. Although described sequentially, many of these

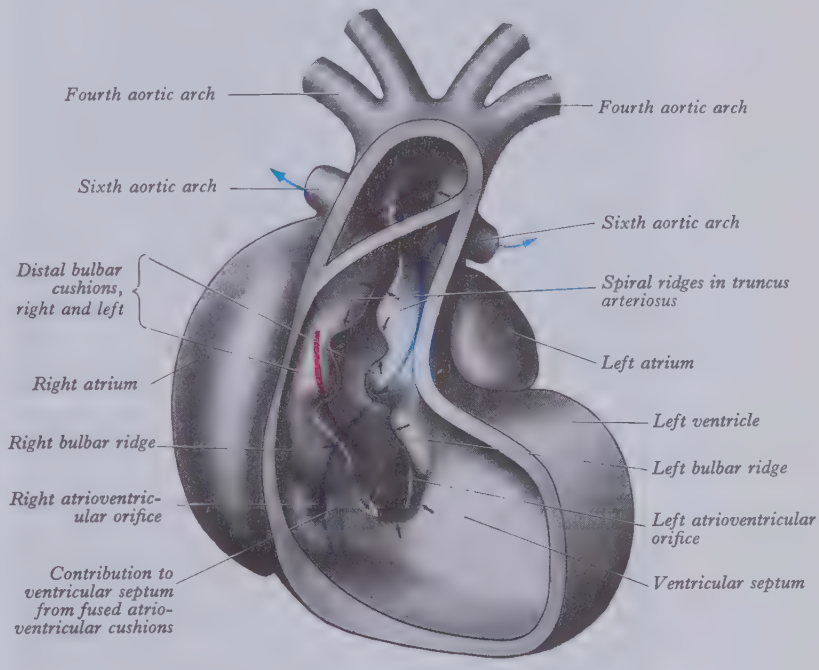
events occur simultaneously. Blood enters the bulboventricular cavity through the right and left atrioventricular canals (ventricular *inflow tracts*) and is ejected through the proximal and distal bulbus (*outflow tracts*). That from the future left ventricle passes obliquely to the *dorsal* part of the bulbus, whereas right ventricular blood has a reverse inclination to the former and is expelled through the *ventral* part of the bulbus. These inclinations impose a mutually spiral flow on the two streams as they traverse the truncus.

Four endocardial cushions—ventral, dorsal, right and left—form in the distal part of the bulbus and the right and left cushions fuse to constitute a *distal bulbar septum*. This separates a ventral, *pulmonary orifice* from a dorsal, *aortic orifice*, and later the cushions divide and become modified to form the *semilunar valves* (vide infra).



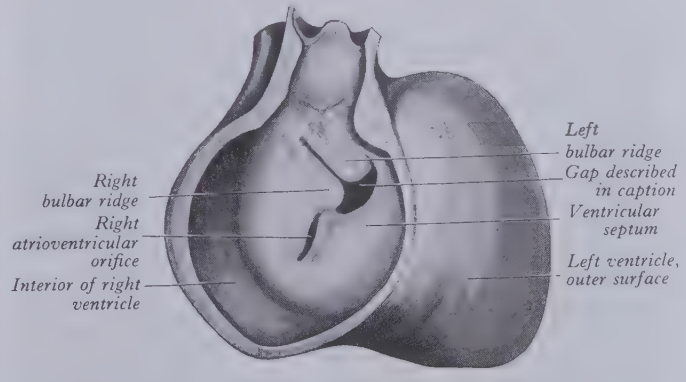
The separation of the pulmonary trunk from the aorta is a more complicated process. Two ridge-like thickenings project into the interior of the truncus arteriosus between the entwined spiralized streams of blood. Proximally, the ridges project from the *lateral* walls of the vessel but, progressing distally, the right ridge passes obliquely on to the *ventral* and then the *left* wall, while the left ridge extends on to the *dorsal* wall and then the *right* wall (**2**.84B). The ridges are therefore spiral, and their fusion forms the *spiral aorticopulmonary septum*. Proximally this meets and fuses with the distal bulbar septum, and in accord with its spiral form the pulmonary trunk, which lies ventral to the aorta at its orifice, curves round to its left side as it ascends and finally lies dorsal to it (**2**.84B). Distally the aorticopulmonary septum meets the dorsal wall of the aortic sac (see p. 214) cranial to the point where it is joined by the sixth pair of aortic arches, and thus the latter become branches of the pulmonary trunk while the remaining arches retain communication with the aorta (**2**.84B).

The separation of the two ventricles from each other leaves the right ventricle in communication (inflow tract) with the right atrium and (outflow tract) the pulmonary artery, and the left ventricle in communication (inflow tract) with the left atrium and an outflow tract via the aorta. This involves a series of complex changes in which three distinct factors contribute to the formation of the *adult ventricular septum*—(*a*) the *fetal ventricular septum*, (*b*) the *proximal bulbar septum* and (*c*) the *atrioventricular endocardial cushions*.



(*a*) During the fifth week the right and left definitive ventricles appear as slight projections on the external surface of the primitive common ventricle. It is uncertain whether the right definitive ventricle is solely a derivative of the common ventricle, or of the caudal end of the primitive bulbus, or of both. In either event, the appearance of a caudal crescentic ridge in the inside of the heart indicates the separation between the two ventricles and, as the heart enlarges, this ridge deepens to form the early *ventricular septum*. The dorsal and ventral horns of the septum grow along the ventricular walls to meet and fuse with the corresponding endocardial cushions of the atrioventricular canal near their *right* extremities (**2**.84A). The septum has a free sickle-shaped margin which, with the endocardial cushions, bounds a circular *interventricular foramen* (**2**.84B).

At first the bulboventricular junction is marked by a distinct notch on the outside of the heart (**2**.82A) and inside is a corresponding *bulboventricular ridge*. The latter between the atrioventricular orifice and the caudal part of the bulb (**2**.84A) and its absorption is essential for the development of a four-chambered heart. Partly by absorption of the bulboventricular ridge and partly growth of the atrioventricular region, the *right* extremity of the atrioventricular canal comes to lie *caudal* to the orifice of the bulb (**2**.84B). This alteration in relative positions of the structures concerned occurs while the ventricular septum is forming, paving the way for completion of ventricular partition (Wenink 1971, 1976).



(*b*) The *proximal bulbar septum* separates the bulbus cordis into pulmonary and aortic channels (*ventricular outflow tracts*), and is formed by the *right* and *left bulbar ridges*, which are in continuity with the corresponding distal bulbar endocardial cushions (which form the *distal bulbar septum*—vide supra). The right bulbar ridge grows across the dorsal wall of the bulb and right extremity of the fused atrioventricular endocardial cushions to reach the dorsal

2.84A Diagram showing an early stage in the relations between the atrioventricular opening and ventricles, the cavity of the bulbus cordis, and the bulboventricular ridge. The endocardial cushions at the distal end of the bulb are shown in a more differentiated state than they really exhibit at this stage. (After J E Frazer.)

2.84B Diagram to show the mode of formation of the septa which separate the aortic and pulmonary channels in the embryonic heart. The red arrow indicates the aortic channel and the blue arrow the pulmonary. The small black arrows indicate the direction of growth. (From a model by James Whillis.)

2.84C Diagram to show the part played by the fusion of the right and left bulbar ridges in the separation of the aortic and pulmonary channels. The darkly shaded area indicates the gap filled by the proliferation of cushion tissue (from the right extremity of the fused atrioventricular cushions) which establishes continuity between the proximal bulbar septum and the ventricular septum. Compare with **2**.84B.

horn of the free, crescentic edge of the ventricular septum and obliterates the ventral or cranial part of the right atrioventricular orifice (**2**.84B). The left bulbar ridge crosses the ventral wall of the bulb to reach the ventral or cranial horn of the ventricular septum. The bulbar ridges fuse thus separating the conus arteriosus of the right ventricle from the aortic vestibule; however, the caudal edge of the bulbar septum is still separated from the free crescentic edge of the ventricular septum by a diminishing interventricular channel. The latter is closed by growth of tissue from the right extremity of the fused atrioventricular cushions (Odgers 1938) and this fuses, on its one aspect with the caudal border of the proximal bulbar septum and on its other with the margin of the ventricular septum. The dorsal part of the bulb largely becomes absorbed, but its position is indicated by the dorsal wall of the aortic vestibule, which, however, is mainly formed by tissue extensions from the fused atrioventricular endocardial cushions.

(*c*) At their time of fusion the *atrioventricular endocardial cushions* are large relative to the size of the atrioventricular orifices. The atrial septal complex meets the approximate centre of the atrial surface of the cushions; the ventricular septum, however, meets them near their right margins. Thus a part of the fused cushions intervenes between the *right atrium* and the *left ventricle*, and it is this which forms the right wall of the aortic vestibule (*atrioventricular septum*, see **6**.34). The *membranous* part of the *interventricular septum*, continuous dorsally with the membranous *atrioventricular septum* in the completed heart (**2**.83C), is also formed by proliferation of cushion tissue from the right extremity of the fused atrioventricular cushions. The persistence of an interventricular communication may follow anomalous development in this region. It may be noted that it is the craniodorsal part of the bulbar orifice, which lies above the ventricular septum (**2**.79B), and normally becomes incorporated in the aortic vestibule through which the left ventricle discharges into the truncal aortic channel. In some cases of persistent interventricular foramen the aortic orifice is described as 'overriding' the free upper border of the muscular interventricular septum (p. 725).

The valve complexes of the heart, four in number, arise in two main cardiac zones: the aortic and pulmonary valves at the distal bulbotruncal junction, the mitral and tricuspid complexes extending from their inception between the atrioventricular junctions and loci on the interior of the ventricular walls. Each commences as an internal endocardial (endothelial) projection of varying form enclosing cardiac mesenchyme (gelatinoreticulum). In some regions the mesenchymatous cells proliferate, transform into fibroblasts, and produce a geometrically organized collagenous framework that varies with site and functional demands. Elsewhere the core is invaded by differentiating cardiac myoblasts.

The *atrioventricular valves* develop as shelf-like projections from the margins of the atrioventricular orifices, directed as almost complete conical sheets towards the ventricles, their advancing edges continuing, initially as trabecular ridges, deep into the ventricular cavity. With continued differential growth and excavation on their ventricular aspects, each sheet develops two (mitral) or three (tricuspid) marginal indentations, defining the principal *valve leaflets*, minor marginal indentations (clefts) subdividing some leaflets into scallops. Each leaflet develops functionally significant regional variations in surface texture; its core condenses as a collagenous lamina fibrosa. The latter blends at its atrioventricular base with the inappropriately named fibroareolar valve 'annulus'—each a part of the complex, functionally crucial, fibrous 'skeleton' of the heart. The intermediate regions of the trabeculae pass between the margins of the leaflets, indentations, clefts and defined zones of the leaflet surface as the white, glistening, compacted, collagenous *chordae tendinae* and these converge towards the tip and sides of the single or grouped *papillary muscles* and blend with their connective tissue framework. The muscles are the ventricular ends of the original trabeculae and, whilst free throughout their length, their mural ends are confluent with mural ventricular musculature and receive a dense population of its nerves and specialized conducting tissues. (For details of the disposition, architecture and some functional implications of the cardiac valve complexes and fibrous skeleton see pp. 702–717.) The *aortic* and *pulmonary valves* are formed from the four endocardial cushions which appear at the distal end of the bulbus cordis. The completion of the distal bulbar septum results in division of each lateral cushion into two; thus the number of thickenings is increased to six: three associated with the pulmonary orifice and three with the aortic. These are the rudiments of the aortic and pulmonary valves. Each cushion-derived intrusion grows and is excavated on its truncal aspect to form a semilunar valve cusp. Similar events affect the adjacent truncal or septal wall. Thus the pouches between the valves and the walls of the vessels gradually enlarge and form their related *sinuses*. The core of each cusp forms a collagenous lamina fibrosa, delicate and thin in each crescentic lunule, thick and compact in the central nodule, with marginal radiate and basal bands. The latter blend with the complex, scalloped, mural valve ring (pp. 715–717). Initially, one cusp of the pulmonary valve lies anteriorly and the other two posterolaterally, whereas one cusp of the aortic valve lies posteriorly and the other two anterolaterally. However, a rotation of the heart to the left before birth changes the orientation of the cusps of the pulmonary and aortic valves and this is reflected in the various schemes for the designation of these cusps in the mature heart (see p. 707-712).

The development of the chambers of the heart has now been traced to a stage at which the main features of the adult heart are established. It is to be noted that the pattern has developed in such a way as to provide for the sudden establishment of the pulmonary circulation at birth (Dawes 1961, 1969), although it is adapted to the persistence of the placental circulation for the remainder of fetal life. The presence of the ductus venosus ensures that a substantial proportion of umbilical oxygenated blood gains the right atrium with a limited loss of oxygen to the liver. However, some umbilical blood and portal venous blood enter the hepatic sinusoids through venae advehentes; their drainage through venae revehentes (eventually the grouped hepatic veins) returns the blood to the hepatic segment of the inferior vena cava, some admixture occurring here. It was claimed that only minor further admixture of relatively oxygenated and deoxygenated blood occurs in the *right* atrium (Barclay et al 1939) and that nearly all the oxygenated blood passes through the foramen ovale into the left atrium, so gaining the *left* ventricle, aorta and systemic circulation. However, there is evidence for the opposing view that there is considerable mixing of the superior and inferior vena caval streams in the right atrium (Born et al 1954, Lind & Wegelius 1954). The inferior vena caval blood is directed by its valve towards the cleft ('foramen ovale') in the atrial septal complex. It has been estimated that about 75% passes through to the left atrium; the remainder mixes with the deoxygenated blood from the superior vena cava; separation occurs at the crista dividens of septum secundum. Because the transition from a placental to a pulmonary circulation occurs suddenly at birth, the right ventricle and the pulmonary trunk of the fetus are relatively large, although only a small amount of blood passes through the lung. Most of the blood expelled by the right ventricle to the pulmonary trunk passes through the ductus arteriosus to the descending aorta and therefore is under higher pressure than blood in the aorta. Thus the muscular wall of the *right* ventricle is *thicker* than the wall of the left, a condition which persists throughout fetal life but is progressively reversed postnatally. The origin of the carotid and subclavian arteries from the aorta above the junction with the ductus arteriosus may be correlated with the relatively rapid growth of the brain, demanding a copious blood supply, with the more advanced development of the upper limbs, relative to the lower, at birth, and the overall cephalocaudal gradient in the growth of the trunk.

In early development the arteries of the embryo are disproportionately large and their walls consist of little more than a single layer of endothelium. The cardiac orifices are also relatively large and the force of the cardiac contraction is weak. As a result, despite the rapid rate of contraction, the circulation is sluggish, but this is compensated for because the tissues are able to draw nourishment, not only from the capillaries but also from the large arteries. As the heart muscle thickens, compacts and strengthens, the cardiac orifices become both relatively and absolutely reduced in size, the valves increase their efficiency and the large arteries

acquire their muscular walls and they too undergo a relative reduction in size. From this time onwards the embryo is dependent for its nourishment on the expanding capillary beds and henceforth the larger arteries' function becomes restricted to controllable distribution channels to keep its tissues constantly and appropriately supplied.

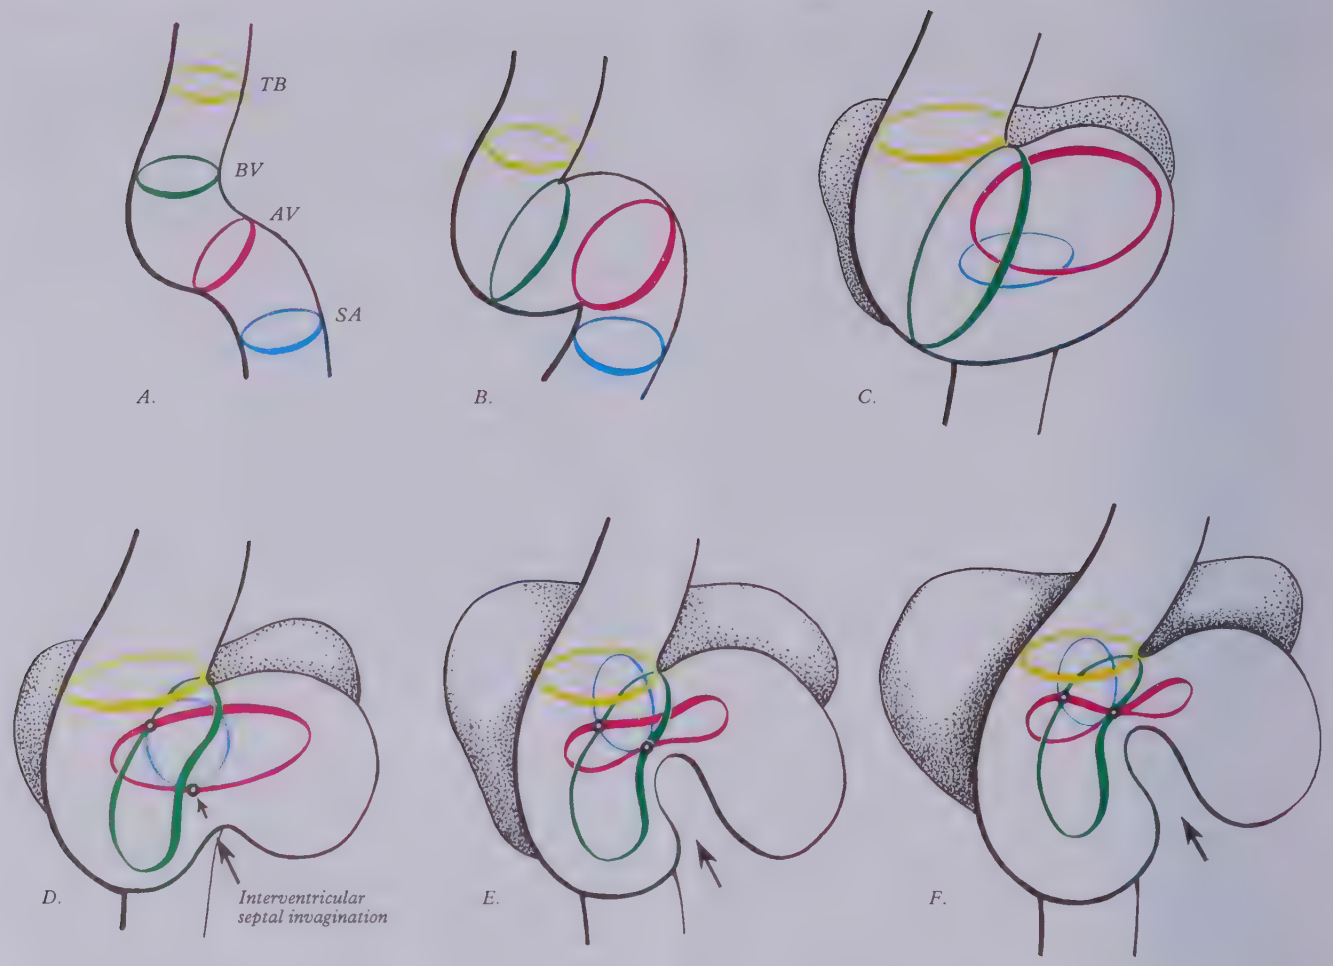
The conducting system of the heart is histologically identifiable towards the middle of the sixth week of embryonic life. Some claim that first to appear is the *atrioventricular node* developing as an outgrowth from the dorsal part of the muscular ring surrounding the atrioventricular canal. On this view the *atrioventricular bundle* is a subsequent extension which passes distally behind the dorsal endocardial cushion thence along the dorsal part of the curved free edge of the muscular ventricular septum, where it gives rise first to the left and then to the right limbs of the bundle (Shaner 1929, Walls 1947). Others maintain that the stem of the atrioventricular bundle appears first as a derivative of the musculature of the dorsal wall of the atrioventricular canal. From this, differentiation spreads both proximally to form the atrioventricular node and distally to form the right and left limbs of the bundle (Field 1951, Muir 1954). Whichever view is subscribed to, after completion of septation in the normal heart, the atrioventricular conducting tissue elements occupy precise sites or courses. The atrioventricular node lies deep to the septal endocardium of the right atrium in the triangle of Koch (for details see p. 703, **6**.34). The main atrioventricular bundle proceeds through a channel traversing the *central fibrous body* (right fibrous trigone), then curves along the posterior and posteroinferior margins of the *pars membranacea septi* (atrioventricular and interventricular parts) to reach its locus of division over the crest of the muscular septum. From diverging fascicles of the main bundle branches a subendocardial terminal network of conducting cells (classic specialized Purkinje myocytes) spread to all myocardial parts of the ventricular walls; the net is particularly dense around the bases of the papillary muscles. Finally, fibres from the network enter the myocardial tissue of the ventricles; the patterned array of their ultimate contacts with general cardiac myocytes is, as yet, undetermined (p. 722).

The *sinuatrial node* is the last part of the conducting system to appear, but its site is indicated by an aggregation of nerve cells and fibres in the wall of the superior vena cava just above its junction with the atrium, before nodal tissue itself can be recognized late in the third month. A narrow band of muscle in the ventrolateral surface of the superior vena cava is modified into the characteristic adult histological structure (p. 720). Although at first caval in position, in late fetal life it becomes incorporated into the atrial wall at the upper end of the sulcus terminalis. Its cranial edge, however, remains in continuity with the muscular coat of the vessel, although elsewhere it makes multiple contacts with the muscular wall of the atrium. The node does not appear until the right horn of the sinus venosus has been incorporated in the right atrium. Sinuatrial nodal tissue appears at an early relative stage in some rodents and recently a *left* sinuatrial node has been described in the murine embryo (Heintzberger 1974) as a transient structure. The occurrence of such a bilateral symmetry has been hypothecated in mankind but not substantiated (Patten 1956).

Studies of conducting tissue development in human embryos emphasize the basic difficulty of identifying such tissue, particularly in its initial stages of differentiation (Wenink 1976). The earlier views, stated above, which derived elements of the conducting system by extensions from localized parts of only two of the muscular rings between successive chambers of the primitive heart tube, were given limited confirmation. However, Wenink (1976) claimed that parts of *all four interchamber rings* (sinuatrial, atrioventricular, ventriculobulbar and truncobulbar) were involved. Following the complex repositioning of the rings during folding and growth of the cardiac tube many parts of the rings retrogress, others variously invaginated, fused, subdivided or extended into surrounding myocardium. From these, it was proposed, the whole system developed (**2**.85,86). It may be noted that the 'four ring hypothesis' when followed in detail could provide a possible explanation of the less widely accepted tracts mentioned below (and pp. 721–722), also the siting of nodal tissue in certain cardiac anomalies.

Controversy persists concerning the development, architecture, operation, or even the existence, of further specialized conductive tissue elements. The latter involve the mode of spreading of intermittent waves of excitation, generated by the rhythmic activity of the sinuatrial nodal tissue, to encompass *both* atria, to converge on the atrioventricular node and proximal bundle, thence to invade the ventricular walls through the ramifications of the main atrioventricular bundle and possibly other (occasional) atrioventricular connections. Some hold that sinuatrial excitation pervades the atrial walls through fascicles of ordinary 'working' cardiac myocytes and the nexuses (electrical couplings) between them. Thus variations in ionic current flow paths and velocities would result from the geometry of the atrial walls, e.g. the position and calibre of the large venous orifices, mural thickness differences over grooves, fossae, ridges, eminences etc. and presumably any rectilinear polarization of the fascicular cardiac myocytes and their nexuses. Others maintain, however, that excitatory dispersion occurs initially along tracts and networks of specialized conducting tissue. In general these may be classed as: *atrial*, to the walls of the right atrium; *interatrial*, crossing the interatrial septal complex from right to left atrium; *internodal* (anterior, middle and posterior *tracts*), converging on aspects of the atrioventricular node; *bypass fibres* joining the nodal end of the atrioventricular bundle directly; finally, slender, irregular, *accessory atrioventricular bundles* may occur at any point in the atrioventricular fibrous annuli (for further details see pp. 721–722.)

The *intrinsic nerves* of the heart, consisting of groups of ganglion cells associated with the great arteries, atria, and atrioventricular grooves, together with a developing epicardial plexus, are observable from the 15 mm stage (Navaratnam 1965, Smith 1970). Later, atrial and ventricular myocardia, coronary vessels and conducting tissues are involved. For a highly detailed description of the state of development of the *extrinsic nerves* of the heart in a human embryo of 8 weeks consult Smith (1971), and Gardner and O'Rahilly (1976). For a review of autonomic cardiac innervation see Gabella (1976); and for a bibliography on control of the fetal circulation see Mott (1982). Further details pp. 722, 723.



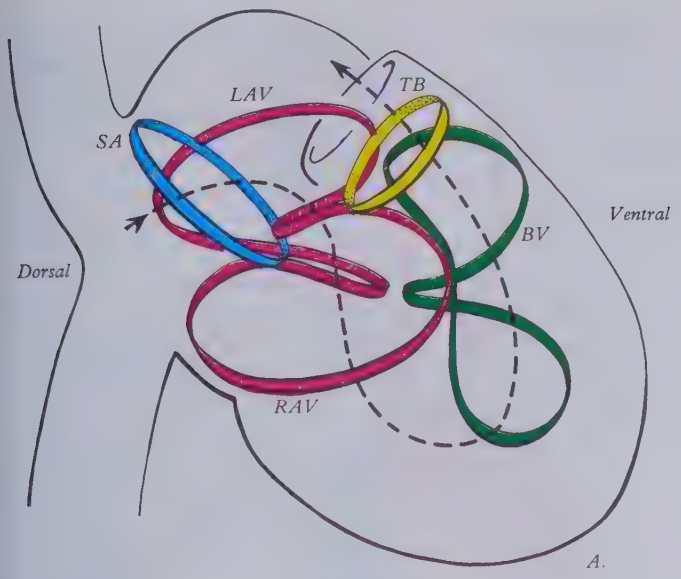
It will be noted that the heart commences to beat early prior to the development of the conducting system, and that a circulation is established before a competent valvular mechanism. The latter has been associated (Streeter 1945) with the incompressible but displaceable cardiac jelly occupying the myoendocardial interval.

FURTHER DEVELOPMENT OF THE ARTERIES

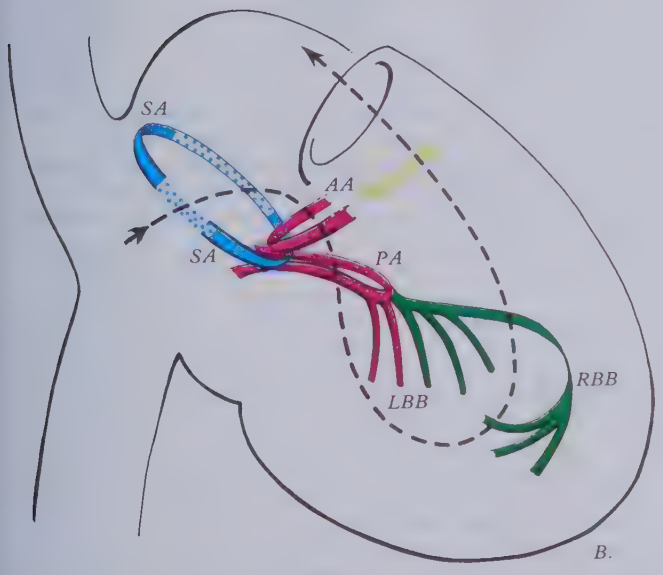
Apart from the aortae none of the main vessels of the adult arise as single trunks in the embryo. Along the course of each vessel a capillary network is first laid down and by selection and enlargement of definite paths in this the larger arteries and veins are defined. The branches of main arteries are not always simple modifications of the vessels of a capillary network but arise as outgrowths from the enlarged stem.

As mentioned, subsequent to head fold formation each primitive aorta consists of ventral and dorsal parts which are continuous through the first embryonic aortic arch. The dorsal aortae run caudally, one on each side of the notochord, but in the fourth week they fuse from about the level of the fourth thoracic to that of the fourth lumbar segment to form a single *definitive descending aorta*. Although in many animals paired ventral aortae arise from the truncus arteriosus and course headwards on the ventral surface of the pharynx, in the human embryo the ventral aortae are fused and form a dilated *aortic sac* (see **2**.87A and consult Congdon 1922). The first aortic arches run through the mandibular arches, and caudal to them five additional pairs are developed within the corresponding branchial arches so that in all six pairs of aortic arches are formed (**2**.88A). The fifth arches are atypical and probably transient, at most, in mankind.

In fishes the aortic arches persist and give off branches to the gills, in which the blood is oxygenated. In mammals some of the



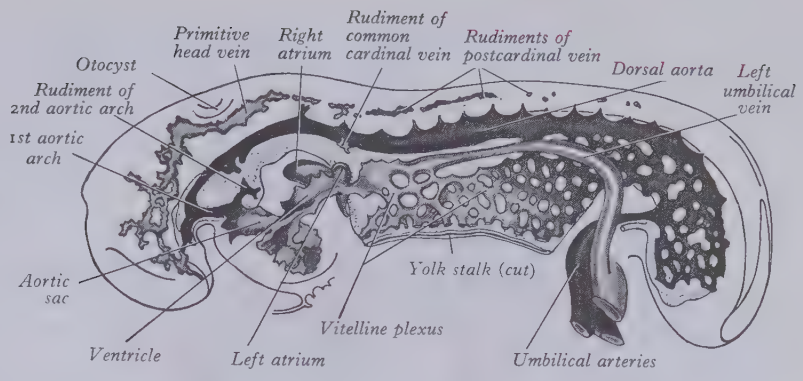
2.85 Development of the cardiac conducting system: the *'four ring' theory*. The successive regions of the early cardiac tube are separated by four initially complete rings of interzonal specialized myocardium, coloured here to aid identification and named: SA — sinuatrial; AV — atrioventricular; BV — bulboventricular; and TB — truncobulbar. With progressive folding, differential expansion and mural changes, and the onset of septation, the positions, planes and shapes of the rings are profoundly modified. In figures A-F the alterations in the cardiac outline and rings are shown from the ventral aspect; in the mural tissue forming the floor of the bulboventricular and atrioventricular grooves loci where originally separated rings make secondary contact and become confluent are indicated.



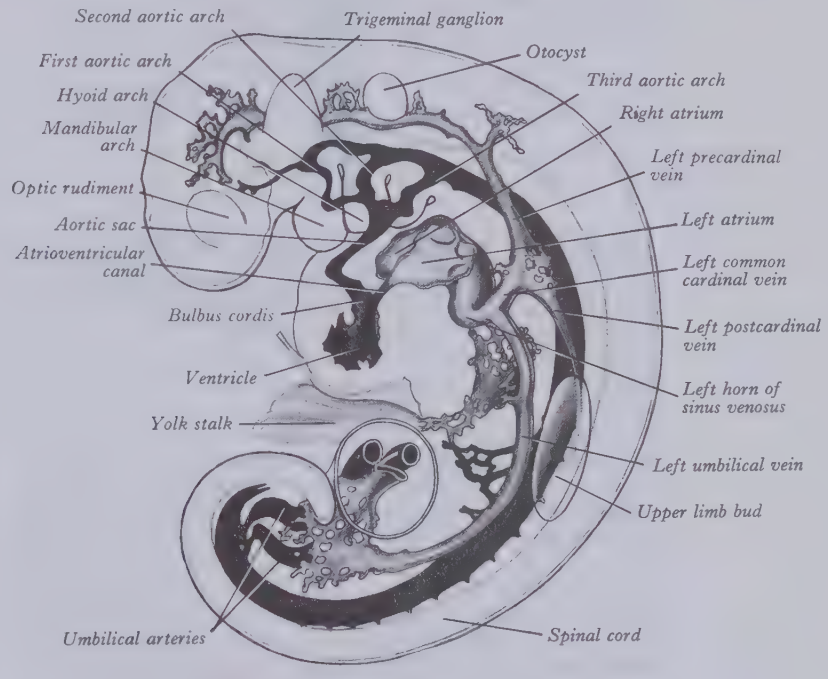
arteries remain as permanent structures, while others disappear or are obliterated (**2**.88A-C).

Caution should moderate unqualified use of the term *aortic arch(es)*. The *embryonic aortic arches* are paired bilateral series joining the ventral aortae (or their fused expanded homologue) with the dorsal aorta of its side after traversing the core of a branchial arch. In contrast the *definitive aorta* consists of ascending aorta, aortic arch and descending (thoracic and abdominal) aorta—all parts of a single vessel in the mature state (but derived from multiple embryonic sources). For one detailed analysis see **2**.88A-C.

The aortic sac represents fused, paired ventral aortae (**2**.87A, B). As the embryo grows and the aorticopulmonary septum is formed part of the caudal end of the sac is incorporated in the pulmonary trunk. The cranial end of the sac becomes drawn out into *right* and *left limbs* as the neck lengthens. The right limb becomes the brachiocephalic trunk and the left limb forms that part of the definitive arch of the aorta which lies between the origin of the brachiocephalic trunk and the left common carotid artery. The remainder of the sac contributes to the formation of the ascending arch of the aorta.

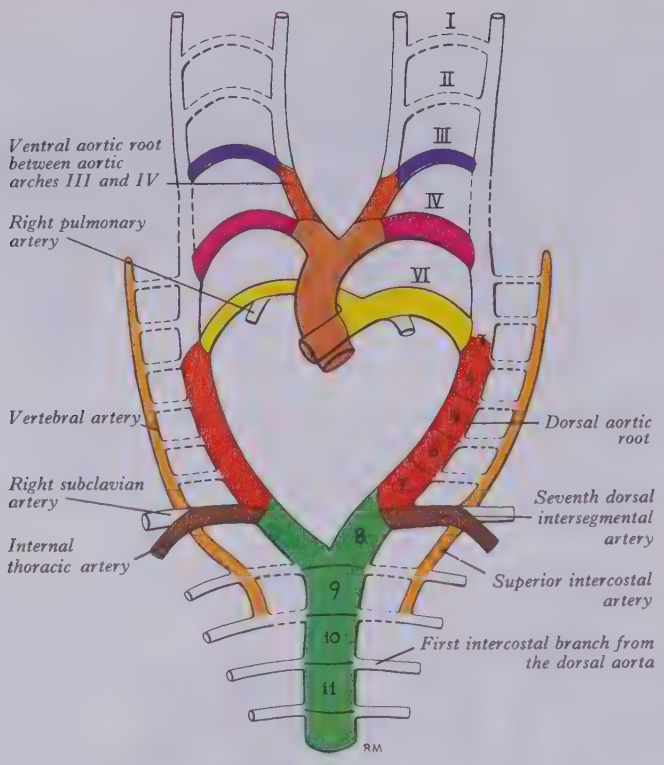


The embryonic aortic arches (**2**.88A-C), with the exception of the fifth, are developed in a craniocaudal sequence, but the more cranial are in process of disappearing before the caudal ones are completed. The *first* and *second embryonic aortic arches* are already dwindling by the time the third is established. The first disappears entirely. The dorsal end of the second arch or *hyoid artery* remains as the stem of the *stapedial artery*, while the remainder of this arch artery also disappears (**2**.89). The external carotid artery first appears as a sprout which grows headward from the aortic sac close to the ventral end of the third arch artery. The common carotid arises from an elongation of the adjacent part of the aortic sac, and the third arch artery becomes the proximal part of the internal carotid artery. (Evidence against this view, however, has also been recorded: e.g. see Moffat 1959, Adams 1957.) The *fourth embryonic aortic arch* on the right forms the proximal part of the right subclavian artery, whilst the corresponding vessel on the left is believed to constitute the arch of the definitive aorta between the origins of the left common carotid and left subclavian arteries. It has, however, proved difficult to assess accurately the contributions of the *fourth embryonic aortic arches* and it has also been variously claimed that the left fourth aortic arch is subsequently drawn into the descending or ascending (or both) limbs of the *definitive aortic arch*, and the corresponding vessel on the right contributes to the brachiocephalic artery. The identity and status of the *fifth embryonic arch artery* is uncertain; it is usually incomplete and may connect the fourth aortic arch or subjacent aortic sac with the dorsal end of the sixth aortic arch (whereas the other embryonic aortic arches pass between sac and dorsal aorta). The fifth aortic arch eventually disappears on both sides. From its inception the *sixth embryonic arch vessel* is associated with a developing lung bud. Initially each bud is supplied by a capillary plexus from the aortic sac. Only later the plexus connects with the dorsal aorta and the sixth aortic arch is defined as a channel in the vascular connection between sac and dorsal aorta; however, this continues to supply the developing lung bud. When the aorticopulmonary septum divides the *truncus arteriosus* into pulmonary trunk and ascending aorta the sixth

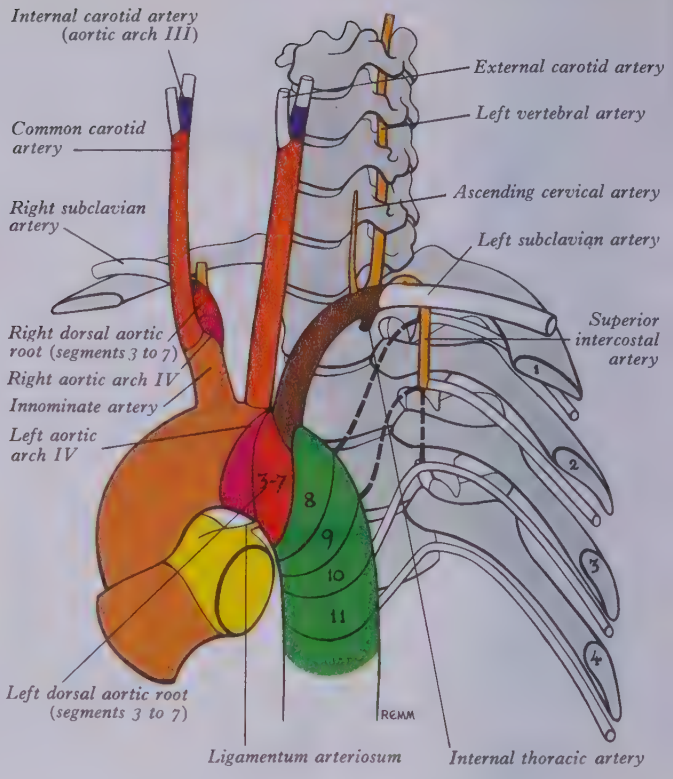


2.86 An approximation of the general cardiac outline and the interzonal ring system after folding, and advancing septation, viewed from the right lateral aspect. In A the rings are represented as complete, but modified. TB —the single truncobulbar ring retains its simple circular form, truncobulbar septation is ignored. BV—the bulboventricular ring displays a deep antero-posterior invagination, reflecting ventricular septation. The atrioventricular ring is divided by subendocardial cushions and associated invaginations (deep anterior, deeper posterior) into left (LAV) and right (RAV) parts. The sinuatrial ring (SA) remains circular but approaches the AV invaginations. The apex of the posterior AV invagination approaches that of the BV ring.

In B parts of the rings retrogress; the regions proposed as contributing to widely accepted parts of the conducting system are shown. SA — dorsocranially forms sinuatrial tissue. Ventrocaudally SA joins AA and PA (anterior and posterior atrioventricular invaginations), forming atrioventricular nodal tissue. PA continues as the common A-V bundle; then is continuous with BV ring invagination. LBB — 'fan' of left bundle branches of dual origin (PA and BV); RBB — compact right bundle branch and terminal divisions; single BV ring origin. TB — stipple, merges with aortic vestibule. SA — stipple, possible origin of more controversial intermodal and interatrial pathways. (Modified after Wenink 1976, with permission from *Journal of Anatomy*.)



2.87A The blood vascular system of a human embryo with 14 paired somites. Estimated age, $23\frac{1}{2}$ days. CR length 2.4 mm. Magnification × *c.* 45. The arteries and veins are only in process of development, so that no true circulation is possible at this stage. Only the endothelial lining of the heart tube is shown. (Streeter 1942.)



2.87B Profile reconstruction of the blood vascular system of a human embryo, having 28 somites. CR length, 4 mm. Estimated age, 26 days. *Note*. Only the endothelial lining of the heart chambers is shown and, as the muscular wall has been omitted, the pericardial cavity appears much larger than the contained heart. Observe that the atrioventricular canal still connects the left atrium with the single ventricle. (Streeter 1942.)

aortic arches retain continuity with the former. On the right the ventral part of the sixth aortic arch persists as the stem of the right pulmonary artery, but its dorsal segment disappears, possibly due to a decreased blood flow resulting from partitioning of the aortic and pulmonary bloodstreams (Navaratnam 1963). On the left side the ventral part of the sixth aortic arch is absorbed into the pulmonary trunk, while its dorsal segment persists as the *ductus arteriosus*, which is functional during intrauterine life but becomes obliterated after birth ultimately forming the fibrous *ligamentum arteriosum*. Postnatal *functional* closure nears completion within a few weeks but *structural* changes continue over many months (p. 724).

The transformation of the aortic arches described above is conditioned by environmental changes and results largely from changes in the pharynx and from the descent of the heart. The whole period of transformation can be divided into two phases, branchial and postbranchial. In the *branchial phase*, which lasts until about the 12 mm crown–rump length stage, the arrangement of the aortic arches resembles that in lower vertebrates. In this phase the course of the blood from the heart to the dorsal aorta follows a succession of different pathways—first arch, first and second arches, second and third arches, third and fourth aortic arches and finally third, fourth and sixth aortic arches. In the *postbranchial*

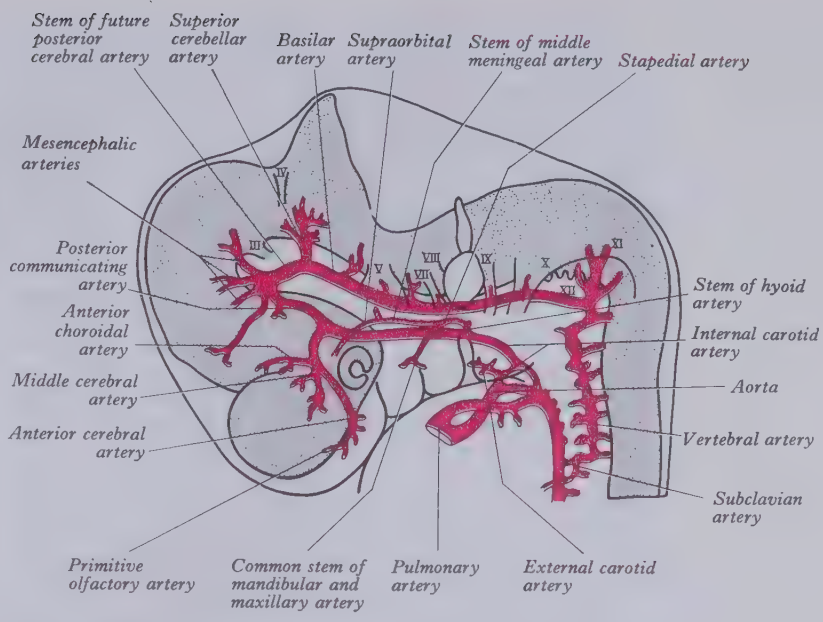
phase, which extends onwards into, and beyond, intrauterine life the definitive human pattern and disposition of the vessels is finally established.



The cranial arteries (2.89) develop in outline as follows (Padget 1948). The *internal carotid artery* is progressively formed from the third arch artery, the dorsal aorta cranial to this and a further forward continuation which differentiates, at the time of regression of the first and second aortic arches, from the capillary plexus extending to the walls of the forebrain and midbrain. At its anterior extremity this *primitive internal carotid artery* divides into *cranial* and *caudal* divisions, the former terminating as the *primitive olfactory artery*, supplying the developing regions implied, and the latter sweeping caudally to reach the ventral aspect of the midbrain, its terminal branches being the

primitive mesencephalic arteries. Simultaneously bilateral longitudinal channels differentiate along the ventral surface of the hindbrain from a plexus fed by intersegmental and transitory presegmental branches of the dorsal aorta and its forward continuation. The most important of the presegmental branches is closely related to the fifth nerve—the *primitive trigeminal artery*. *Otic* and *hypoglossal* presegmental arteries also occur (Padget 1948); sometimes these persist. The longitudinal channels later connect, cranially, with the caudal divisions of the internal carotid arteries, each of which gives rise to an *anterior choroidal artery* supplying branches to diencephalon and midbrain, and caudally with the vertebral arteries through the first cervical intersegmental arteries. Fusion of the longitudinal channels results in the formation of the *basilar artery*, whilst the caudal division of the internal carotid artery becomes the *posterior communicating artery* and the stem of the *posterior cerebral artery*. The remainder of the latter develops comparatively late, probably from the stem of the posterior choroidal artery which is annexed by the caudally expanding cerebral hemisphere, its distal portion becoming a choroidal branch of the posterior cerebral artery. In the rat, where the vascular pattern is essentially similar to that in man, this artery is derived from the posterior communicating artery, the common stem of origin of the posterior choroidal, mesencephalic and diencephalic arteries, together with a new channel formed in the plexus on the medial wall of the cerebral hemisphere initially supplied by the anterior choroidal artery (Moffat 1961a). The cranial division of the internal carotid artery gives rise to *anterior choroidal, middle cerebral* and *anterior cerebral arteries*, the stem of the primitive olfactory artery remaining as a small medial striate branch of the anterior cerebral artery. In the rat the primitive olfactory artery and its recurrent branch form the anterior cerebral artery, the territory of which is initially supplied by the primitive maxillary and the cranial ramus of the internal carotid arteries (Moffat 1961b). The *cerebellar arteries*, of which the superior is the first to differentiate, emerge from the capillary plexus on the wall of the rhombencephalon.

Source of blood supply to the territory of the trigeminal nerve varies at different stages in development. When the first and second aortic arch arteries begin to regress the supply to the corresponding arches is derived from a transient *ventral pharyngeal artery*, which grows from the aortic sac. It terminates by dividing into *mandibular* and *maxillary branches*. Later the *stapedial artery* develops from the dorsal stem of the second arch artery and passes through the condensed mesenchymal site of the future ring of the stapes to anastomose with the cranial end of the ventral pharyngeal artery thereby annexing its terminal distribution. The fully developed stapedial artery possesses three branches, *mandibular, maxillary* and *supraorbital*, which follow the divisions of the trigeminal nerve (**2**.89). The mandibular and maxillary branches diverge from a common stem. When the external carotid artery emerges from the base of the third arch it incorporates the stem of the ventral pharyngeal artery, and its maxillary branch communicates with the common trunk of origin of the maxillary and mandibular branches of the stapedial artery and annexes these vessels. The proximal part of the common trunk persists as the root of the *middle meningeal artery*. More distally the meningeal artery is derived from the proximal part of the supraorbital artery. The maxillary branch becomes the infraorbital artery and the mandibular branch forms the inferior alveolar artery.

When the definitive *ophthalmic artery* differentiates as a branch from the terminal part of the internal carotid artery, it communicates with the supraorbital branch of the stapedial artery; distally this becomes the *lacrimal artery*. The latter retains an anastomotic connection with the middle meningeal artery. The dorsal stem of the original second arch artery remains as one or more *caroticotympanic branches* of the internal carotid artery.

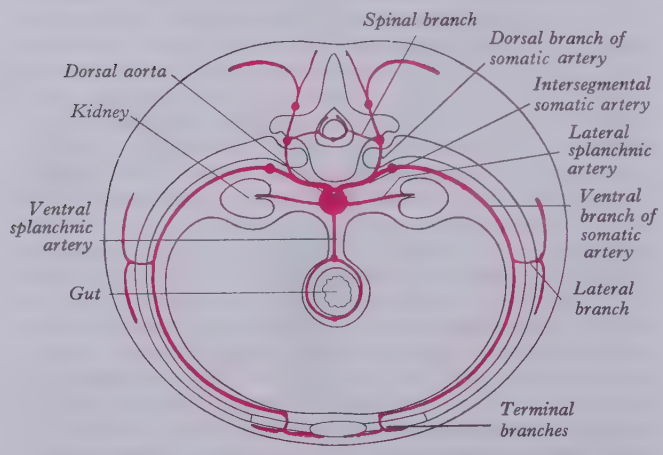
The dorsal aortae (**2**.88A-C) persist on the cranial side of the third aortic arches as continuations of the internal carotid arteries. The dorsal aorta between the third and fourth aortic arches, the *ductus caroticus*, diminishes and finally disappears; but from fourth arch to the origin of the seventh intersegmental artery the right dorsal aorta becomes part of the right subclavian artery (**2**.88A-C). Caudal to the seventh intersegmental artery the right dorsal aorta disappears as far as the locus of fusion of thoracic

2.89 Diagram to show the origins of the main cranial arteries. (After Padget 1948.)

aorta. After disappearance of the left ductus caroticus. The remainder persists to form the descending part of the arch of the aorta. Thence the fused right and left embryonic dorsal aortae persist as the definitive descending thoracic and abdominal aorta. A constriction, the *aortic isthmus*, is sometimes present in the aorta between the final site of origin of the left subclavian artery and reception of the ductus arteriosus (see *coarctation* of the aorta, p. 766).

In the adult, the right subclavian artery occasionally arises from the arch of the aorta distal to the origin of the left subclavian and then passes upwards and to the right behind the trachea and oesophagus. This condition is possibly explained by the persistence of the embryonic right dorsal aorta and the obliteration of the fourth aortic arch of the right side.

In birds the right fourth aortic arch is transformed into the definitive arch of the aorta; in reptiles the fourth arches of both sides persist and give rise to their characteristic double aortic arch. In both these classes, development of the heart and aortic arches is probably along phylogenetic lines so divergent from the mammalian pattern that comparisons may be inappropriate.



The heart originally lies ventral to the pharynx, immediately caudal to the stomatodeum (**2**.87A); with the elongation of the neck and the development of the lungs it recedes within the thorax and, correspondingly, the vessels are drawn out and the original position of the fourth and sixth aortic arches is greatly modified. Thus, on the right the fourth aortic arch only recedes to the thoracic inlet, while on the left side it descends *into* the thorax. The recurrent laryngeal nerves (in contrast to the other arch nerves) originally pass to the larynx *caudal* to the sixth pair of aortic arches, and are therefore affected by the descent of these structures; thus in the adult the left nerve hooks round the ligamentum arteriosum *within* the thorax; on the right owing to the disappearance of the fifth and the dorsal part of the sixth aortic arch, the right recurrent laryngeal nerve hooks round the fourth aortic arch, i.e. the commencement of the right subclavian artery.

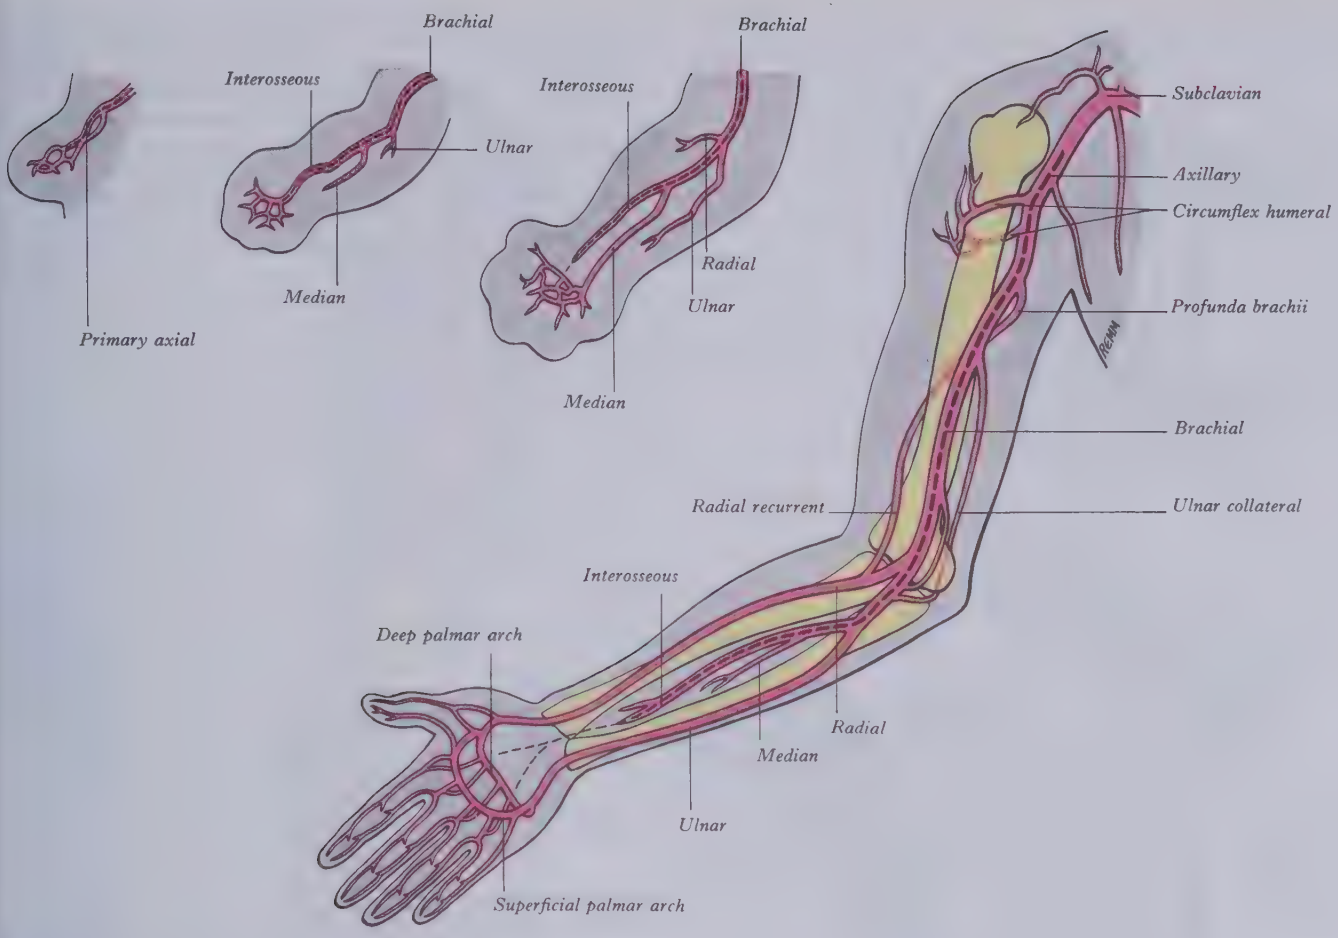
At first the aortae are the only longitudinal vessels present, for their branches all run at right angles to the long axis of the embryo. Later these transverse arteries become connected in certain situations by longitudinal anastomosing channels, which in part persist, forming such arteries as the internal thoracic, the superior and inferior epigastric, the gastro-epiploic, etc. Each primitive dorsal aorta gives off *segmental* branches to the digestive tube (*ventral splanchnic arteries*) and to the mesonephric ridge (*lateral splanchnic arteries*) and *intersegmental* branches to the body wall (*somatic arteries*).

The ventral splanchnic arteries are originally paired vessels which are distributed to the capillary plexus in the wall of the yolk sac, but after fusion of the dorsal aortae they merge as unpaired trunks distributed to the increasingly defined and lengthening primitive digestive tube. Longitudinal anastomotic channels connect these branches along the dorsal and ventral aspects of the tube, forming dorsal and ventral splanchnic anastomoses (2.90) (Ennabli & Niveiro 1967). These vessels obviate the need for so many 'subdiaphragmatic' ventral splanchnic arteries, and these are reduced to three: the coeliac trunk and superior and inferior mesenteric arteries. As the viscera supplied descend into the abdomen their origins migrate caudally, by differential growth; thus the origin of the coeliac artery is transferred from the level of the seventh cervical segment to the level of the twelfth thoracic, the superior mesenteric from the second thoracic to the first lumbar and the inferior mesenteric from the twelfth thoracic to the third lumbar. (Above the diaphragm, however, a variable number of ventral splanchnic arteries persist, usually four or five, supplying the thoracic oesophagus.) The dorsal splanchnic anastomosis persists in the gastro-epiploic, pancreaticoduodenal and the primary branches of the colic arteries, while the ventral splanchnic anastomosis forms the right and left gastric and the hepatic arteries. These arterial rearrangements have been investigated recently by angiography and explanatory haemodynamic hypotheses have been advanced (Barth et al 1976).

The lateral splanchnic arteries supply, on each side, the mesonephros, metanephros, the testis or ovary, and the suprarenal gland; all these structures develop, in whole or in part, from the intermediate mesoderm of the mesonephric ridge (p. 248). One testicular or ovarian artery and three suprarenal arteries persist on each side. The phrenic artery branches from the most cranial suprarenal artery, and the renal artery arises from the most caudal. Additional renal arteries are frequently present and may be looked on as branches of persistent lateral splanchnic arteries.

The somatic arteries are *intersegmental* in position and they persist, almost unchanged, in the thoracic and lumbar regions, as the posterior intercostal, subcostal and lumbar arteries. Each gives off a dorsal ramus which passes backwards in the intersegmental interval and divides into medial and lateral branches to supply the muscles and superficial tissues of the back (2.90). It also gives off a spinal branch, which enters the vertebral canal and divides into a series of branches to the tissues constituting the walls and joints of the osteoligamentous canal and neural branches to the spinal cord and spinal nerve roots (Somogyi et al 1973, Undi et al 1973). Having produced its dorsal branch the intersegmental artery runs ventrally in the body wall, gives off a lateral branch and terminates in muscular and cutaneous rami. Before their division, the stems of the somatic arteries, at thoracic and lumbar levels, provide small rami which enter the developing vertebral bodies.

2.90 Diagram of the segmental and intersegmental arteries. Note the positions of the longitudinal anastomoses.



Numerous longitudinal anastomoses link up the intersegmental arteries and their branches (2.90). On both sides a *postcostal anastomosis* connects their dorsal branches in the intervals between the necks of ribs and the vertebral transverse processes. This persists in the cervical region where it forms the greater part of the vertebral artery. A *post-transverse anastomosis* also connects the dorsal branches and forms the greater part of the deep cervical artery. A *precostal anastomosis* connects intersegmental arteries beyond the origins of their dorsal branches. The ascending cervical and the superior intercostal arteries are persistent parts of this vessel. Lastly, near the anterior median line intersegmental arteries are linked by a *ventral somatic anastomosis*. Most of these vessels persist bilaterally as the internal thoracic, the superior and inferior epigastric arteries.

The *umbilical arteries* at first are the direct caudal continuation of the primitive dorsal aortae and are present in the body stalk before any vitelline (yolk sac) or visceral branches emerge, indicating the dominance of the chorionic over the vitelline circulation in the human embryo. (On a comparative basis the umbilical vessels are chorioallantoic and therefore 'somatovisceral'.) After the fusion of the dorsal aortae the umbilical arteries arise from their ventrolateral aspects and pass medial to the primary excretory duct (Wolffian) to the umbilicus. Later the proximal part of each umbilical artery is joined by a new vessel which leaves the aorta at its termination and passes lateral to the primary excretory duct. This, possibly the fifth lumbar intersegmental artery, constitutes the *dorsal root* of the umbilical artery (the original stem, the *ventral root*). The dorsal root gives off the axial artery of the lower limb, branches to the pelvic viscera and, more proximally, the external iliac artery. The ventral root disappears entirely, the umbilical artery now arising from that part of its dorsal root distal to the external iliac artery, i.e. the internal iliac artery.

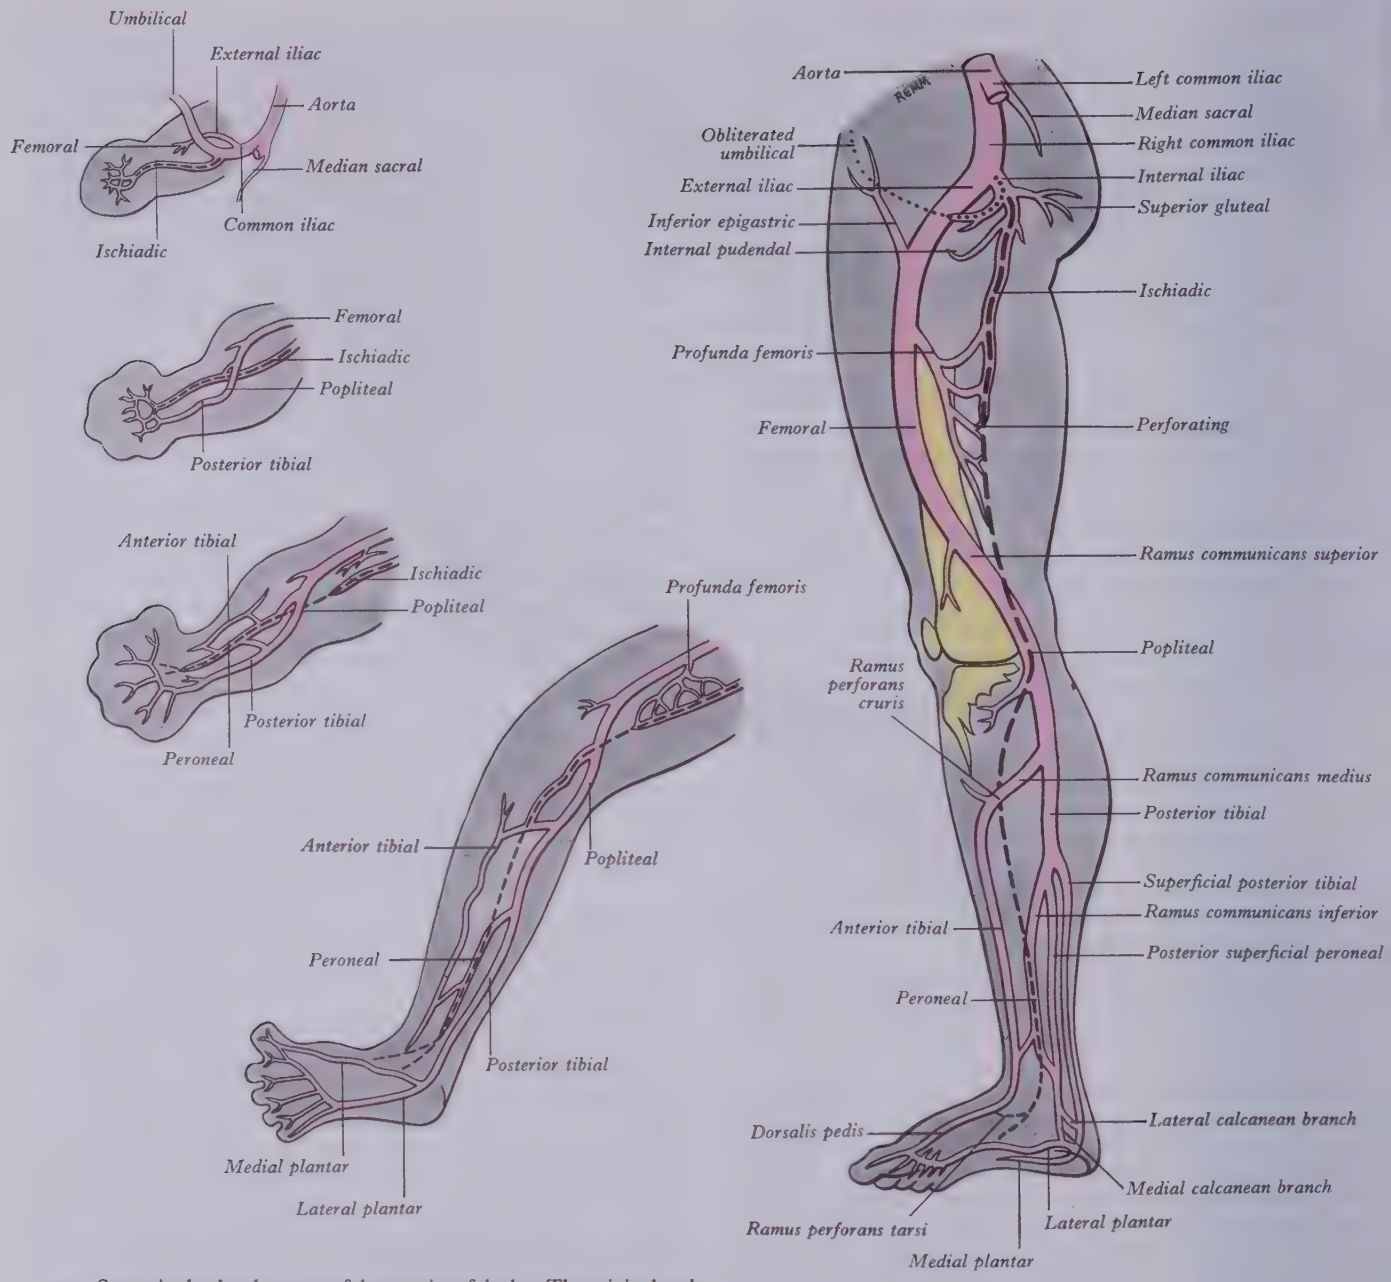
The arteries of the limbs: initially a number of vessels contribute to a primitive capillary plexus. In the upper limb bud, usually only one trunk—the subclavian—persists and it probably represents the lateral branch of the *seventh intersegmental artery*. Its main continuation (*axis artery*) to the upper limb (2.91), later the *axillary* and *branchial arteries*, passes into the forearm deep to the flexor muscle mass and terminates as a deep plexus in the developing hand. This vessel ultimately persists as the *anterior interosseous artery* and the *deep palmar arch*. A branch from the main trunk passes dorsally between the early radius and ulna as the *posterior interosseous artery*, while a second accompanies the median nerve into the hand, where it ends in a *superficial capillary plexus*. The *radial* and *ulnar arteries* are the latest arteries to appear in the forearm; at first the radial artery arises more proximally than the ulnar and crosses in front of the median nerve, supplying the biceps. Later, the radial artery establishes a new connection with the main trunk at or near the level of origin of the ulnar artery and the upper portion of its original stem usually disappears to a large extent (see also p. 759). On reaching the hand the ulnar artery becomes linked up with the superficial palmar plexus, from which the *superficial palmar arch* is derived, while the median artery commonly loses its distal connections and is reduced to a small vessel. The radial artery passes to the dorsal surface of the hand but, after giving off dorsal digital branches, it traverses the first intermetacarpal space and joins the deep palmar arch.

Because of their multiple and plexiform sources, the temporal succession of emergence of principal arteries, anastomoses and periarticular networks and functional dominance followed by regression of some paths, anomalies of the forelimb arterial tree are fairly common. In the main, such anomalous patterns present as divergences in the mode and proximodistal level of branching, the presence of unusual compound arterial segments, abberrant vessels connecting other principal vessels, arcades or plexuses and vessels occupying exceptional tissue planes (e.g. superficial fascia instead of the usual subfascial route) or having unexpected neural, myological or osteoligamentous relationships. For example, see variations on pp. 758, 759, 760, 762.

The *axis artery* of the lower limb (2.92) arises from the dorsal root of the umbilical artery, and courses along the *dorsal* surface of the thigh, knee and leg; below the knee it lies between tibia and popliteus and in the leg between the crural interosseous

2.91 Stages in the development of the arteries of the arm. The original path of the axis artery is indicated by an interrupted line. (After Patten.)

membrane and tibialis posterior. Ending distally in a *plantar network*, it gives off a perforating artery traversing the sinus tarsi to form a *dorsal network*. The *femoral artery* passes along the *ventral* surface of the thigh, opening a new channel to the lower limb. It arises from a capillary plexus, connected proximally with the femoral branches of the external iliac artery and distally with the axis artery. At the proximal margin of the popliteus the axis artery provides a *primitive posterior tibial* and a *primitive peroneal branch*, which run distally on the dorsal surface of that muscle and on tibialis posterior to gain the sole of the foot. At the distal border of popliteus the axis artery gives off a *perforating branch*, which passes ventrally between the tibia and the fibula and then courses to the dorsum of the foot, forming the *anterior tibial artery* and *arteria dorsalis pedis*. The primitive peroneal artery communicates with the axis artery at the distal border of the popliteus and in its course in the leg (Senior 1919, 1920).



The femoral artery gradually increases in size and coincidentally most of the axis artery disappears; proximal to its communication with the femoral the root of the axis artery, however, persists as the *inferior gluteal artery* and the *arteria comitans nervi ischiadici*.

The proximal parts of the primitive posterior tibial and peroneal arteries fuse, but distally remain separate. Ultimately much of the primitive peroneal artery disappears, although a part of the axis artery is incorporated in the permanent peroneal artery. As in the forelimb (above) the same considerations apply to anomalies and variations.

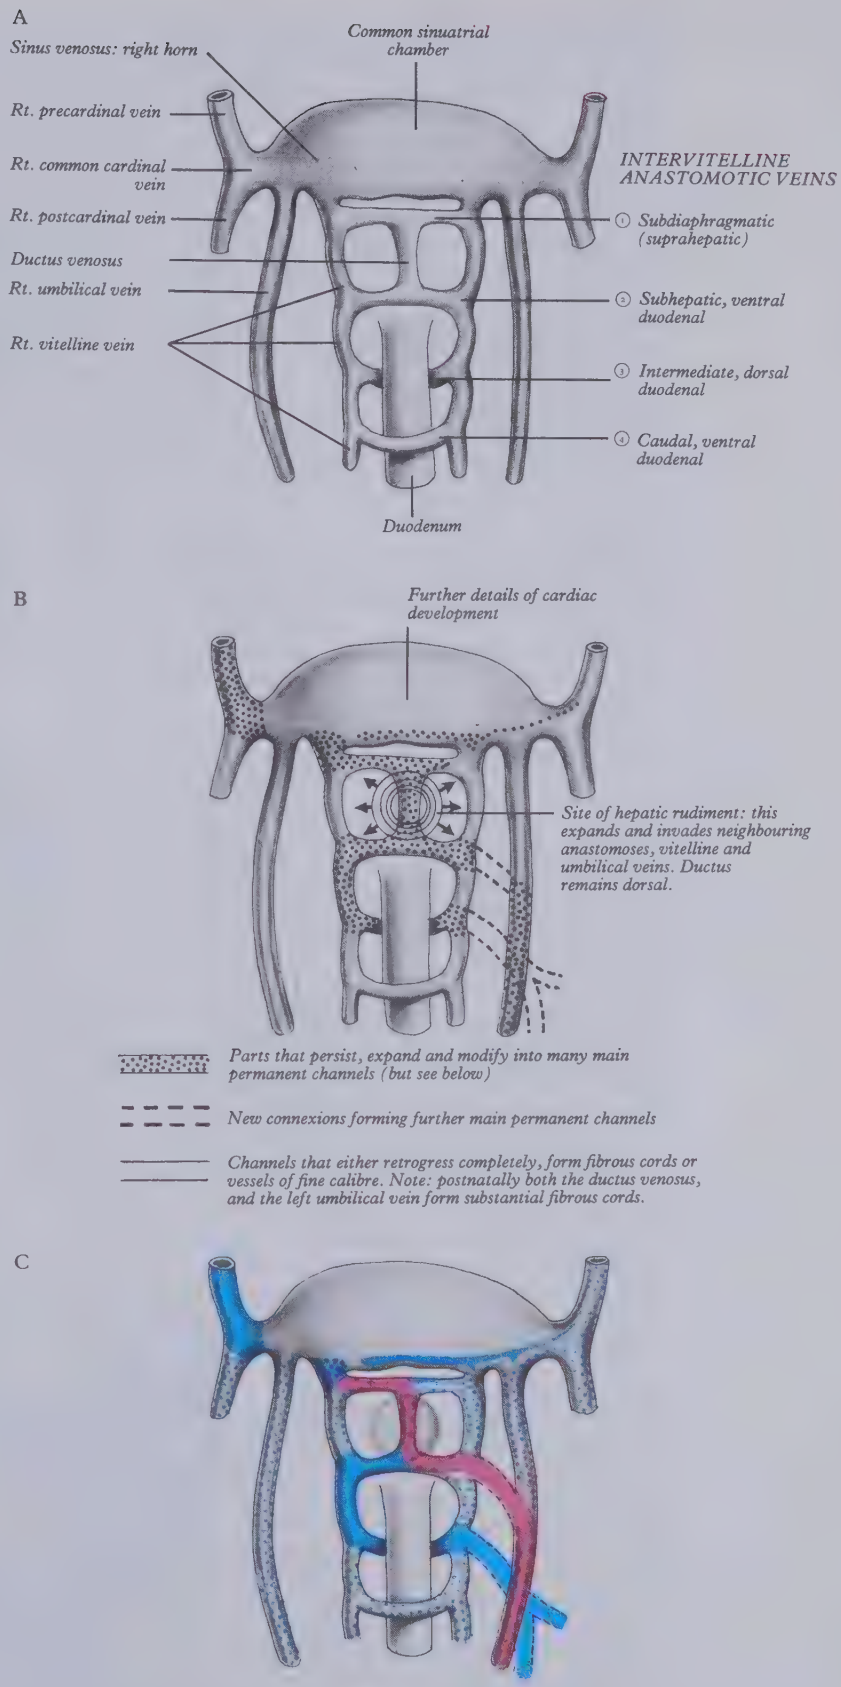
FURTHER DEVELOPMENT OF THE VEINS

Often, for convenience and apparent simplicity, the early embryonic veins are segregated into two groups, *visceral* and *parietal* (or *somatic*). The visceral group comprises the derivatives of the vitelline and umbilical veins, the somatic group includes all remaining veins. Such a classification is a potentially misleading oversimplification, based on inadequate criteria. Many embryonic veins, with time, change the principal tissues they drain; others have some radicles from patently parietal tissues that become confluent with drainage channels that are clearly visceral, thus forming a compound vessel; finally some veins differentiate from contrasting mesenchymal layers at different points along their course (each having its distinct phylogenetic history).

Less confusion attaches to the recognition of three main groups of veins — the *vitelline, umbilical* and *cardinal* vein complexes; nevertheless, even here, some imprecision persists where, for instance anastomoses or convergence of radicles from different groups occurs, where ontogenetically compound tissues are drained or when distinct developmental layers are traversed. The early embryonic veins develop initially with a symmetrical bilateral array of channels; the *principal* events correlated with changes in this are the craniocaudal and mediolateral gradients in growth and differentiation of the nervous system, skeleton and musculature; diversion of cardiac venous return to the right with concomitant cardiac asymmetry; 'descent' of the heart and lungs; gut rotation and repositioning; and venous involvement by the developing liver, pancreas, spleen and mesonephric ridges. (Clearly, the temporospatial developmental sequences of *all* vascularized tissues are involved to varying, but less obvious extents.) As noted, the primitive tubular symmetrical heart receives its venous return through the right and left sinual horns (horns of the sinus venous). The horns are initially embedded in the mesenchyme of the septum transversum and each receives, most medially, the termination of the principal vitelline vein (but vide infra), more laterally, the umbilical vein and, most laterally,

2.92 Stages in the development of the arteries of the leg. The original path of the axis artery is indicated by a dashed line. (After Senior.)

having encircled the coelomic duct, the common cardinal vein. These cardiac inputs correspond, in large measure, but not exclusively, with the groups of veins mentioned above.



The vitelline veins drain capillary plexuses developed in the splanchnopleuric mesenchyme of the secondary yolk sac. With head, tail and lateral fold formation, the upper recesses of the yolk sac are enclosed within the embryo as the splanchnopleuric gut tube extending from the stomatodeal oropharyngeal membrane to the proctodeal cloacal membrane. It may be emphasized that derivatives from *all* these levels possess a venous drainage, originally *vitelline in origin*, although many accounts are limited to the (mainly subdiaphragmatic-sacral) regions drained via the hepatic portal vein. The deep aspects of the maxillo-mandibular facial prominences, retrogingival oral cavity, the pharyngeal walls and their lymphoid and endocrine derivatives and the cervicothoracic oesophagus, all have drainage channels that connect with the *precardinal complex*, ultimately returning blood to the heart via the superior vena cava. Laryngeal and tracheobronchial veins also drain to the precardinal complex, whilst the capillary plexuses developed in the (splanchnopleuric) walls of the fine terminal respiratory passages and alveoli, converge on *pulmonary veins* of increasing calibre, finally making secondary connections with the left atrium of the heart and may be grouped with the vitelline systems. Even the heart, itself, first differentiates in splanchnopleure that, after head fold formation, forms the dorsal wall of the primitive pericardial cavity (floor of the rostral foregut) and may therefore be considered a highly specialized vitelline vascular derivative. Similarly at the caudal extremity of the splanchnopleuric gut tube (the future lower rectum and upper anal canal—p. 233) the vitelline venous drainage makes connections with the internal iliac radicles of the *postcardinal complex*.

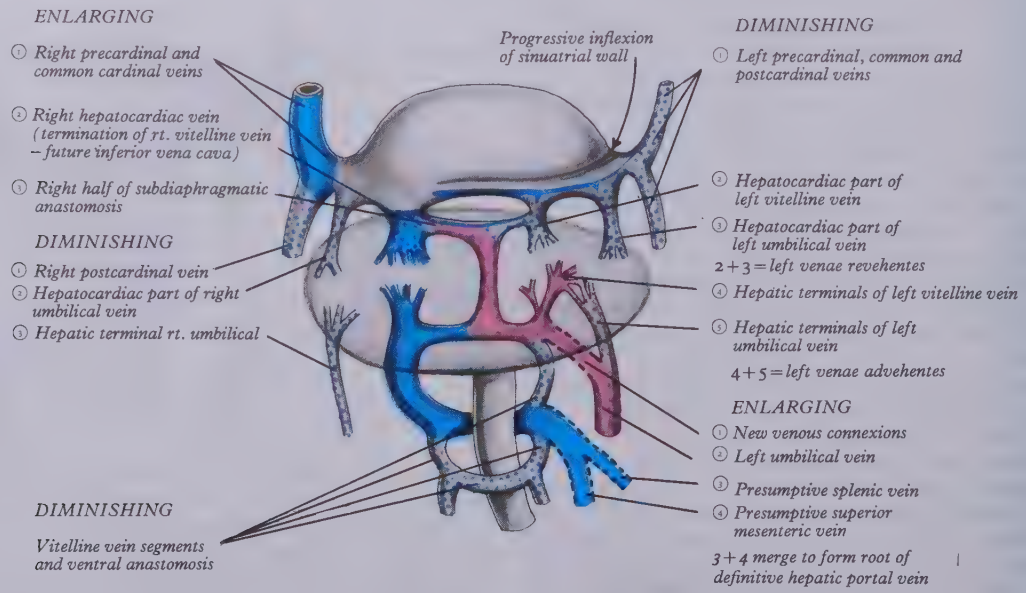
The increasingly extensive remainder of the gut tube, from the gastric terminal segment of the future oesophagus to the upper rectum, is, as elsewhere, clothed with splanchnopleuric mesoderm permeated by a capillary plexus; the latter drains into an anastomosing network of veins. The net is denser ventrally and in the central midgut region; for a while, it receives a leash of small veins from the definitive yolk sac that enter the embryo through the umbilicus, embedded in the yolk stalk. Later, in normal development, both stalk and vessels atrophy. Within the splanchnopleuric net, progressing rostrally, longitudinal channels anterolateral to the gut, become increasingly well

defined —the embryonic abdominal *vitelline veins*. Entering the septum transversum, the right and left vitelline veins incline slightly, becoming parallel to the lateral aspects of the gut; they establish connections with capillary plexuses in the septal mesenchyme, then continue, finally curving to enter the medial part of the cardiac sinual horn of their corresponding side. The parts of the gut closely related to the presinual segments of the vitelline veins, just described, are the future subdiaphragmatic end of the oesophagus, primitive stomach, the superior (first) and descending (second) regions of the duodenum, and the remainder of the duodenal tube. The early septum transversum is a thick mass of mesenchyme filling the interval between the median foregut and ventral body wall, and extending from the primitive pericardium to the rostral lip of the umbilicus; in it somatopleuric and splanchnopleuric mesoderms are confluent. When, later, the cardiac sinuatrium rises into the pericardium, the rostral part of the septum (*pars diaphragmatica*) is one of the multiple contributors to the framework of the definitive diaphragm; its caudal *pars mesenterica* provides ventral mesenteries, serous coats and mural tissues for the abdominal foregut, listed above. Where foregut continues into midgut (initially the rostral rim of the yolk stalk) the hepatic (and, transiently, ventral pancreatic) rudiments form as protrusions of the gut; the rapid and asymmetrical invasion of the septum cranioventrally is correlated with profound modifications of the transeptal parts of the vitelline and umbilical veins, and the splanchnopleuric mesothelium, framework and mesenteries of the liver, stomach and duodenum (pp. 240–248). The stem of the earliest hepatic rudiment projects from the ventral wall of the future second (descending) part of the duodenum; whilst expansion of the body of the liver continues as indicated, with gut rotation and differential growth, the ultimate derivative of the stem, the common bile duct, curves posterior to the proximal duodenum to reach its termination through the left posteromedial aspect of the second part of the duodenum.

The principal ascending vitelline veins flanking the sides of the abdominal part of the foregut receive venules from its splanchnopleuric capillaries, and those of the septal mesenchyme. Within these venular nets, enlarged (but still plexiform) anastomoses connect the two vitelline veins. (For clarity these are represented diagrammatically as simple transverse channels, 2.93A–C.) A *subdiaphragmatic intervitelline anastomosis* develops in the rostral septal mesenchyme, lying a little caudal to the cardiac sinuatrial chamber, connecting the veins near their sinual terminations. (Sometimes termed *suprahepatic* because of the position of the hepatic primordium, with expansion of the latter, the channel becomes partly *intrahepatic*.) The presumptive duodenum is crossed by three transverse *duodenal intervitelline anastomoses*; their relation to the gut tube alternates—most cranial, the *subhepatic* is ventral, the *intermediate* is dorsal and the *caudal* is ventral. It has become customary to describe the paraduodenal vitelline veins and their associated anastomoses as forming a figure 8. At this early stage when left and right embryonic veins are still symmetrical, the cranial duodenal anastomosis becomes connected with the subdiaphragmatic anastomosis by a *median* longitudinal channel, the *primitive ductus venosus*, which is dorsal to the expanding hepatic primordium, but ventral to the gut. The further development of the vitelline veins and anastomoses is, as indicated, closely interlocked with rapid hepatic expansion and gut changes; also umbilical vein disposition and modification is closely involved, and their early emergence and arrangement must be outlined before an account of later asymmetries is undertaken. The latter differs in part from long held descriptions, following the detailed analyses of goat and human embryos by Dickson (1957).

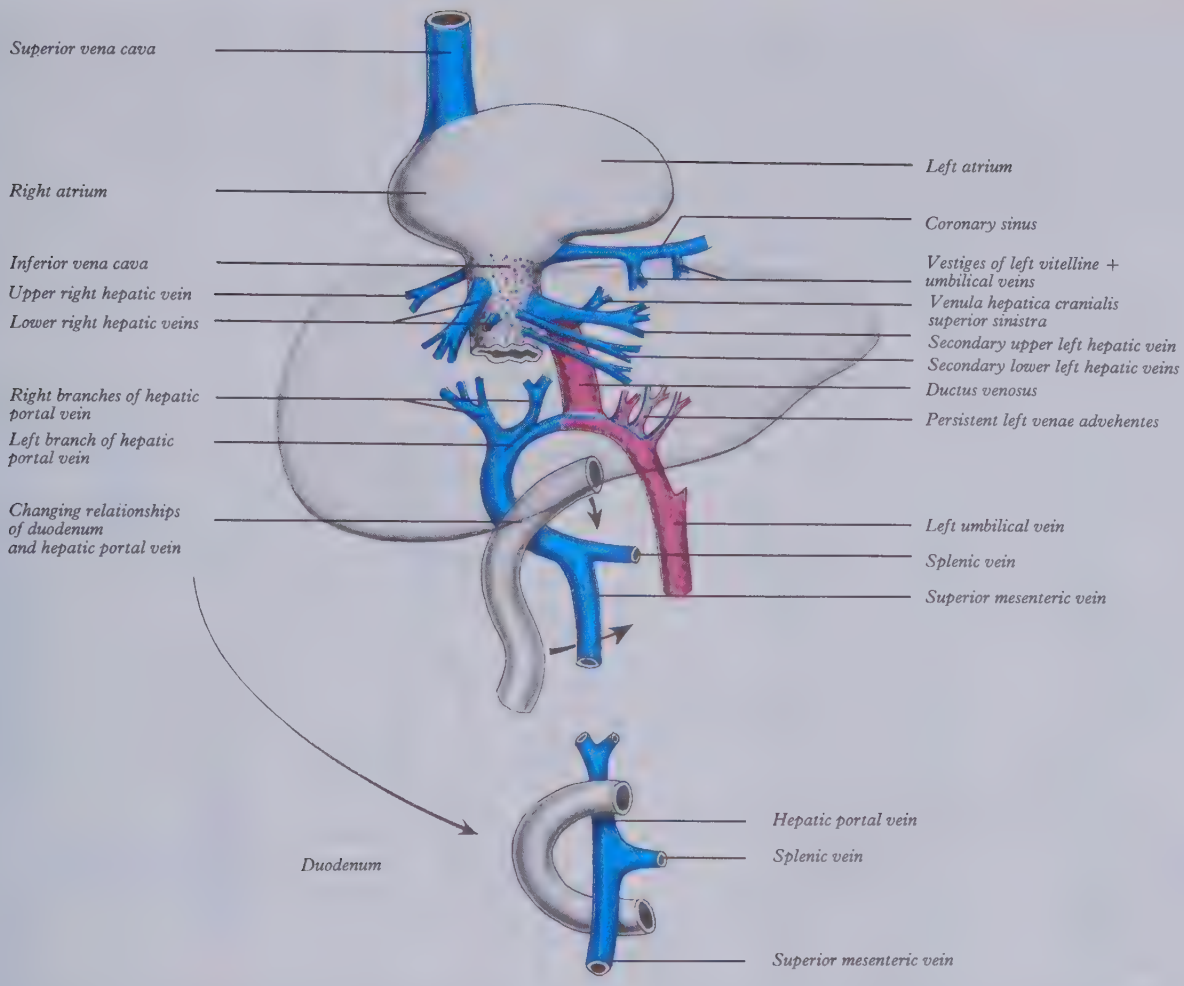
The umbilical veins form by the convergence of venules draining the splanchnopleure of the extraembryonic allantois. Throughout *Amniota* the allantois arises as a diverticulum from the caudal yolk sac wall (later, the ventrorostral wall of the cloacal part of the hindgut, or future bladder). Its degree of vesicular, then sometimes saccular, expansion is extremely variable; on occasion it virtually fills the extraembryonic coelom; the human endodermal allantois is diminutive, projecting merely into the embryonic end of the connecting stalk. The latter is regarded by many as precociously formed allantoic mesoderm, and the

2.93 Development of the vitelline, umbilical, and terminal cardinal vein complexes: the early symmetrical condition. A The topography and nomenclature of the veins forming the right and left sinual horns; the intervitelline anastomoses; the median ductus venosus. B To assist understanding of later changes the symmetrical pattern is used to indicate which segments persist, retrogress, and the sites of formation of new channels and the intimately involved hepatic rudiment. C A simplified representation of the subsequent main flow paths of oxygenated and deoxygenated blood.



umbilical vessels as *allantoic* (with close affinities, because of their common phylogenetic history, with the vitelline vessels). In the human embryo the peripheral venules drain the mesodermal cores of the chorionic villous stems and terminal villi (extraembryonic *somatopleuric* structures); these are the radicles of a, usually single, *vena umbilicales impar* which traverses the compacting mixed mesenchyme of the umbilical cord, to reach the caudal rim of the umbilicus. Here, the single cordal vein divides into primitive right and left umbilical veins; each curves rostrally in the somatopleuric lateral border of the umbilicus (i.e. where intraembryonic and extraembryonic or amniotic somatopleure are continuous), where it lies *lateral* to the communication between both the intraembryonic and extraembryonic coeloms. Rostrolateral to the umbilicus the two umbilical veins reach, enter and traverse the junctional mesoderm of the septum transversum, connect with septal capillary plexuses, then continue, to enter their corresponding cardiac sinual horns (lateral to the terminations of the vitelline veins). This early symmetrical disposition of the vitelline veins and anastomoses, umbilical and common cardinal veins and locus of the hepatic primordial complex is summarized in **2**.93A-C.

Progressive changes in the vitello-umbilical veins are rapid, profound and closely linked with regional modifications of shape and position of the gut, expansion and invasion of venous channels by hepatic tissue, asymmetry of the heart and cardiac venous return. The principal events are summarized in **2**.93–95, only brief textual allusions can be included here; see Dickson (1957) for details and bibliography.

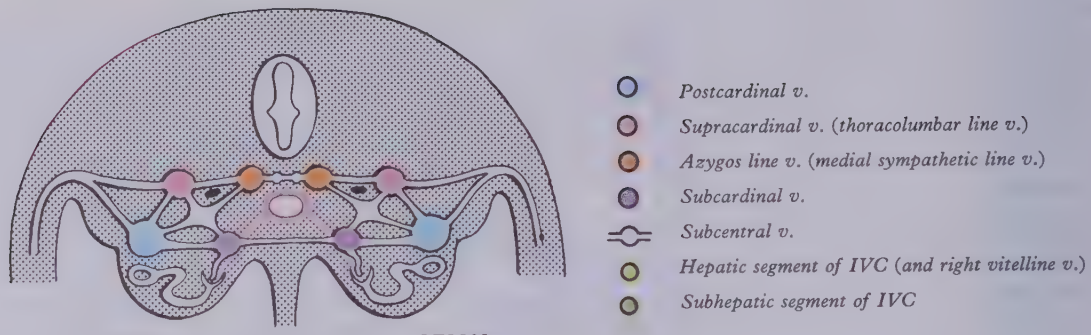


From the pars hepatica of the ventral hepatopancreatic rudiment (p. 237) interconnected sheets and 'cords' of endodermal cells, the presumptive hepatocytes, penetrate the mesenchyme-filled spaces of the pre-existing septal capillary plexuses. Possibly, under the inductive influence of the endodermal sheets, the plexuses become more profuse by the addition of angioblastic septal mesenchyme, which also forms masses of perivascular intrahepatic haemopoietic tissue. These processes extend along the plexiform connections of the vitelline, and later the umbilical veins until their intrahepatic (transeptal) zones themselves become largely plexiform—initially capillary in nature, but transform to a mass of rather wider, irregular, sinusoidal vessels with a discontinuous endothelium containing many phagocytic cells (p. 1392). The lengths of vitelline veins involved in these processes are the intermediate parts of the segments extending from the subhepatic (cranioventral duodenal) to the suprahepatic (subdiaphragmatic) transverse intervitelline anastomoses and the corresponding lengths of the umbilical veins. Thus at this early stage the liver sinusoids are perfused by mixed blood reaching them through a series of branching vessels collectively called the *venae advehentes*, or *venae afferentes hepatis*; they are deoxygenated from the gut splanchnopleure via vitelline vein hepatic terminals and oxygenated from the placenta via hepatic terminals of the umbilical veins. Blood leaves the liver through four *venae revehentes* (*venae efferentes hepatis*), two on each side reach and open into their respective cardiac sinual horns; this full complement of four *hepatocardiac veins* is only transient, becoming reduced to one dominant, rapidly enlarging channel. As detailed below the originally bilaterally symmetrical cardinal vein complexes, both rostral and caudal, develop transverse or oblique anastomoses whereby the cardiac venous return is restricted to the definitive right atrium. (The pulmonary veins are the only major ones returning to the left atrium.) The increasingly deep inflexion of the left wall of the common sinuatrial chamber, separation of the left sinual horn and 'body' of the sinus venosus, movement to the right of the sinuatrial orifice, and right atrial inclusion of the right sinual horn have been noted, (p. 209).

With these cardiac and concomitant hepatoenteric changes are accompanying events in supra-, intra- and sub-hepatic parts of the vitello-umbilical veins. Some vessels enlarge, persisting as definitive vessels to maturity and, in places, are joined later by other channels becoming defined in already established capillary plexuses. Other vessels retrogress, either disappearing completely, or remain as vestigial tags and occasionally vessels of fine calibre. Finally, some vessels of crucial importance in the circulatory patterns of embryonic and fetal life, *postnatally* become obliterated and transformed to substantial fibrous cords. Both right and left umbilical hepatocardiac and the left vitelline hepatocardiac veins continue, for a time, to discharge blood into their sinual horns; however they begin to retrogress (**2**.93,94). The right umbilical channel atrophies completely; the left channels also disappear, but their cardiac terminals may, on occasion, be found as conical fibrous tags attached to the inferior wall of the coronary sinus. The right vitelline hepatocardiac vein continues enlarging and ultimately forms the terminal segment of the inferior vena cava. The latter receives the right venae revehentes and new channels draining the territories of the left venae revehentes; these collectively form the upper and lower groups of right and (secondary) left hepatic veins. The terminal caval segment also shows the orifice of the right half of the intervitelline subdiaphragmatic anastomosis (p. 221) and a large new connection with the right subcardinal vein (vide infra).

The hepatic terminals of the right and left duodenal parts of the vitelline veins are destined to form the corresponding branches of

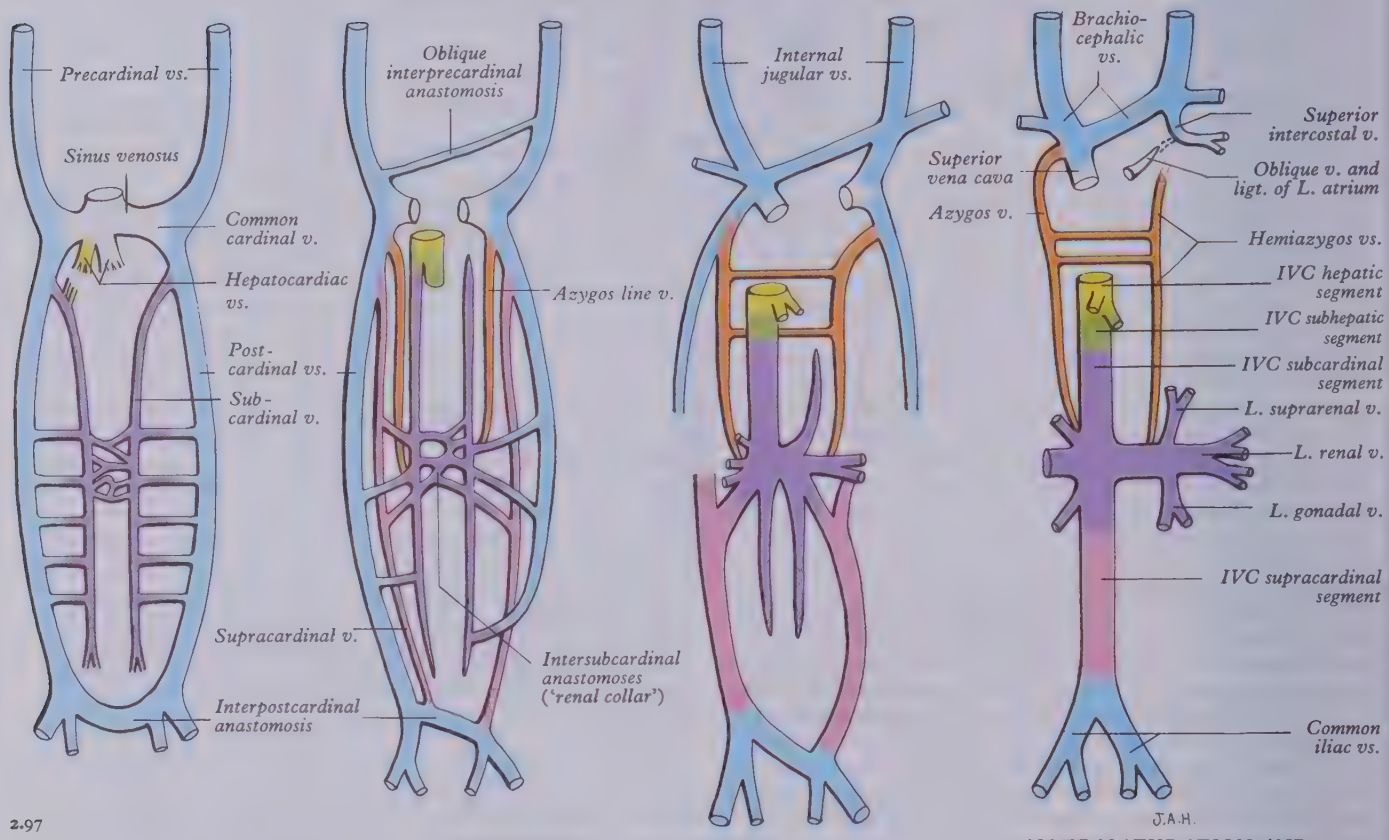
2.94 Development of the vitelline, umbilical and terminal cardinal vein complexes: a mid-stage of asymmetry has been reached between the early symmetrical condition (**2**.93A-C) and the definitive late prenatal state. Note the definition of the coronary sinus, the central role of the liver, and compare homologous left and right sided vessels.



2.95 The condition of some main upper abdominal and intrathoracic right atrial terminal veins in the later prenatal months. Note the coronary sinus and attached vestiges, the terminations of the superior and inferior venae cavae; the grouped hepatic veins; the convergent formation and heaptic divarication of the hepatic portal vein, and the routes available for return of oxygenated left umbilical venous blood; also the changing disposition of the duodenal loop and its relationship to the definitive portal vein; the manner in which the left terminal branch of the latter establishes connections with the ductus venosus and the left umbilical vein. Return of placental blood to the fetal heart is along an (embryologically) complex path; illustrations **2.93-95** should assist clarification. See text for further details.

the *hepatic portal vein*, the left branch incorporating the cranial ventral intervitelline anastomosis. With rotation of the gut and formation of the duodenal loop, segments of the original vitelline veins and the caudal transverse anastomosis (indicated in **2.93-95**) atrophy, whilst new splanchnopleuric venous channels, the superior mesenteric and splenic veins, converge and join the left end of the dorsal intermediate anastomosis. The numerous other radicles of the portal vein and its principal branches, including the inferior mesenteric vein, are later formations.

For a period placental blood returns from the umbilicus via right and left umbilical veins, both discharging through venae advehentes into the hepatic sinusoids, where admixture with vitelline blood occurs. At approximately 7 mm crown-rump length, the right umbilical vein retrogresses completely; the left umbilical vein retains some vessels discharging directly into the sinusoids, but new enlarging connections with the left half of the subhepatic intervitelline anastomosis emerge. The latter is the commencement of a *by-pass channel* for the majority of the placental blood, that continues through the median ductus venosus, and finally the right half of the subdiaphragmatic anastomosis to reach the termination of the inferior vena cava. Postnatally these channels are obliterated, with the resulting ligamentum teres extending from the umbilicus to the porta hepatis, whence, having established connections with the left branch of the portal vein, it continues as the ligamentum venosum to join an upper left hepatic vein, and terminates in the suprahepatic inferior vena cava.



The cardinal venous complexes (**2.96,97**) are first represented by two large vessels on each side, the *precardinal* and *postcardinal veins*; the former drain the rostral part of the embryo, the latter its caudal region. The two veins on each side unite to form a short *common cardinal vein*, which passes ventrally, lateral to the pleuropericardial canal (p. 239), to open into the corresponding horn of the sinus venosus (**2.87B**). (The cardinal complexes are often, less appropriately, called parietal or somatic. In addition to drainage of the latter, they receive many radicles from splanchnopleuric structures.)

Owing to the rapid development of the head and brain the precardinal veins become enlarged. They are further augmented by the *subclavian* veins from the upper limb buds, and so become the chief tributaries of the common cardinal veins; these gradually assume an almost vertical position in association with the descent of the heart into the thorax. That part of the original precardinal vein rostral to the subclavian is now the *internal jugular vein*, and their confluence the *brachiocephalic vein* of each side. The right and left common cardinal veins are originally of the same diameter. By the development of a large oblique transverse connection, the *left brachiocephalic vein* carries blood across from the left to the right (**2.97**). The part of the original right precardinal vein between the junction of the two brachiocephalics and the azygos veins forms the upper part of the **superior vena cava**; the caudal part of the latter vessel (below the entrance of the azygos vein) is formed by the right common cardinal. Caudal to the transverse branching of the left brachiocephalic vein the left precardinal and left common cardinal veins largely atrophy, the former constituting the terminal part of the left superior intercostal vein, while the latter is represented by the ligament of the left

2.97 Plan of development of principal somatic veins from the early symmetrical state, through states of increasing asymmetry, to the definitive arrangement. (Modified from Williams et al 1969.)

vena cava and the oblique vein of the left atrium (2.97). The remainder of the left superior intercostal vein is developed from the cranial end of the postcardinal vein and drains the second, third and, on occasion, the fourth intercostal veins. The oblique vein passes downwards across the back of the left atrium to open into the coronary sinus, which, as already indicated, represents the persistent left horn of the sinus venosus. Right and left superior venae cavae are present in some animals, and occasionally persist in mankind.

The inferior vena cava (2.96,97) of the adult is a composite vessel, and the precise mode of development of its postrenal segment (caudal to the renal vein) still somewhat uncertain. Its function is initially carried out by the right and left *postcardinal veins*, which receive the venous drainage of the lower limb buds and pelvis and run in the dorsal part of the mesonephric ridges, receiving tributaries from the body wall (*intersegmental veins*) and from the derivatives of the mesonephroi.

A second pair of longitudinal channels, the *subcardinal veins*, form in ventromedial parts of the mesonephric ridges and become connected to the postcardinal veins by a number of vessels traversing the medial part of the ridges. The subcardinal veins intercommunicate by a *pre-aortic anastomotic plexus*, which later constitutes the part of the *left renal vein* crossing anterior to the abdominal aorta.

The formation of an oblique transverse anastomosis between the iliac veins—which itself becomes the major part of the definitive *left common iliac vein*—diverts an increasing volume of blood into the right longitudinal veins, accounting for the ultimate disappearance of most of those on the left.

At its cranial end the subcardinal vein receives the *suprarenal*

vein on each side, but on the right side it comes into intimate relationship with the liver. An extension of the vessel takes place in a cranial direction and meets and establishes continuity with a corresponding new formation which is growing caudally from the right vitelline hepatocardiac (common hepatic) vein. In this way on the right side a more direct route is established to the heart and the *prerenal* (cranial) segment of the inferior vena cava is defined.

The enlargement of the metanephros (p. 250) diverts the postcardinal vein from its course and the venous drainage of the mesonephric ridge is assumed by the subcardinal vein. At the same time new longitudinal channels appear and take over intersegmental venous drainage and the whole of the postcardinal vein disappears—except its extreme cranial and caudal ends. There are at least three such channels on each side, in addition to the *postcardinal* and *subcardinal* already mentioned, but, so far as is known, only two of them persist as large vessels in the adult: (1) A bilateral longitudinal channel forms dorsolateral to the aorta and *lateral* to the sympathetic trunk and takes over the intersegmental venous drainage from the posterior cardinal vein. This is the *supracardinal* or *thoracolumbar 'complex'*; alternatively *lateral sympathetic line vein*. (2) A second channel forms on each side, also dorsolateral to the aorta but *medial* to the sympathetic trunk. This, the *azygos line vein* or *medial sympathetic line vein*, gradually takes over the intersegmental venous drainage from the thoracolumbar line. The intersegmental veins now obviously reach their longitudinal channel by passing medial to the autonomic trunk, the relationship which the lumbar and intercostal veins maintain thenceforth. Cranially the azygos lines join the persistent cranial ends of the posterior cardinal veins. (3) Two *subcentral veins* are laid down directly dorsal to the aorta in the interval between the origins of the paired intersegmental arteries. These veins communicate freely with each other and with the azygos line veins, and these connections ultimately form the retro-aortic parts of the left lumbar veins and of the hemiazygos veins. (4) Some authorities also recognize a *precostal* or *lumbocostal* venous line, anterior to the vertebrocostal element, and posterior to the supracardinal. a possible derivative is the ascending lumbar vein (p. 818).

The thoracolumbar or supracardinal veins are, as indicated, lateral to the aorta and sympathetic trunks, which therefore intervene between them and the azygos lines. These veins communicate caudally with the iliac veins and cranially with the subcardinal veins in the neighbourhood of the pre-aortic intersubcardinal anastomosis. In addition, the supracardinal veins communicate freely with each other through the medium of the azygos lines and the subcentral veins. The most cranial of these connections, together with the supracardinal–subcardinal and the intersubcardinal anastomoses, complete a venous ring around the aorta below the origin of the superior mesenteric artery, termed the *'renal collar'* (Huntington 1920).

The right supracardinal vein persists and forms the greater part of the postrenal segment of the inferior vena cava, the continuity of the vessel being maintained by the persistence of the anastomosis between the right supracardinal and the right subcardinal in the 'renal collar'. The left supracardinal disappears, but some of the 'renal collar' formed by the left supracardinal-subcardinal anastomosis persists in the left renal vein. It must be added that much confusion and disagreement exists with regard to the disposition, homologies, and derivatives of the complicated array of longitudinal veins described above.

The inferior vena cava (2.97) is, therefore, formed from below upwards by (1) confluence of the common iliac veins, (2) short segment of the right postcardinal vein, (3) postcardinal-supracardinal anastomosis, (4) part of the right supracardinal vein, (5) right supracardinal–subcardinal anastomosis, (6) right subcardinal vein, (7) a new anastomotic channel of double origin —the hepatic segment of the inferior vena cava, and (8) the cardiac termination of the right vitelline hepatocardiac vein (common hepatic vein). It should be noted that only the supracardinal part of the inferior vena cava receives the intersegmental venous drainage, and that the postrenal (caudal) segment of the inferior vena cava is on a plane which lies dorsal to the plane of the prerenal (cranial) segment. Thus the right phrenic, suprarenal and renal arteries, which represent persistent mesonephric arteries, pass behind the inferior vena cava, while the testicular or ovarian, which has a similar developmental origin, passes anterior to it.

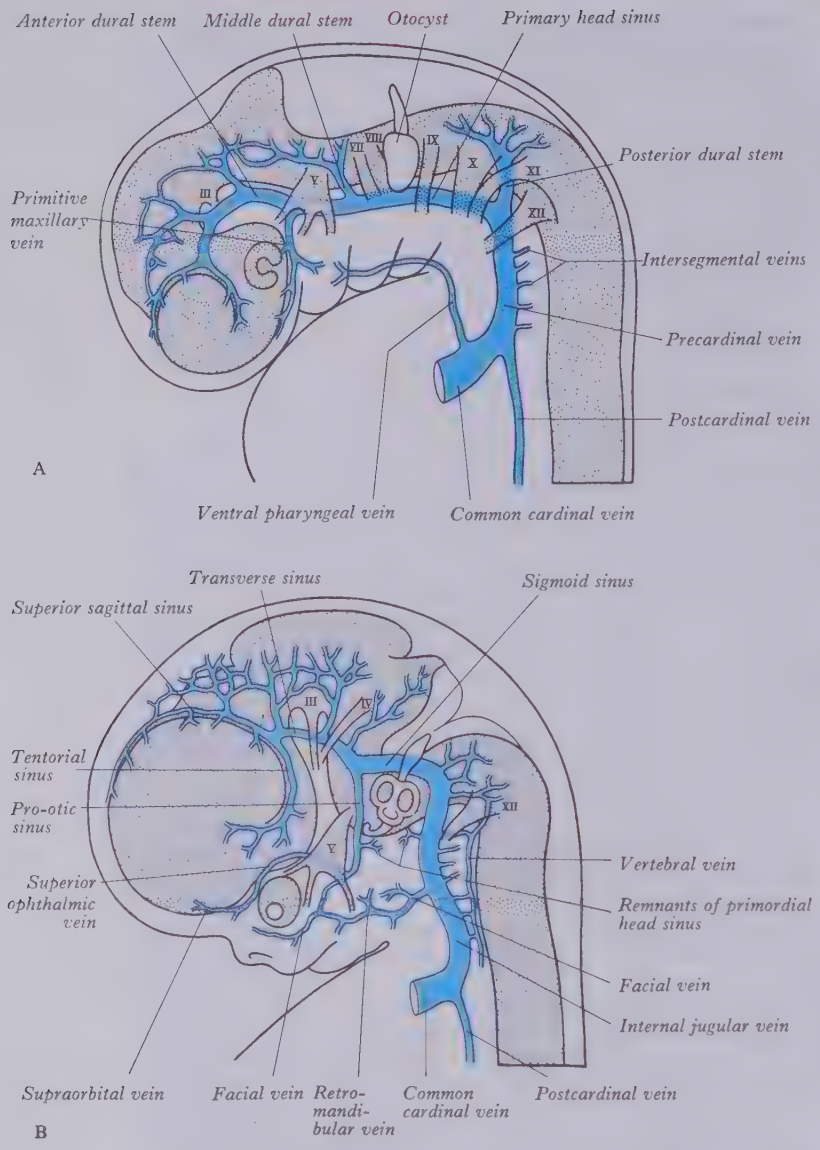
In some animals the right postcardinal vein constitutes a large part of the postrenal segment of the inferior vena cava. In these cases the right ureter, on leaving the kidney, passes medially dorsal to the vessel and then, curving round its medial side, crosses its ventral aspect. Rarely, a similar condition is found in the human subject, and indicates the persistence of the right postcardinal vein and failure of the right supracardinal to play its normal part in the development of the vessel.

The ultimate arrangement of some of the embryonic abdominal and thoracic longitudinal cardinal veins may be summarized:

(1) The terminal part of the left postcardinal vein forms the distal part of the left superior intercostal vein; on the right side its cranial end persists as the terminal part of the vena azygos.

(2) The caudal part of the subcardinal vein is in part incorporated in the testicular or ovarian vein (McClure & Butler 1925) and partly disappears. The cranial end of the right subcardinal vein is incorporated into the inferior vena cava and also forms the right suprarenal vein. The left subcardinal vein, cranial to the intersubcardinal anastomosis, is incorporated into the left suprarenal vein. The renal and testicular or ovarian veins on both sides join the supracardinal-subcardinal anastomosis. On the left side this is connected directly to the part of the inferior vena cava which is of subcardinal status through an intersubcardinal anastomosis.

(3) The right supracardinal vein forms much of the postrenal (caudal) segment of the inferior vena cava. The left supracardinal vein disappears entirely.



(4) The right azygos line persists in its thoracic part to form all but the terminal part of the vena azygos. Its lumbar part can usually be identified as a small vessel which leaves the vena azygos on the body of the twelfth thoracic vertebra and descends on the vertebral column, deep to the right crus of the diaphragm, to join the posterior aspect of the inferior vena cava at the upper end of its postrenal segment. The left azygos line forms the hemiazygos veins.

(5) The subcentral veins give rise to the retro-aortic parts of the left lumbar veins and of the hemiazygos veins.

The veins of the head have a complicated developmental history (2.98A,B, and consult Markowski 1911, Streeter 1918, Padget 1957, Butler 1957, 1967, Browder & Kaplan 1976).

The primary vessels consist of a close-meshed capillary plexus drained on each side by the precardinal vein, which is at first continuous cranially with a transitory *primordial hindbrain channel*, lying on the neural tube medial to the cranial nerve roots. This is soon replaced by the *primary head vein* which runs caudally from the medial side of the trigeminal ganglion, lateral to the facial and vestibulocochlear nerves and otocyst, then medial to the vagus nerve, to become continuous with the precardinal vein. A lateral anastomosis subsequently brings it lateral to the vagus nerve. The cranial part of the precardinal vein forms the internal jugular vein; its caudal moiety has already been described on p. 223.

The primary capillary plexus of the head becomes separated into three fairly distinct strata by the differentiation of the skull and meninges. The superficial vessels, draining the integument and underlying soft parts, eventually discharge in large part into the *external jugular system*. They retain some connections with the deeper veins through so-called emissary veins. Deep to this is the *venous plexus of the dura mater*, from which the dural venous sinuses differentiate. This plexus converges on each side into *anterior*, *middle* and *posterior dural stems*. The anterior stem drains the prosencephalon and mesencephalon entering the primary head vein rostral to the trigeminal ganglion. The middle stem drains the metencephalon and empties into the primary head vein caudal to the trigeminal ganglion, while the posterior stem drains the myelencephalon into the commencement of the precardinal vein (2.98A,B). The deepest capillary stratum is the pial plexus from which the veins of the brain differentiate; it drains at the dorsolateral aspect of the neural tube into the adjacent dural venous plexus. In addition the primary head vein also receives, at its cranial end, the *primitive maxillary vein*, draining the maxillary prominence and region of the optic vesicle.

2.98 Diagrams illustrating successive stages in the development of the veins of the head and neck, (A) at approximately 8 mm and (B) at approximately 24 mm CR length.

The vessels of the dural plexus undergo profound changes, largely accommodating the growth of the cartilaginous otic capsule of the membranous labyrinth and expansion of the cerebral hemispheres. With growth of the otic capsule the primary head vein is gradually reduced and a new channel joining anterior, middle and posterior dural stems appears dorsal to the cranial nerve ganglia and the capsule (Butler 1967). Where this new vessel joins the middle and posterior stems, together with the posterior dural stem itself, forms the adult *sigmoid sinus* (2.98B).

Between the growing cerebral hemispheres and along the dorsal margins of the anterior and middle plexuses there forms a curtain of capillary veins, the *sagittal plexus*, in the position of the future falx cerebri. Rostrodorsally this plexus forms the *superior sagittal sinus* and is continuous behind with the anastomosis between the anterior and middle dural stems, which forms most of the *transverse sinus*. Ventrally the sagittal plexus differentiates into the *inferior sagittal* and *straight sinuses* and the *great cerebral vein*, and drains, more commonly, into the left transverse sinus. (For right/left variations in the terminations of sagittal and straight sinuses, and occurrence of a confluence see p. 800.)

The vessels along the ventrolateral edge of the developing cerebral hemisphere form the transitory *tentorial sinus*, which drains the convex surface of the cerebral hemisphere and basal ganglia, and the ventral aspect of the diencephalon, to the transverse sinus. With expansions of the cerebral hemispheres, and in particular the emergence of the temporal lobe, the tentorial sinus becomes elongated, attenuated and eventually disappears, and its territory is drained by enlarging anastomoses of pial vessels which become the *basal veins*, radicles of the *great cerebral vein*.

The anterior dural stem disappears and the caudal part of the primary head vein dwindles; it is represented in the adult by the *inferior petrosal sinus*. The cranial part of the primary head vein, medial to the trigeminal ganglion, persists and still receives the stem of the primitive maxillary vein. The latter has now lost most of its tributaries to the anterior facial vein, its stem becoming the main trunk of the *primitive supra-orbital vein*, which will form the *superior ophthalmic vein* of the adult. Thus, the main venous drainage of the orbit and its contents is now carried via the augmented middle dural stem, the *pro-otic sinus*, into the transverse sinus and at a later stage into the cavernous sinus. The *cavernous sinus* is formed from a secondary plexus, derived from the primary head vein and lying between the otic and basioccipital cartilages. This forms the *inferior petrosal sinus* and drains through the primordial hindbrain channel into the internal jugular vein. The *superior petrosal sinus* arises later from a ventral metencephalic tributary of the pro-otic sinus; it communicates secondarily with the cavernous sinus (Butler 1957, 1967). The pro-otic sinus meanwhile has developed a new and more caudally situated stem draining into the sigmoid sinus; this new stem is the *petrosquamosal sinus* (p. 801) and the pro-otic sinus becomes, with progressive ossification of the skull, diploic in position. The development of the venous drainage and portal system of the hypophysis cerebri is closely associated with that of the venous sinuses (Wislocki 1937, Niemineva 1950, also p. 1455).

The venous drainage of the face, scalp and neck becomes established after the development of the skull. The first identifiable vessel is the *ventral pharyngeal vein*, draining the massive mandibular and hyoid arches into the common cardinal vein. With the elongation of the neck its termination is transferred to the cranial part of the precardinal vein which later becomes the *internal jugular*. The ventral pharyngeal vein, receiving tributaries from the face and tongue, becomes the *linguofacial* vein. With development of the face the primitive maxillary vein extends its drainage into the territories of supply of the ophthalmic and mandibular division of the fifth nerve, including the pterygoid and temporal muscles, and over the lower jaw it anastomoses with the linguofacial vein. This anastomosis becomes the *facial vein*; it receives a strong *retromandibular vein* from the temporal region, and drains through the linguofacial vein into the internal jugular. The stem of the linguofacial vein is now the lower part of the facial vein, whilst the dwindling connection of the facial with the primitive maxillary becomes the *deep facial vein*. The *external jugular vein* is developed from a tributary of the cephalic vein from the tissues of the neck and anastomoses secondarily with the anterior facial vein. At this stage the *cephalic vein* forms a *venous ring* around the clavicle from which it is connected with the caudal part of the precardinal. The deep segment of the venous ring forms the *subclavian vein* and receives the definitive external jugular vein. The superficial segment of the venous ring dwindles, but may persist in adult life (Padget 1957).

THE LYMPHATIC SYSTEM

Two different views are current as to the initial stages in the development of the lymphatic system (Rusznyák et al 1960). According to the first view (Huntington 1908, McClure & Butler 1925) lymphatic spaces commence as clefts in the mesenchyme, and their lining cells take on the characteristics of endothelium (Kampmeier 1969). These spaces form capillary plexuses from which certain *lymph sacs*, to be noted later, are derived. The connections of the lymphatic and venous systems are regarded as entirely secondary. In contrast, however, according to Sabin (1912), the earliest lymph vessels arise as capillary offshoots from the endothelium of the veins, as capillary plexuses. These plexuses lose their connections with the venous system and become confluent to form lymph sacs. The balance of the

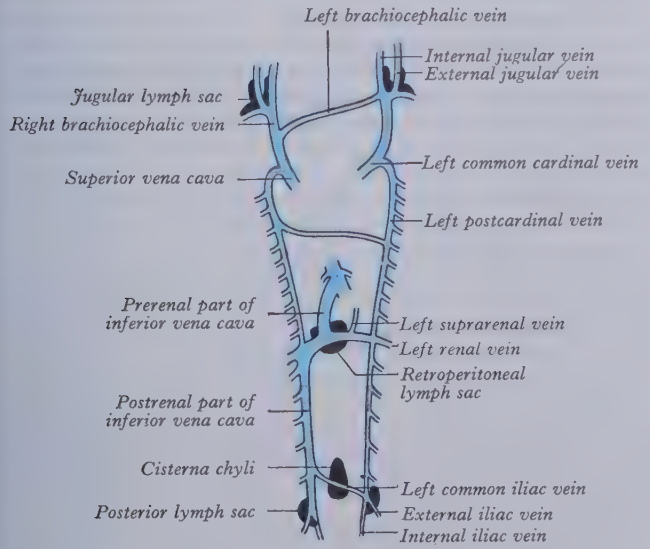
evidence suggests that all but the earliest lymphatic channels originate independently of the venous system and only acquire connections with it at a later stage (Kampmeier 1969).

In the human embryo the lymph sacs from which the lymph vessels are derived are six in number; two paired (the *jugular* and the *posterior lymph sacs*) and two unpaired (the *retroperitoneal* and the *cisterna chyli*). In lower mammals an additional pair (the *subclavian*) is present, but in the human embryo these are merely extensions of the jugular sacs.

The position of the sacs is as follows (2.99): (1) the *jugular*, the first to appear, at the junction of the subclavian vein with the precardinal, with later prolongations along the internal and external jugular veins; (2) the *posterior* encircling the left common iliac vein; (3) the *retroperitoneal*, in the root of the mesentery near the suprarenal glands; (4) the *cisterna chyli*, opposite the third and fourth lumbar vertebrae. From the lymph sacs the lymph vessels bud out along lines corresponding more or less closely with the course of embryonic blood vessels, most commonly veins, but many arise *de novo* in the mesenchyme and establish connections with existing vessels. In the body wall and that of the intestine the deeper plexuses are the first to be developed; by continued growth of these, the vessels in the superficial layers are gradually formed. The *thoracic duct* is, phylogenetically, a bilateral structure. In man it comprises the caudal part of the right vessel, a transverse anastomosis and the cranial part of the left vessel. According to the second view cited above it is formed from anastomosing outgrowths from the jugular sacs and cisterna chyli. At its connection with the cisterna it is at first double, but the vessels soon join. Numerous valves are laid down in the duct during the fifth month, but many of them disappear prior to birth. Those which persist are formed in situations where the duct may be subjected to pressure, e.g. where it is crossed by the oesophagus and the aortic arch.

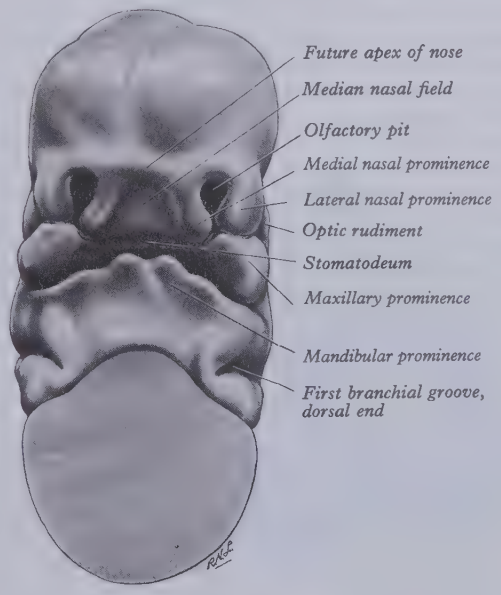
All the lymph sacs except the cisterna chyli are, at a later stage, divided by a number of slender connective tissue bridges. Subsequently they are invaded by lymphocytes and transformed into groups of lymph nodes, the lymph sinuses representing portions of the original cavity of the sac. The caudal part of the cisterna chyli is similarly converted, but its rostral part remains as the definitive cisterna; in many cases the cisterna chyli is plexiform (p. 842). The siting of the major groups of lymph nodes follows a similar basic pattern amongst the mammals (Spira 1962).

Haemal lymph nodes are said to develop as mesenchymal condensations in close relation to blood vessels rather than lymphatics (Meyer 1917, Turner 1969).



The Development of the Alimentary and Respiratory Apparatus

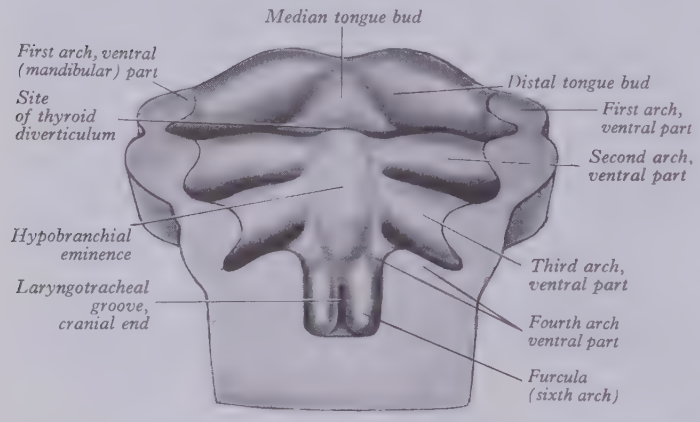
THE BUCCAL CAVITY AND PHARYNX



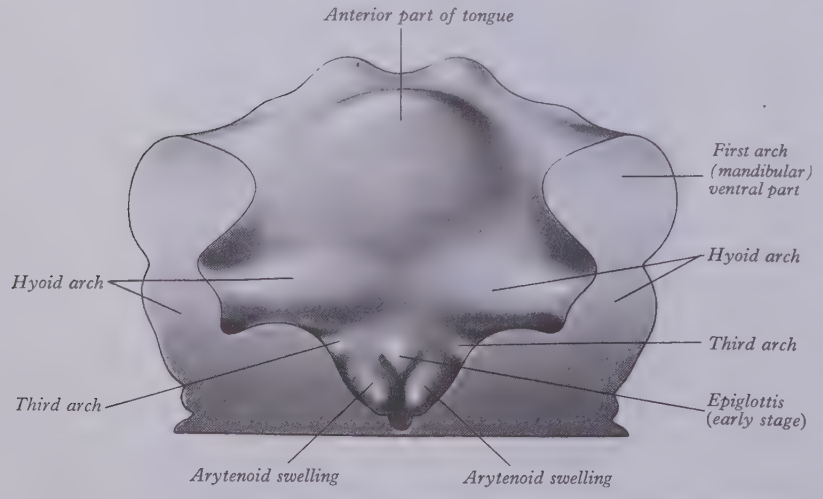
The mouth is developed partly from the stomatodeum, and partly from the floor of the cranial portion of the foregut. By the rostral growth of the embryo and formation of the head fold, the pericardial area and oropharyngeal membrane come to lie on the ventral surface of the embryo (p. 140). With further expansion of the brain and bulging of the pericardium, the membrane is soon depressed between the two elevations. This depression is the *stomatodeum* or *primitive buccal cavity* (2.100). It is lined with ectoderm and separated from the cranial end of the foregut by the oropharyngeal membrane, which is formed by the apposition of stomatodeal ectoderm with foregut endoderm; at the end of the fourth week the membrane disappears and a communication is established between stomatodeum and cranial end of the foregut or future oropharynx. No vestige of the membrane is evident in the adult, and this embryonic communication must not be confused with the permanent oropharyngeal isthmus. The epithelium of the lips and gums and the enamel of the teeth are ectodermal in origin, from the stomatodeal walls, but the epithelium of the tongue and adnexa, developed in the floor of mouth and pharynx, is derived from endoderm. The development of the teeth and gums is described on p. 1310 et seq.

The branchial arches grow in a ventral direction and lie progressively between stomatodeum and pericardium; with the completion of the mandibular prominences and the development of the maxillary prominences (p. 167), the opening of the stomatodeum assumes a pentagonal form, bounded cranially by the frontonasal prominence, caudally by the mandibular prominences and laterally by the maxillary prominences (2.100). With the inward growth and fusion of the palatine processes (2.51B,C), the stomatodeum is divided into a nasal and a buccal part. Along the free margins of the prominences bounding the mouth cavity appears a shallow groove, and the ectoderm in its floor thickens and invades the underlying mesoderm; it divides into a medial *dental lamina* and a lateral *vestibular lamina*. The central cells of the latter degenerate and the furrow becomes deepened. It is now termed the *labiogingival groove* or *sulcus*; its inner wall contributes to the formation of the alveolar processes of the maxillae and the mandible, while its outer wall forms the lips and cheeks.

The salivary glands arise from the epithelial lining of the mouth. The *parotid gland* can be recognized in human embryos



2.99 Scheme showing the relative positions of the primary lymph sacs. (After F R Sabin.)



2.100 The head of a human embryo in the sixth week. Ventral aspect. (From a model by K Peter.)

8 mm long as an elongated furrow running dorsally from the angle of the mouth between the mandibular and maxillary prominences. The groove, which is converted into a tube, loses its connection with the epithelium of the mouth, except at its ventral end, and grows dorsally into the substance of the cheek. The tube persists as the *parotid duct* and its blind end proliferates to form the gland. Subsequently the size of the oral fissure is reduced by partial fusion between the maxillary and mandibular prominences and the duct opens thereafter on the inside of the cheek at some distance from the angle of the mouth. The *submandibular gland* is identifiable in human embryos 13 mm long as an epithelial outgrowth from the floor of the *linguogingival groove* (vide infra). It increases rapidly in size, giving off numerous branching processes which later acquire lumina. At first the connection of the submandibular outgrowth with the floor of the mouth lies at the side of the tongue, but the edges of the groove in which it opens come together, from behind forwards, and form the tubular part of the *submandibular duct*. As a result, the orifice of the duct is shifted forwards till it is below the tip of the tongue, close to the median plane. The *sublingual gland* arises in embryos about 20 mm long as a number of small epithelial thickenings in the linguogingival groove and on the groove's lateral side, which later closes to form the submandibular duct. Each thickening canalizes separately; many of the multiple sublingual ducts open separately on the summit of the sublingual fold, others join the submandibular duct (p. 1293).

The tongue appears as a small median elevation, named the *median tongue bud (tuberculum impar)*, in the endodermal floor of the pharynx before the branchial arches meet ventrally; it subsequently becomes incorporated in the anterior part of the tongue. A little later two oval *distal tongue buds (lingual swellings)* appear on the endodermal aspect of the mandibular prominences. They meet each other in front, and caudally they converge on the median tongue bud, with which they fuse (2.101A,B). A sulcus forms along the ventral and lateral margins of this elevation and deepens, internal to the future alveolar process of the mandible, to form the *linguogingival groove*, while the elevation constitutes the anterior or buccal (presulcal) part of the tongue.

2.101A The floor of the pharynx of a human embryo at the beginning of the sixth week. (From a model by K Peter.)

2.101B The floor of the pharynx of a human embryo, about 6 weeks old. (From a model by K Peter.)

Caudal to the median tongue bud, a second median elevation, the *hypobranchial eminence* (copula of His), forms in the floor of the pharynx, and the ventral ends of the fourth, the third and, later, the second visceral arches converge into it. A transverse groove separates its caudal part to form the epiglottis, while ventrally it approaches the tongue rudiment, spreading in the form of a V, and forming the posterior or pharyngeal part of the tongue. In the process the third arch elements grow over and bury the elements of the second arch, excluding it from the tongue. As a result the mucous membrane of the pharyngeal part of the tongue receives its sensory supply from the glossopharyngeal, the nerve of the third arch. In the adult the union of the anterior and posterior parts of the tongue approximately corresponds to the angulated *sulcus terminalis*, its apex at the *foramen caecum*, a blind depression produced at the time of fusion of the constituent parts of the tongue, but also marking the site of ingrowth of the median rudiment of the thyroid gland.

At first the tongue consists of a mass of mesoderm covered on its surface by endoderm. During the second month occipital myotomes are often stated to migrate from the lateral aspects of the myelencephalon, then invading the tongue to form its musculature. They are held to pass ventrally round the pharynx to reach its floor accompanied by their nerve (the hypoglossal), which therefore crosses superficial to both the internal and external carotid arteries; however, see p. 175 for alternative views.

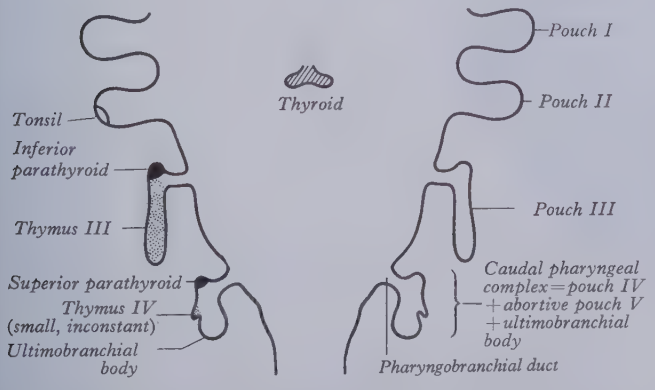
The composite character of the tongue is indicated by its innervation. Impulses from the anterior, buccal part are mediated by: (*a*) the lingual nerve, derived from the post-trematic nerve of the first arch (mandibular nerve); and (*b*) the chorda tympani, often held to be the pretrematic nerve to the first arch (but see p. 172). The posterior, pharyngeal part of the tongue is innervated by the glossopharyngeal, the nerve of the third arch. The muscles of the tongue being possibly 'myotomic' analogues, if not homologues, receive their nerve supply from the hypoglossal nerve, which is usually regarded as serially homologous with spinal ventral nerve roots.

The sulcus terminalis cannot be distinguished earlier than the 52 mm stage according to some observers. The vallate papillae appear at about the same time, increasing in number until the 170 mm stage. Serial reconstructions also suggest that the territory of the glossopharyngeal nerve extends considerably beyond these papillae.

The thyroid gland is first identifiable in embryos of about 20 somites, as a median thickening of endoderm in the floor of the pharynx between the first and second pharyngeal pouches and immediately dorsal to the aortic sac (Davis 1923). This area is later invaginated to form a median diverticulum which appears late in the fourth week in the furrow immediately caudal to the median tongue bud (2.101A). It grows caudally as a tubular duct the tip of which bifurcates and subsequently the whole mass divides into a series of double cellular plates, from which the isthmus and the lateral lobes of the thyroid gland are developed. The *primary thyroid follicles* differentiate by reorganization and proliferation of the cells of these plates. *Secondary follicles* subsequently arise by budding and subdivision (Norris 1916). These primary and secondary endodermal cells are the progenitors of the follicular parenchyma proper. The claim that the fourth pharyngeal pouches contribute thyroid tissue to the lateral lobes of the gland was long disputed and perhaps seemed unlikely on the grounds of comparative embryology. (But vide infra—the *ultimobranchial body* and the derivation of *parafollicular* or *C cells*.)

The original diverticulum, its bifurcation and generations of follicles invade mixed hypobranchial mesenchyme. From the latter are derived the thin connective tissue capsule, thinner 'interlobular' septa and delicate perifollicular investments. These

carry the main vasculature, characteristic fenestrated capillaries, lymphatics and autonomic nerve supply.



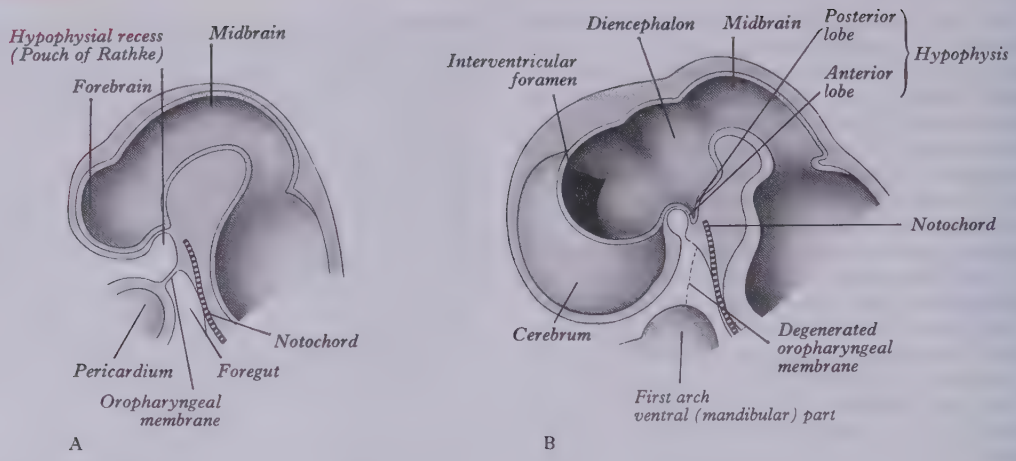
The connection of the median diverticulum with the pharynx is termed the *thyroglossal duct*. The site of its initial continuation with the endodermal floor of the mouth is marked by the foramen caecum. From here it extends caudally in the median line ventral to the primordium of the hyoid bone, behind which it later forms a recurrent loop. The distal part of the duct commonly differentiates variably as the pyramidal lobe and levator muscle (or 'suspensory' fibrous band) of the thyroid. The remainder fragments and disappears, but the lingual part is often identifiable until late in fetal life and may branch and give rise to miniature salivary glands (Boyd 1964). Occasionally parts of the midline thyroglossal duct persist (occurring in lingual, suprahyoid, retrohyoid, or infrahyoid positions). They may form aberrant masses of thyroid tissue, cysts, fistulae or sinuses, usually in the midline (see p. 1459). A *lingual thyroid* situated at the junction of the buccal and pharyngeal parts of the tongue is not uncommon, but nodules of glandular tissue may also be found other than in the midline, e.g. laterally placed posterior to sternocleidomastoid, and, on occasion, below the level of the thyroid isthmus (see p. 1459).

The tonsils are developed from the parts of the second pharyngeal pouches which lie between the tongue and the soft palate. The endoderm lining these pouches grows into the surrounding mesenchyme as a number of solid buds. These buds are excavated by degeneration and shedding of their central cells, and thus the tonsillar *fossulae* and *crypts* are formed. Lymphoid cells accumulate around the crypts and become grouped as lymphoid follicles. A slit-like *intra-tonsillar cleft* (**8**.97) extends into the upper part of the tonsil and is a remnant of the second pharyngeal pouch.

The thymus is derived from the endoderm of the ventral part of the third pharyngeal pouch on each side (**2**.102). It cannot be recognized prior to the differentiation of the inferior parathyroid glands (vide infra), which occurs when the embryo is 10–12 mm long, but thereafter it is represented by two elongated diverticula which soon become solid cellular masses and grow caudally into the surrounding mesenchyme. Ventral to the aortic sac (p. 214) the two thymic rudiments meet and are subsequently united by connective tissue only; the rudiments themselves remain unfused. The connection with the third pouch is soon lost, but the stalk may persist for some time as a solid, cellular cord.

The development of thymic tissue from the ventral recess of the fourth pharyngeal pouch probably occurs in a proportion of embryos, although this has been denied by some authorities (Weller 1933, Norris 1938). Thymic tissue developing from this site is usually found near but outside the thyroid gland in close association with the superior parathyroid gland. An ectodermal contribution to the thymus, probably of placodal origin, occurs in some mammals but a similar contribution in man is conjectural (Garrett 1948).

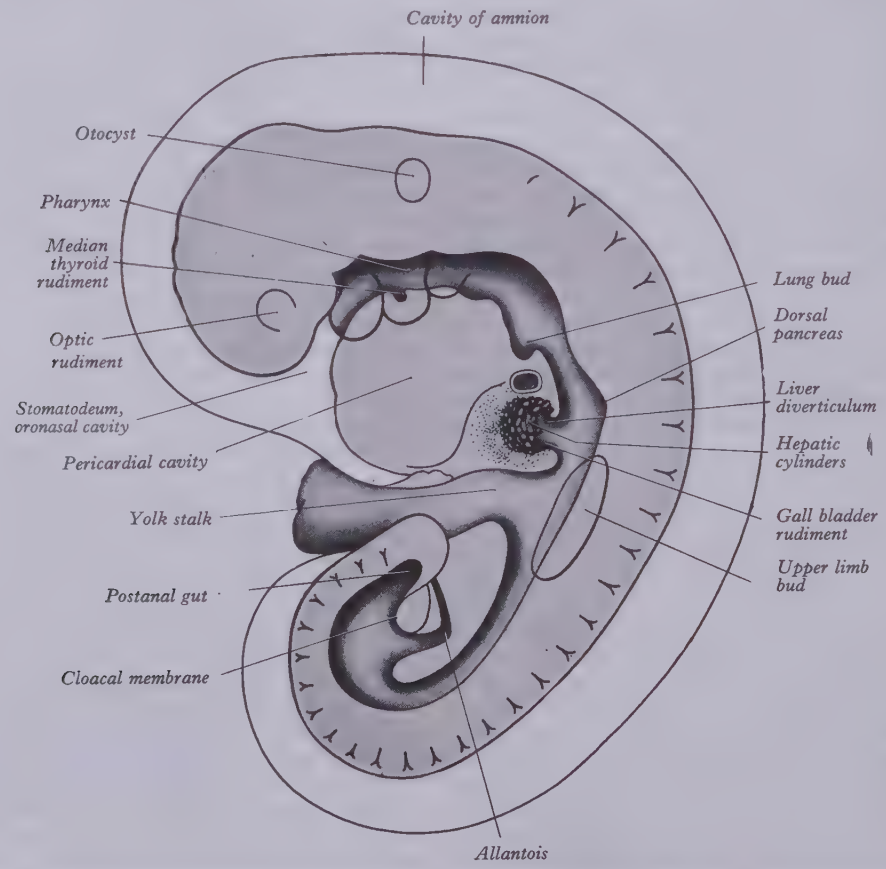
Vascularized mesenchyme, including lymphoid stem cells, invades the cellular mass of the endodermal thymus and becomes partially lobulated. The cells of the cytoreticulum and the concentric corpuscles of the thymus are endodermal in origin. The epithelial character of these cells is more obvious in fetal life; some are even ciliated (Sebuwufu 1968). Lymphoid cells enter and colonize the thymus from the haemopoietic tissue stem cells during the third month, according to observations from in vitro and animal experiments (Auerbach 1960, 1961, Taylor 1965, Moore & Owen 1967).



2.102 Scheme showing the development of the branchial epithelial bodies. The numbered sacs are the edodermal pharyngeal pouches.

At birth the thymus is large relative to total body weight. Its absolute weight increases in the first two years after birth, but its relative weight decreases. There is little change thereafter until about the seventh year, when rapid growth again occurs to reach a maximum at about eleven years. After this it begins to decline to an adult weight which is very variable but averages 12–15 g. In old age the gland shrinks still further, especially after wasting diseases. For this and other reasons it is rarely identifiable in the preserved cadaver of the aged (Keynes 1954, Lasi 1959, and p. 833).

The parathyroid glands are also derivatives of the endoderm and adjacent mixed branchial mesenchyme. Prior to the appearance of the thymic rudiment from the third pharyngeal pouch, the epithelium on the dorsal aspect of the pouch and in the region of its duct-like connection with the cavity of the pharynx becomes differentiated as the primordium of the *inferior parathyroid gland*, recognizable by its cells, which stain more lightly than the other endodermal cells lining the pouch. Although the connection between the pouch and the pharynx is soon lost, the connection between the thymic and parathyroid rudiments persists for some time, and the latter passes caudally with the developing thymus. The *superior parathyroid glands* develop in a similar manner from the dorsal recess of the fourth pharyngeal pouches. They come into relation with, and appear anchored by, the lateral lobes of the thyroid gland and thus remain cranial to the parathyroid glands derived from the third pouch (see p. 1463). The mesenchyme provides the connective tissue envelopment, vasculature including fenestrated capillaries and lymphatics; also a route for vasomotor nerves.



The ultimobranchial body has already been noted as an endodermal diverticular part of the *caudal pharyngeal complex* (**2**.102). This separates from the ectoderm of the fourth branchial cleft and loses its connection with the pharynx by attenuation and rupture of the common pharyngobranchial duct. It becomes closely associated with the expanding lateral lobe of the thyroid gland, and the superior parathyroid (parathyroid IV) component of the complex lying dorsally and outside the thyroid gland. The remainder of the complex, which includes the ultimobranchial body and possibly some vestiges of the ventral recess of the fourth pharyngeal pouch and of the transitory fifth pharyngeal pouch, is enveloped by the thyroid gland. Although some controversy reigned, it is now strongly supported by evidence that the cells of the ultimobranchial body give rise to the 'C' or parafollicular cells producing calcitonin in the thyroid gland of many, if not all mammals (Halmi 1986). Calcitonin has been isolated from ultimobranchial tissue in vertebrates other than mammals (Copp et al 1967, Taylor 1968). The derivation of thyroid parafollicular cells has now been clearly demonstrated in embryonic sheep (Jordan et al 1973). For bibliographical sources see p. 1463 et seq.

The hypophysis cerebri consists of the adenohypophysis and the neurohypophysis; the former is derived from the placodal ectoderm of the stomatodeal roof (cf neural crest), the latter from the neurectoderm of the floor of the forebrain. (Consult p. 1451 for the varied usages of the older terms, anterior and posterior lobes, with the more satisfactory adenohypophysis and neurohypophysis, and their subdivisions.) From the outset the placodal roof and overlying forebrain are in close apposition and adherent, with no intervening mesenchyme; elsewhere, and up to the placodal margins, mesenchyme is interposed. Before rupture of the oropharyngeal membrane, proliferation of the periplacodal mesenchyme results in the placode forming the roof and walls of a saccular depression. This hypophysial recess (*pouch of Rathke*) (**2**.103A) is the rudiment of the adenohypophysis, lying immedately ventral to the dorsal border of the membrane, extending in front of the rostral tip of the notochord, and retaining contact with the ventral surface of the forebrain. It is constricted off by continued proliferation of the surrounding mesenchyme to form a closed vesicle, but remains for a time connected to the ectoderm

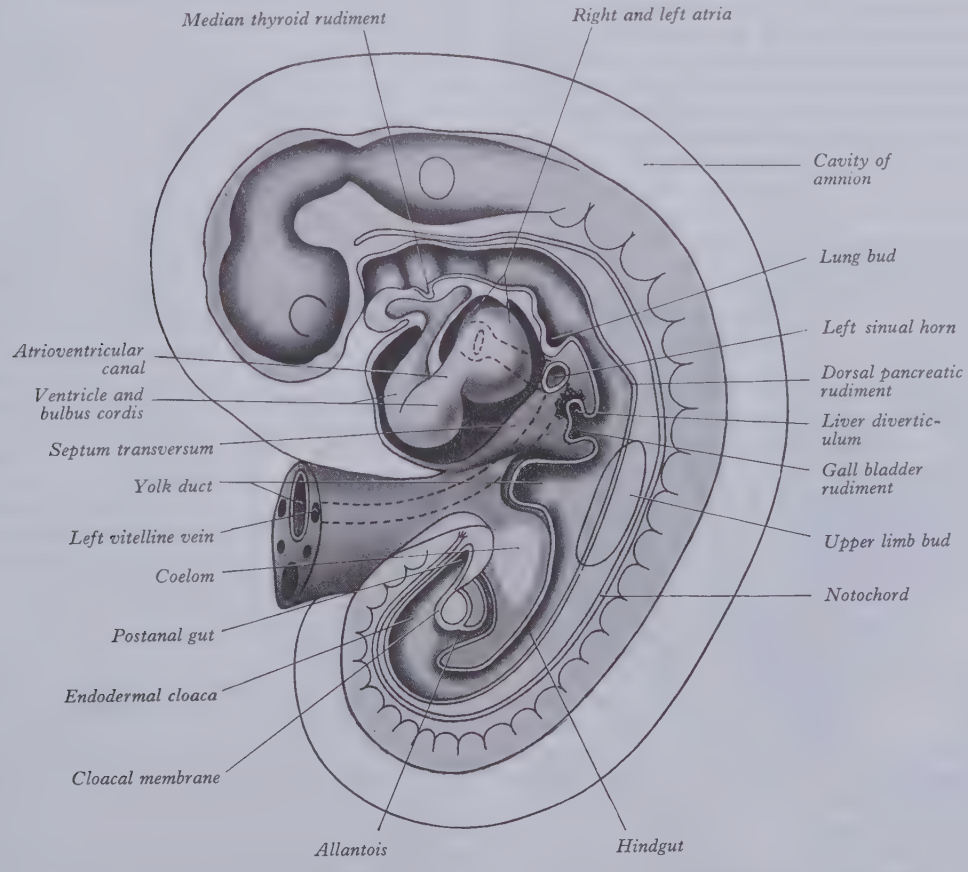
2.103 Schematic sagittal sections of heads of early embryos to show first stages in the development of the hypophysis.

of the stomatodeum by a solid cord of cells, which can be traced down the posterior edge of the nasal septum. Masses of epithelial cells form mainly on each side and in the ventral wall of the vesicle, and the development of the adenohypophysis progresses by the ingrowth of a mesenchymal stroma. Differentiation of epithelial cells into stem cells and three differentiating types is said to be apparent during the early months of fetal development (Dubois 1967). Recent work also suggests that different types of cells arise in succession, and that they may be derived in differing proportions from different parts of the hypophysial recess (Conklin 1968, see also p. 1451 et seq). A *craniopharyngeal canal*, which sometimes runs from the anterior part of the hypophysial fossa of the sphenoid bone to the exterior of the skull, is often said to mark the original position of the hypophysial recess (of Rathke). Traces of the stomatodeal end of the recess are invariably present at the junction of the septum of the nose with the palate (see the *pharyngeal hypophysis* p. 1455). Others have claimed, however, that the craniopharyngeal canal itself is a secondary formation caused by the growth of blood vessels, and is quite unconnected with the stalk of the anterior lobe (Arey 1949). Just caudal to, but in contact with, the adenohypophysial recess a hollow diverticulum elongates towards the mouth from the floor of the diencephalon (2.103B). This neural outgrowth forms an *infundibular sac*, the walls of which increase in thickness until the contained cavity is obliterated except at its upper end, where it persists as the *infundibular recess* of the third ventricle. Formed in this way the neurohypophysis becomes invested by the adenohypophysis which extends dorsally on each side of it. In

2.104A The digestive tube of a human embryo with 29 paired somites, a CR length of 3.4 mm and an estimated age of 27 days. Note branchial development. Magnification × *c.*25. (Streeter 1942.)

addition, the adenohypophysis gives off two processes from its ventral wall which grow along the infundibulum and fuse to surround it, coming into relation with the tuber cinereum and constituting the *tuberal portion* of the hypophysis. The original cavity of Rathke's pouch remains first as a cleft, and later scattered vesicles, and can be identified readily in sagittal sections through the mature gland. The dorsal wall of Rathke's pouch, which remains thin, fuses with the adjoining part of the neurohypophysis as the *pars intermedia*.

A small endodermal diverticulum, named *Seessel's pouch*, projects towards the brain from the cranial end of the foregut, immediately caudal to the oropharyngeal membrane. In some marsupials this pouch forms a part of the hypophysis, but, in man, it apparently disappears entirely; initially it may contribute some cells to the general head mesenchyme of mixed origin, and possibly functions as one of many rostral head organizers (together with the prechordal plate of endoderm).

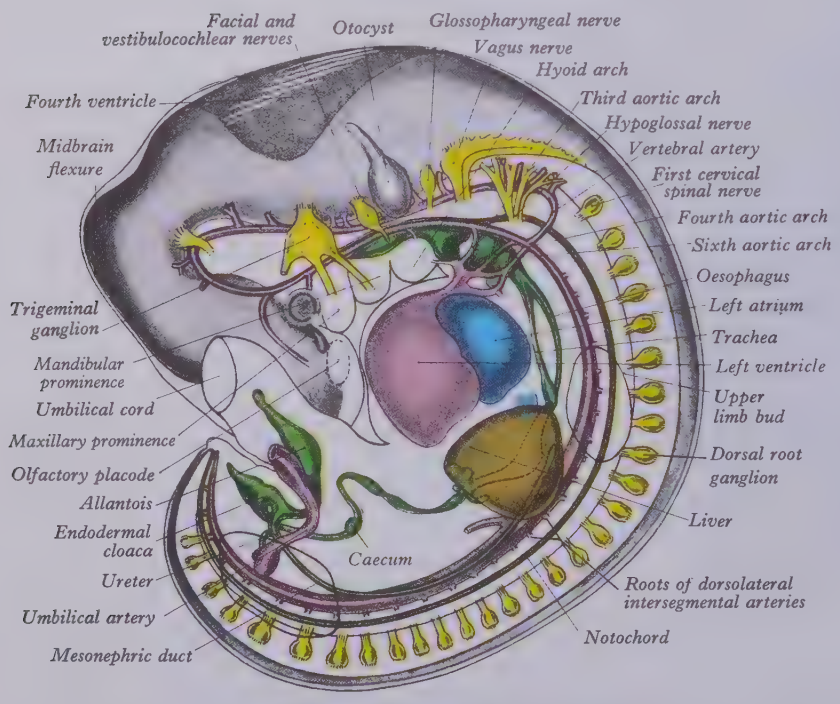


The Pharynx

The pharynx is the cranial end of the foregut, and the branchial arches and pharyngeal pouches play an important part in its development (**2**.104A,B). The endodermal aspect of the first (maxillomandibular) arch in its dorsal part contributes to the formation of the lateral wall of the nasopharynx in front of the orifice of the auditory tube. The ventral end of the first pouch becomes obliterated, but its dorsal end persists and deepens as the head enlarges. It remains close to the ectoderm of the dorsal end of the first cleft (p. 170) and, together with the adjoining lateral part of the pharynx and dorsal part of the second pharyngeal pouch, constitutes the *tubotympanic recess*, which forms the tympanic cavity and the auditory tube (p. 204), and ultimately their extensions. The site of the second arch is partly indicated by the *palatoglossal arch*, but its dorsal end is separated from its ventral end by the forward growth of the third arch, which obliterates the intermediate part. Some believe that the site of the second pharyngeal pouch is represented by the *intratonsillar cleft*, around which the tonsil is developed. The third arch forms the *lateral glosso-epiglottic fold*, and its dorsal end takes part in the formation of the floor of the auditory tube. The ventral ends of the fourth arches fuse with the caudal part of the hypobranchial eminence and so contribute to the formation of the *epiglottis* (p. 165). The adjoining portion becomes connected to the *arytenoid swelling* and may be identified in the *aryepiglottic fold*.

After the caudal part of the hypobranchial eminence has separated from the pharyngeal (posterior) part of the tongue (p. 238), it is in continuity with two linear ridges which appear in the ventral wall of the pharynx, the whole forming an inverted U, sometimes regarded as an independent formation, the *furcula* (of His). These vertical ridges have been identified as the sixth arches, placed very obliquely owing to the shortness of the pharyngeal floor compared with the greater extent of the roof. The ridges of the furcula are carried downwards on the ventral wall of the foregut and bound the median *laryngotracheal groove*, from which the lower part of the larynx, the trachea, bronchi and lungs are developed (p. 238). At the cranial end of the groove paired arytenoid swellings arise which convert the slit-like upper aperture of the respiratory system into a T-shaped opening. The aryepiglottic folds (fourth arch derivatives) can be recognized at this stage.

DEVELOPMENT OF THE POSTPHARYNGEAL GUT



The profound changes occurring late in the third and throughout the fourth weeks as, with head, tail and lateral folding, the trilaminar mass begins to assume its definitive embryonic form, have been outlined (p. 140). In the present context, the derivatives of the embryonic gut, a splanchnopleuric tube extending from oropharyngeal to cloacal membranes, are considered further; as a preliminary, they are summarized here. The central (intermediate, or 'middle') regions of the gut are initially still in

2.104B Composite diagram of a graphic reconstruction of a human embryo at the end of the fourth week. The alimentary canal and its outgrowths are shown in median section. The brain is shown in outline, but the spinal cord is omitted. The heart is shown in perspective, the left horn of the sinus venosus having been divided. The somites are indicated in outline. (After Streeter 1942.)

wide communication with the extraembryonic secondary yolk sac through the relatively large umbilicus (bounded by the advancing somatopleuric body folds). The *foregut* extends from the oropharyngeal membrane (floor of the stomatodeum) to its opening, or continuation, into the central midgut region through the anterior intestinal portal. Foregut derivatives are part of the buccal cavity, the pharynx (and their numerous sub-regions), the laryngo-tracheobronchio-pulmonary system, the oesophagus, stomach, the superior and about the proximal half of the descending parts of the duodenum, the liver, gallbladder and biliary duct systems, the pancreas and ducts; closely associated with these, but 'mesenteric' in origin, the spleen. The site of the original anterior intestinal portal is immediately caudal to the common hepatopancreatic ampulla and papilla. The *midgut*, between the intestinal portals, becomes tubular (with constriction and atrophy of the yolk duct), lengthens, being destined to form the remaining duodenum (postpapillary descending, transverse and finally ascending parts, then the jejunum, ileum, caecum and appendix, ascending colon, and much of the transverse colon. The site of the posterior portal remains controversial—from two-thirds across the transverse colon to the splenic flexure. The *hindgut* extends from the neighbourhood of the splenic flexure to (and a little beyond) the cloacal membrane. Its gut derivatives are the descending colon, sigmoid colon, rectum, and anal canal to the level of the anal valves. The caudoventral part of the hindgut is continuous with the allantoic duct; it separates from the alimentary hindgut, and contributes to the urinary bladder, urethra and associated glands.

The foregut immediately caudal to the pharynx remains as a splanchnopleuric tube which elongates to form the *oesophagus*. At five weeks its epithelium is two cells thick, the luminal columnar cells developing cilia at approximately 10 weeks, and only later begin to differentiate into stratified squamous epithelium, in the fifth month. Non-striated circular and longitudinal layers of muscle are identifiable at about the ninth week; striated fibres begin to appear at the tenth week. As the neck and thorax develop the oesophagus lengthens rapidly. At the end of the fourth and beginning of the fifth week the *stomach* can be recognized as a fusiform dilation (**2**.104–106), and a little beyond this is the wide opening of the midgut into the yolk sac; by the fifth week the opening has narrowed into a tubular *yolk stalk* (containing the endodermal *yolk duct*) (**2**.104–106), which soon loses its connection with the digestive tube (**2**.106). At this stage the stomach is median in position and separated cranially from the pericardium by the septum transversum (p. 140), which extends caudally on to the cranial side of the yolk duct and ventrally to the somatopleure. Dorsally, the stomach is related to the aorta and, reflecting the presence of the pleuroperitoneal canals on each side, is connected to the body wall by a short dorsal mesentery, the *dorsal mesogastrium* (**2**.114). The latter is directly continuous with the dorsal mesentery (*mesenteron*) of almost all of the remainder (except its caudal short segment) of the intestine. The liver develops as a hollow outgrowth from the ventral aspect of the foregut and grows cranially into the substance of the septum transversum (**2**.104,106), this part of the septum (*pars mesenterica*) now being termed the *ventral mesogastrium*. The rest of the intestine has no ventral mesentery.

2.105 A human embryo of 7 mm greatest length. Fifth week. Left lateral aspect. (After Thompson.)

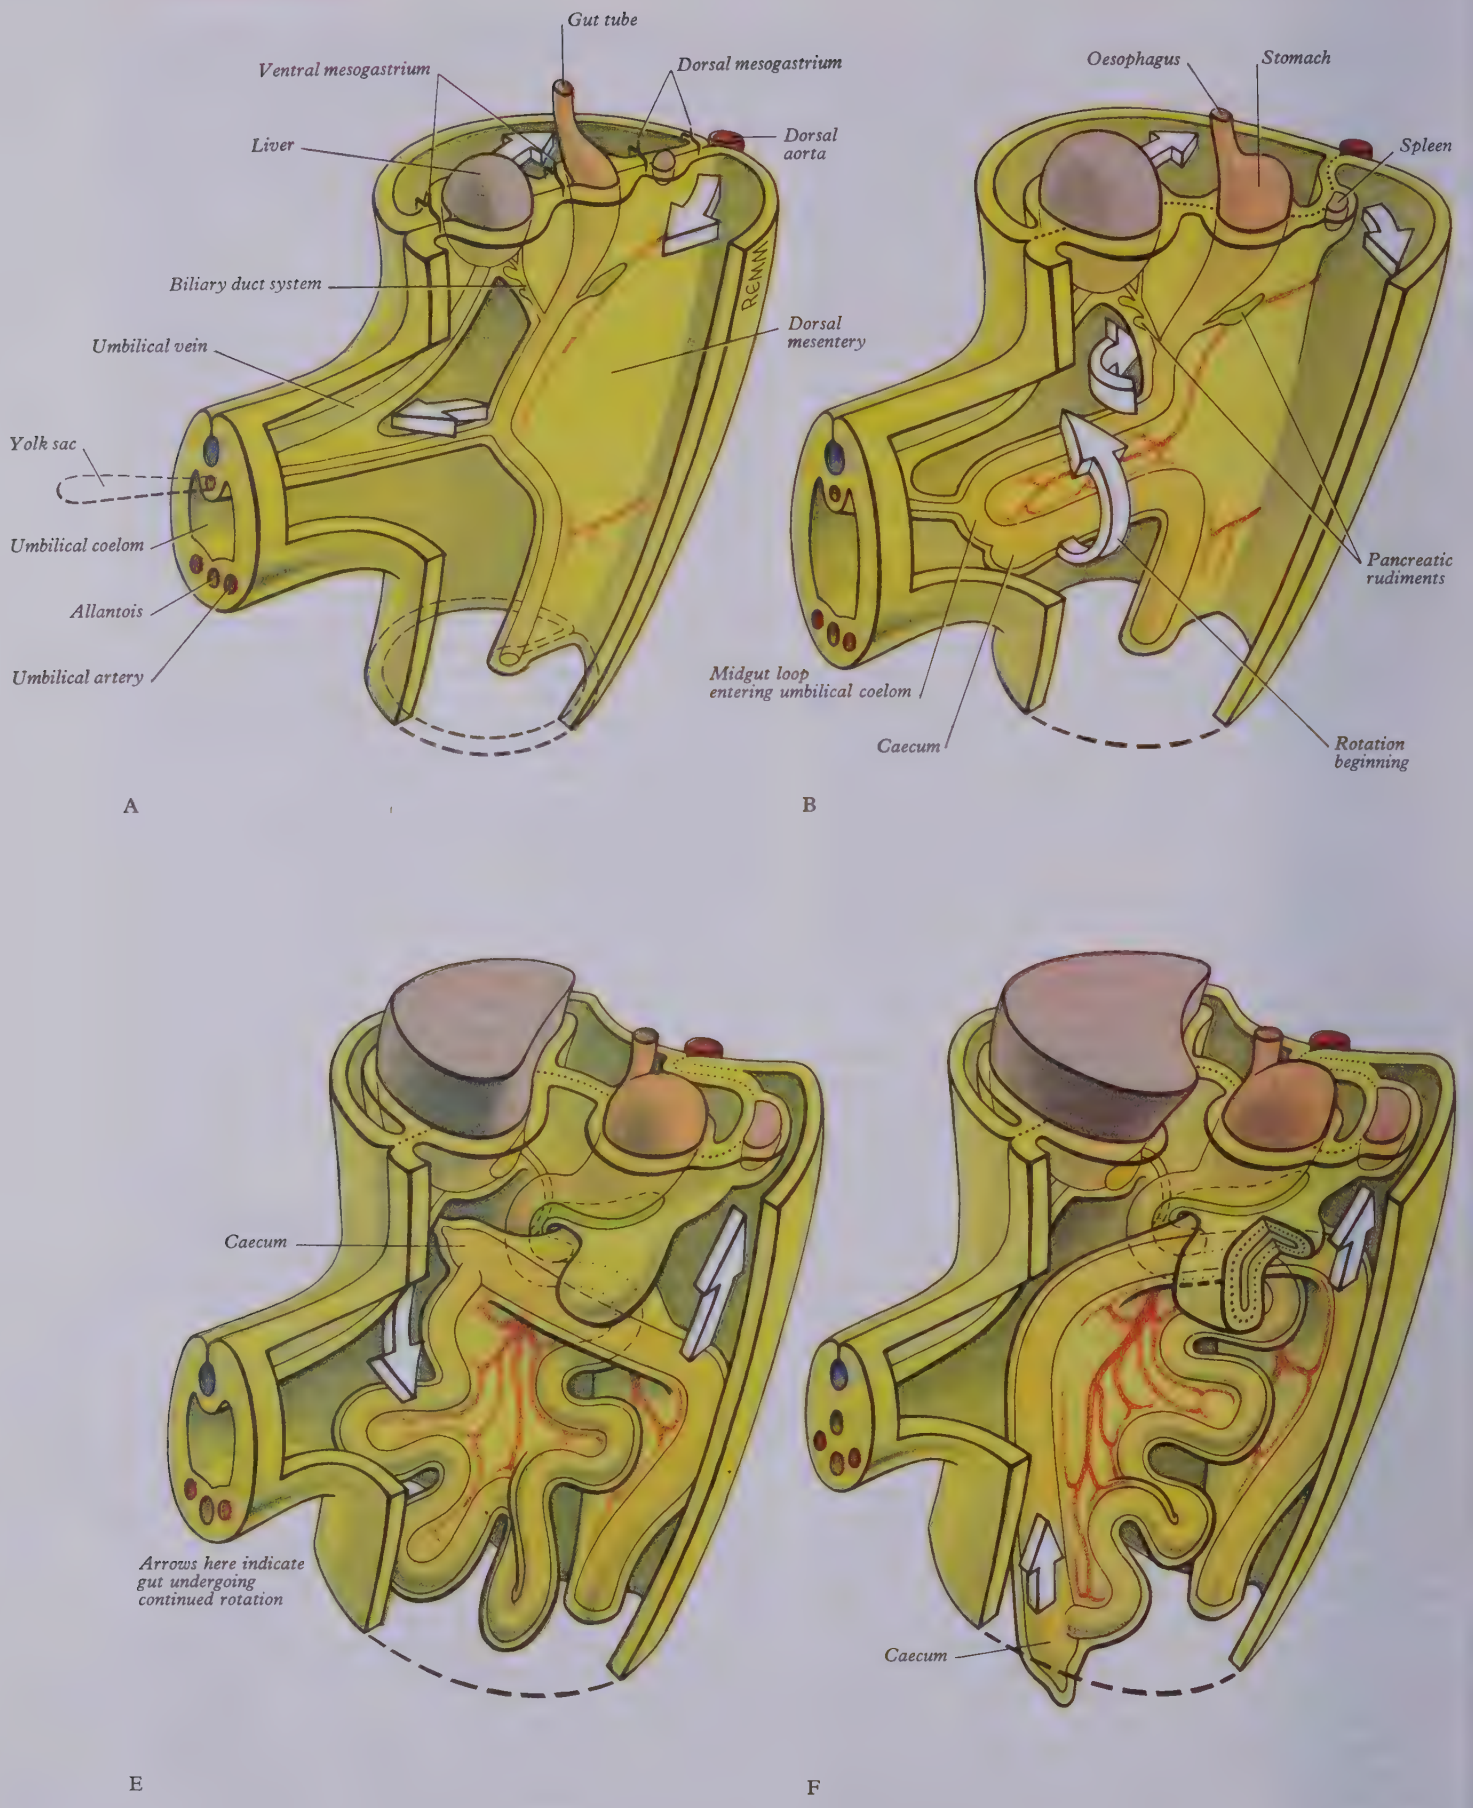
In human embryos of 10 mm, the characteristic gastric curvatures are already recognizable. (What follows in this paragraph is largely a summary of long-held traditional views of gastric and omental development. More recently close reappraisal of human embryonic serial sections has led to many major descriptive changes and alternative proposals, see p. 240.) Growth is more active along the dorsal border of the viscus; its convexity markedly increases and the rudimentary fundus appears. Because of more rapid growth of the dorsal border, the pyloric end of the stomach turns ventrally and the concave lesser curvature becomes apparent (**2**.106). The stomach is now *displaced* to the left of the median plane and apparently becomes physically *rotated*, thus its originally right surface becomes dorsal and its left ventral. Accordingly the right vagus nerve is distributed mainly to the dorsal and the left mainly to the ventral surface of the organ. The dorsal mesogastrium increases in depth and becomes folded on itself; the ventral mesogastrium becomes more coronal than sagittal. The pancreatico-enteric recess (p. 240), hitherto usually described as a simple depression on the right side of the dorsal mesogastrium, becomes dorsal to the stomach and excavates downwards and to the left between the folded layers. It may now be termed the inferior recess of the *bursa omentalis*. The displacement, morphological changes and apparent 'rotation' of the stomach has been attributed variously to its own and surrounding differential growth changes, extension of the pancreatico-enteric recess with changes in its mesenchymal walls, and pressure, particularly by the rapidly growing liver (Kanagasuntheram 1957). (As intimated, the account just given prevails in basic courses and textbooks and perhaps suffices for some purposes. For a more complete treatment see p. 240 et seq.)

The midgut, while the gastric changes just outlined are occurring, increases in length more rapidly than the vertebral column, and forms a *midgut loop*, which acquires a dorsal mesentery as it lengthens, and projects into the coelomic cavity (**2**.106). The rapidly growing liver and the developing mesonephroi encroach on much of the available space in the coelom, and the midgut loop is extruded into the *umbilical coelom*, i.e. that part of the extraembryonic coelom which lies in the proximal end of the umbilical cord (p. 143). This protrusion (often, quite inappropriately, called a 'physiological hernia') is a *normal* condition in human embryos between the 10 mm (end of fifth week) and the 40 mm (third month) stages; abnormally it may persist until term.

The rotation of the stomach reacts on the position of the duodenum, which prior to this stage is also a (smaller) right ventrolaterally directed *duodenal loop*, but is now carried further dorsally and to the right. At this stage the duodenum possesses a thick dorsal mesentery (*dorsal mesoduodenum*) which is continuous with the dorsal mesogastrium, rostrally, and the mesentery of the intestinal midgut loop, caudally. The extreme caudal free edge of the ventral mesogastrium extends on to the short initial segment of the duodenum (as a '*ventral mesoduodenum*'): this also retains a coextensive part of the *dorsal mesoduodenum* (**2**.106). Later, the approximation of the duodenum to the dorsal abdominal wall leads first to the adhesion of the right side of its mesentery to the parietal peritoneum and later to the absorption of both layers. In this way almost the whole duodenum comes to be sessile or 'retroperitoneal' (except the short initial segment just mentioned). It may be restated that the second (descending) part of the duodenum includes the foregut-midgut junction. The lining epithelium of the duodenum proliferates and almost occludes the lumen by the sixth week; the channel is re-established by the third month when the epithelium reverts to a simple columnar form.

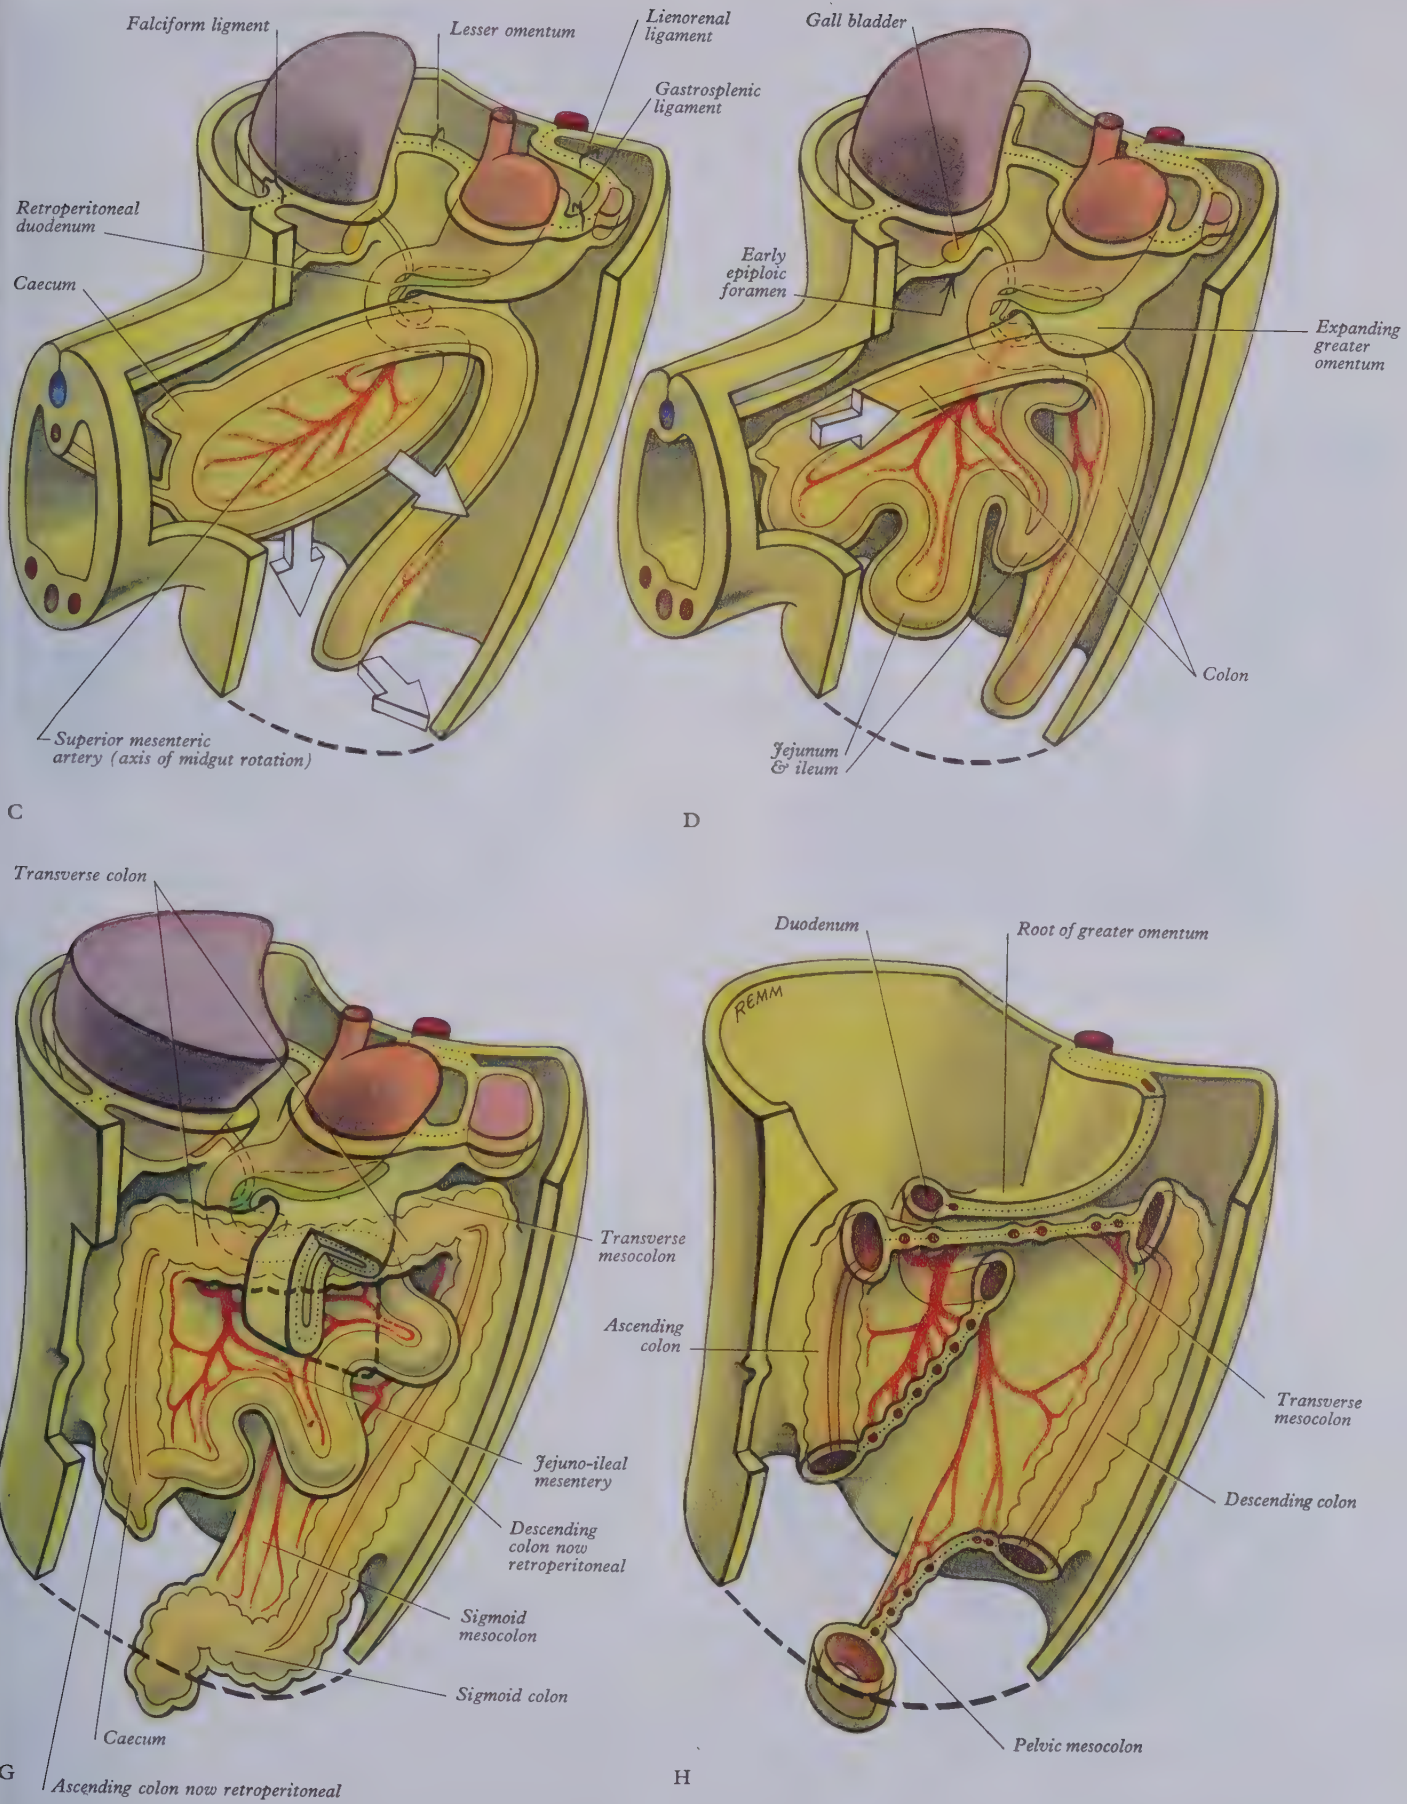
Early in the sixth week a small diverticulum appears on the antimesenteric border of the caudal limb of the midgut loop (**2**.105,106), and this later differentiates into *caecum* and *vermiform appendix*. Therafter it is possible to distinguish large from small intestine. Until the fifth month the diverticulum is conical, but thereafter its distal part remains rudimentary and forms the vermiform appendix, while its proximal part expands to form the caecum. At birth the vermiform appendix extends from the *apex* of the caecum; owing to unequal growth in the walls of the latter, it subsequently opens on the posteromedial caecal wall (p. 1366).

When the midgut loop enters the umbilical coelom it has already rotated through an angle of 90° so that the proximal limb (i.e. the limb nearer to the stomach) lies to the right and the distal limb to the left (**2**.106). This relative position is roughly maintained so long as the protrusion persists, but during this period the proximal part forming the small intestine becomes elongated and coiled, and the mesentery adapts itself to these changes in the gut. Thus its intestinal attachment also elongates and becomes folded, roughly along a 'horizontally' disposed zone, whereas its parietal attachment is much shorter, straight and for a while median and vertical. Overall, therefore, the mesenteric sheet is 'spiralized', with its contained vessels, through some 90°. The colic part of the loop elongates less rapidly and has no tendency to become coiled. By the time the fetus has attained a length of 40 mm (middle of third month), the peritoneal cavity has enlarged sufficiently for re-entry of the midgut to occur fairly rapidly, but in a definite sequence. The orderly progression is significant because, throughout, the gut *continues* the process of *rotation*, resulting ultimately, after differential growth, in the establishment of the definitive relationships which characterize the adult large intestine, including the relation of the transverse colon to the duodenum. The process has been analysed as follows: Frazer & Robbins (1915) may be consulted for the classic account of gut rotation: the present account, however, differs substantially from previous accounts in accord with the data presented by Harris & Jones (1976), from a radiological study of 64 fresh fetuses of 11 to 20 weeks of gestation. It should be noted, however, that *interpretation* of observations of the latter authors has not been followed in its entirety, and some common misconceptions stemming from the classic account will be pointed out.



While the midgut is still in the umbilical coelom the dorsal mesentery forms a dorsally median, but ventrally spiralized, partition from the dorsal wall to the umbilicus. As the gut re-enters the abdominal cavity, the coils of the small intestine, which return first, necessarily enter to the *right* of this partition, thrusting it over to the *left* and thus determining the position of the descending colon. They pass dorsal to the (oblique) superior mesenteric artery and determine its adult relationship to the horizontal part of the duodenum. This disposition of the duodenum is probably an important factor modulating midgut rotation. The caecum is the last to re-enter and at first lies on the surface of coils of ileum. Subsequently, with growth and some continued rotation the caecum is carried *dorsocaudally* and to the *right* where it lies *in*, or even a little *caudal* to the diminutive *right iliac fossa*. It must be appreciated that at this stage the fetal liver is still relatively grossly enlarged and the caecum can be termed *subhepatic* in position, but that the term does *not* imply (as it is held to do in most textbook accounts) that the caecum returns to the right *upper* quadrant of the abdominal cavity. Harris and Jones named midgut-derived colon *presplenic* and hindgut-derived colon *postsplenic*, the transitional zone, of course, corresponding to the presumptive splenic flexure. At an early stage, after the completion of gut rotation, the proximal part of the presplenic colon runs largely *transversely* across the *lower* abdominal cavity, its left extremity curving cranially to reach the *primitive splenic flexure*, from which point the postsplenic colon first descends vertically, and then curves to the right, finally descending in the midline—the primitive rectum.

The hindgut and colon: further development. The longitudinal muscle coat differentiates earlier in the small than in the large intestine, and it has been suggested that this may play a role in the return of the midgut into the abdomen from the umbilical coelom (Kanagasuntheram 1960). As the coils of small intestine re-enter, the mesentery of the *descending* postsplenic colon is thrust against the left dorsal abdominal wall and their opposed peritoneal surfaces become adherent and gradually absorbed. The descending colon thus loses its mesentery, becoming sessile. Since this change takes place towards the end of the third month, the position of the left colic vessels, on the posterior abdominal wall, is secondary and thus ventral to such structures as the left ureter and gonadal vessels, which are primarily associated with the posterior wall. The pelvic part of the postsplenic colon, however, does not become sessile but retains its dorsal mesentery; nevertheless, the original midline parietal attachment of the latter, by *partial* adherence and fusion, gradually assumes the inverted V shape characteristic of the adult.

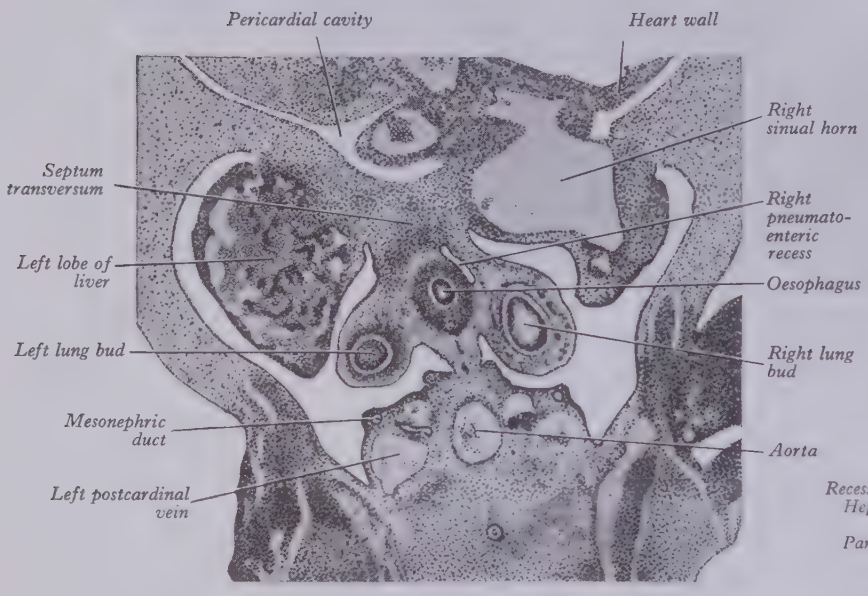


As the visceral surface of the enlarged liver gradually recedes towards the costal margin, the presplenic colon changes its early disposition, becoming first oblique, then progressively develops its *ascending* and *transverse* parts. The former becomes sessile in the same manner as the descending colon, whilst the proximal part of the transverse colon is usually also sessile, and passes ventral to the descending (second) part of the duodenum, to which it adheres. The remainder of the transverse colon retains its dorsal mesentery, the *transverse mesocolon*, which now has a *horizontal* parietal attachment to the head, neck and body of the developing pancreas. Whilst this is occurring the omental bursa is expanding and the transverse colon passes dorsal to the bursal extension; a variable degree of fusion follows between the transverse mesocolon and the dorsal fold of that part of the dorsal mesogastrium destined to become the greater omentum (**2**.106). Meanwhile, as the hepatic flexure is gradually defined, there occurs a slow, short *ascent* of the ileo-caecal junction to the upper part of the right iliac fossa, and a more rapid ascent of the splenic flexure to its definitive position. (This account is in complete contrast to earlier descriptions, which maintained that the early caecum *descended* by slow growth from the subhepatic right upper abdominal quadrant caudally to the right iliac fossa.)

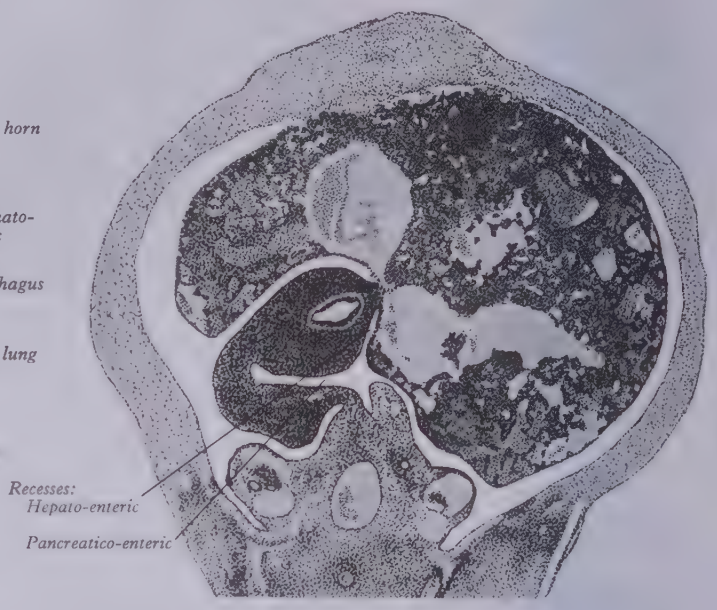
Rectum and *anal canal* development is associated with the growth of the tail fold, described earlier (pp. 140, 258). Further, it is intimately associated with that of the bladder and other elements of the urogenital system, hence associated illustrations appear later (see p. 258 and **2**.122A-F). As growth proceeds, the gut lengthens, at first *pari passu* with the embryo, and an increasing segment of *hindgut* emerges between the caudal aspect of the yolk stalk and the root of the allantois (**2**.104B). The hindgut caudal to the latter level dilates forming a pouch, the *endodermal cloaca*, and in its ventral wall the *cloacal membrane* (p. 259) occupies the midline (**2**.122A). Proliferation of the surrounding mesoderm causes the cloacal membrane to lie as the floor of a shallow depression, the *ectodermal cloaca* (**2**.122A). The hindgut and allantois open into the endodermal cloaca from its inception, but in the fifth week the mesonephric ducts pierce its wall. When this occurs the ventral cloaca is wider than the dorsal. The latter remains very narrow, and it is into the dorsolateral corner (lateral horn) of the ventral part that the mesonephric duct opens (**2**.122B,C).

The mesenchyme outside the line of union of the dorsal and ventral parts of the cloaca grows rapidly and thrusts the endodermal epithelium inwards. As a result the two opposing walls come into apposition and fuse. This process commences opposite the connection of the allantoic canal with the cloaca and is continued caudally to form a *urorectal septum*, which separates the *dorsal segment* or presumptive rectum and upper anal canal from the *ventral segment*, which forms the urinary bladder and the urogenital sinus (**2**.122B). Caudally the urorectal septum reaches the cloacal membrane and divides it into *anal* and *urogenital membranes*. For a time a *cloacal duct* connects the two parts of the cloaca proximal to the growing urorectal septum (**2**.122C), and occasionally persists as an anomalous fistula between rectum and bladder or urethra. Anal tubercles (ectodermal elevations over loci of mesodermal proliferation) form round the margin of the anal part of the cloacal membrane, which thus comes to lie at the bottom of a depression, the ectodermal *proctodeum* (Tench 1936). With the absorption and disappearance of the anal membrane the anorectum communicates with the exterior (**2**.122E). The lower part of the anal canal is formed from the proctodeal ectoderm and surrounding mesoderm, but its upper part is lined by endoderm splanchnopleuric in origin and is derived from the caudal end of

2.106 Three-dimensional schematization of the major developmental sequences of the subdiaphragmatic embryonic and fetal gut, together with its associated major glands, peritoneum and mesenteries, viewed from the left anterolateral aspect. The developmental sequence A–F spans 1½ months to the perinatal period. H denotes the general disposition of the

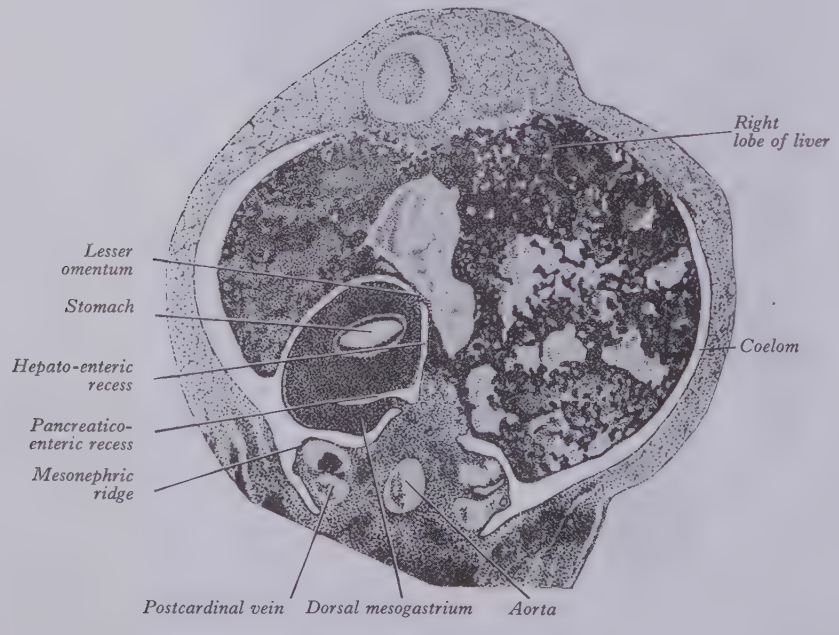


remaining viscera, mesenteric roots with their lines of attachment, and principal contained vessels, which approximate to the adult state for comparison. Some features of the sequence presented do not correspond to traditional descriptions—see text for further comment.

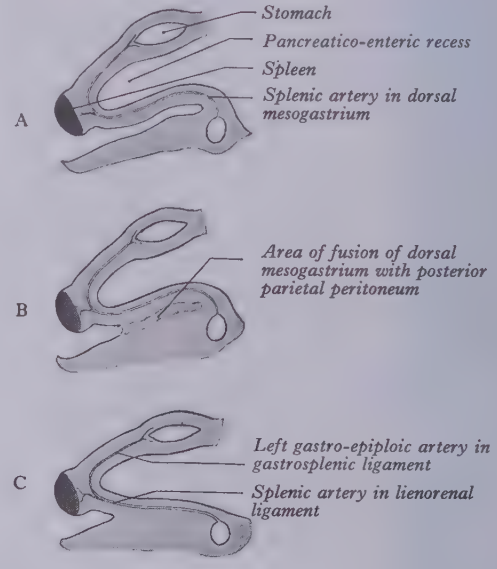


the dorsal division of the cloaca; the line of union corresponds with the edges of the anal valves in the adult (p. 1370). In the fourth and fifth weeks a small part of the hindgut, named the *postanal gut* (2.122A), projects caudally beyond the anal membrane; it usually disappears before the end of the fifth week. The dual origin of the anal canal is reflected by differences in arterial supply, venous and lymphatic drainage, innervation and epithelial specialization (summarized on p. 1373).

The development of the *nerve supply* of the gut has received relatively little attention in human material. A migration of neuroblasts to establish a vagal innervation has been described in human embryos between the eighth and twelfth weeks (Okamoto & Ueda 1967), which is distributed in a craniocaudal direction to establish the myenteric plexus; the vagal ramifications in the oesophageal wall have been identified at the 15 mm stage (Lecco & Balli 1968). Ultrastructural and histochemical observations suggest that, in the fetal small intestine and colon, the mucous membranes have already developed a potential for absorption (Lev & Orlic 1974).



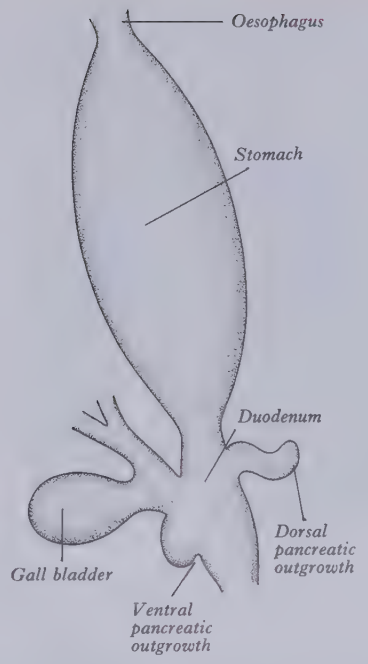
The further development of the main body cavities, pericardial, thoracic and abdominal, their separation and serous membrane complexes and the differential growth of their contained viscera are so interdependent that any descriptive order chosen is defective, either because of over-simplification or omission in some



2.107A Transverse section of a human embryo, 8 mm long, showing the right pneumato-enteric recess.

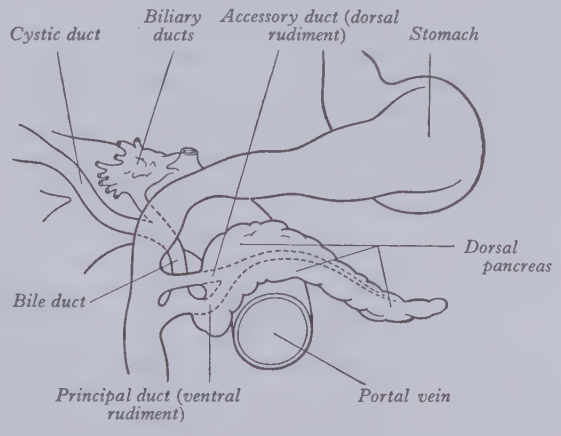
2.107C Transverse section through the same embryo as 2.98B, but 150 μm more caudally. Compare with the preceding figure and observe that the omental bursa (pancreatico-enteric recess) communicates with the general peritoneal cavity at this level.

2.107B Transverse section through the same embryo as 2.98A but 530 μm more caudally. Note that rotation of the stomach has taken place and that the sinusoidal spaces in the liver communicate freely with one another.



2.107D Diagram to show the fusion of the proximal part of the dorsal mesogastrium with the peritoneum on the posterior abdominal wall. Note also the conversion of the dorsal mesogastrium into the gastrosplenic and lienorenal ligaments. A represents a transverse section of an embryo in which the dorsal mesogastrium is still at the stage shown in 2.107. B and C represent transverse sections of older embryos made at the same level (simplified, however, by retaining the shape and size of the stomach and spleen).

parts or, conversely, constant repetition. Cross references may help to minimize these problems. Here, brief accounts of the liver, pancreas and spleen, precede attempts to summarize the peritoneum and omental bursa, intestinal anomalies, then the respiratory system and separation of the body cavities.



The liver arises in the fourth week as a diverticulum from the ventral surface of the duodenal foregut, close to its junction with the midgut, where the latter is continuous with the yolk stalk (**2**.104A,B). This diverticulum, lined with endoderm, grows ventrally and cranially into the septum transversum; its tip diverges into two solid *hepatic buds* of cells, the future right and left lobes of the liver. The buds develop into epithelial trabeculae or sheets (so called *hepatic cylinders*), which branch and anastomose to form a close meshwork (*labyrinth* or *muralium*). The intervals of the meshwork become filled with blood *sinusoids*, and on section the organ has the appearance of a vascular sponge (**2**.107C). These vessels arise in situ possibly as the result of the influence exercised by the endodermal cells of the liver on the potentially angiogenic cells of the mesenchyme of the septum transversum (Streeter 1942); but also by dilatation of pre-existing septal capillaries that are plexiform tributaries of the transeptal vitelloumbilical veins (p. 220). The commonly described simple direct invasion of the vitelline veins by the epithelial trabeculae of the liver to form a sinusoidal system occurs only over a restricted area in a few mammals (Elias 1955). By the continued growth and ramification of the endodermal hepatic sheets the mass of the liver is gradually formed, but its connective tissue stroma and phagocytic sinusoid-lining cells are derived from the included mesenchymal cells of the septum transversum. Recent observations suggest that the formation of intrahepatic ducts is dependent upon contact between the developing embryonic liver mass and a preformed extrahepatic duct system (Elias 1967). The original diverticulum from the duodenum forms the *bile duct*, and from its distal part the cystic duct and gallbladder arise as an outgrowth, solid at first but later canalized. The bile duct first opens into the ventral wall of the duodenum; later, after gut rotation, it migrates to the left across the dorsal (originally right) surface of the duodenum to the position which it occupies in the adult on the medial border. The migration is ascribed to differing rates of growth in the duodenal walls and is aided by proliferation of the lining epithelium of the duodenum, which is most marked in this position (Kanagasuntheram 1960).

As the liver enlarges, it projects more and more into the abdominal cavity from the caudal surface of the septum transversum. In the process, mesenchyme of the septum becomes drawn out and cavitated ventral to the liver to form the falciform ligament, and craniodorsally to form the coronary right and left triangular ligaments, and the lesser omentum. These peritoneal folds are collectively the *ventral mesogastrium*. (Strictly, the lesser omentum, in and near its free border, also includes the less extensive *ventral mesoduodenum*.) At three months the liver almost fills the abdominal cavity and its left lobe is nearly as large as its right. Later the relative development of the liver is less active, more especially that of the left lobe, which actually undergoes some degeneration and becomes smaller than the right. The dominance of the right lobe is reflected in the large expanse of the coronary and right triangular ligaments, compared with the diminutive left triangular ligament. Until birth the liver remains relatively larger than in the adult.

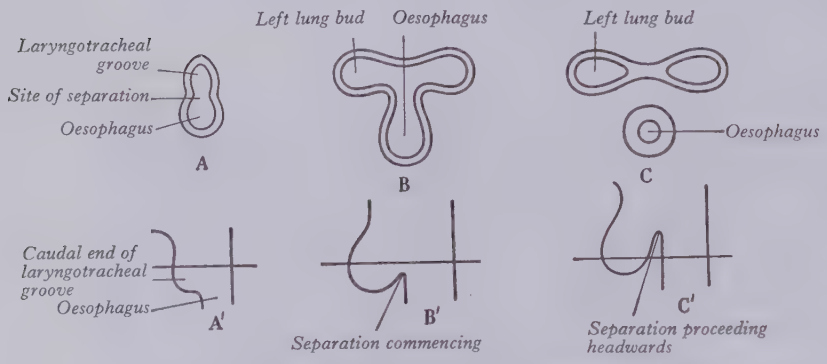
The pancreas (**2**.108A,B) is developed in *dorsal* and *ventral* parts. The former arises in the latter half of the fourth week as a diverticulum from the dorsal wall of the duodenum a short distance cranial to the hepatic diverticulum; growing craniodorsally in the dorsal mesoduodenum it enters that part of the dorsal mesogastrium which is, before fusion, forming the dorsal wall of the inferior part of the bursa omentalis. (See pancreatico-enteric recess, p. 246.) It forms the whole of the neck, body and tail of the pancreas and a part of the head. The *ventral* part grows out from the primitive bile duct near the opening of the latter into the duodenum. This outgrowth is at first double, but the two fuse and the resulting mass, initially in the ventral mesoduodenum, soon grows round the gut into the dorsal mesoduodenum where it enlarges to form the remainder of the head of the gland (Odgers 1930). The duct of the dorsal part (the *accessory pancreatic duct*)

2.108A Diagram of an early stage in the development of the pancreas in a human embryo, 7.5 mm long; lateral view. (After Streeter.)

2.108B A later stage in the development of the pancreas in a human embryo, 14.5 mm long; ventral view. (After Streeter.)

therefore opens directly into the duodenum, while that of the ventral part (the *main pancreatic duct*) opens with the bile duct. Early in the seventh week the two parts of the pancreas meet and fuse, and an oblique communication is established between their ducts (**2**.108B). After this the accessory duct undergoes little or no enlargement, while the duct of the ventral part increases in size and forms the terminal of the main duct of the gland. The duodenal opening of the accessory duct is sometimes obliterated, and, even when patent, it is probable that most of the pancreatic secretion is conveyed through the main duct.

At first the body of the pancreas extends from the dorsal mesoduodenum, and progresses craniodorsally between the layers of the dorsal mesogastrium in the dorsal wall of the bursa omentalis (**2**.114). When the upper part of this wall fuses with the dorsal parietal peritoneum, the process of fusion continues caudally as far as the inferior border of the pancreas, and thus the gland finally becomes almost wholly sessile on the dorsal wall of the abdomen. The anterior border of the gland now provides the main line of attachment for the ascending (posterior two) layers of the greater omentum and the variably adherent transverse mesocolon. Having reached the anterior surface of the left kidney, the left end of the body ceases to be sessile and, as the glandular



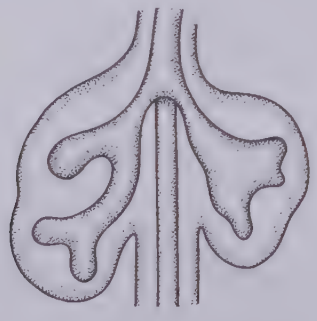
tail, passes between the (dorsal mesogastrial) layers of the lienorenal ligament to the hilum of the spleen.

For details of cytogenesis, exocrine and endocrine, of the human fetal pancreas consult Conklin (1962) and Laitio et al (1974).

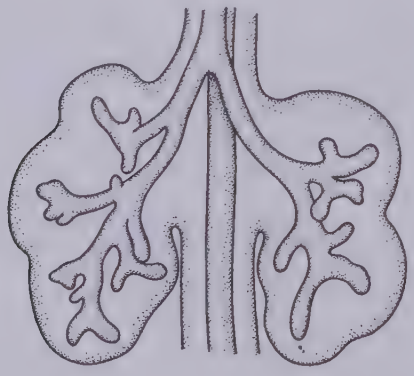
The spleen (2.106,107D,114) is not a constituent part of the digestive system, but it is convenient to refer to its development here. It appears about the sixth week as a localized thickening of the coelomic epithelium of the dorsal mesogastrium near its cranial end, and the proliferating cells invade the underlying mesenchyme, which becomes condensed and vascularized. The process occurs simultaneously in several adjoining areas which soon fuse to form a lobulated spleen, of dual origin from coelomic epithelium and from mesenchyme of the dorsal mesogastrium. With enlargement, the spleen projects to the left so that its surfaces are covered by the peritoneum of the mesogastrium on its left aspect, thus forming a boundary of the general extrabursal (greater) sac. When fusion occurs between the dorsal wall of the bursa omentalis and the dorsal parietal peritoneum, fusion does not extend to the left as far as the spleen (2.107D, 114), which remains connected to the dorsal abdominal wall (left kidney and suprarenal) by a short lienorenal ligament, while its original connection with the stomach persists as the gastrosplenic ligament. The lienorenal ligament contains the tail of the pancreas. The earlier lobulated character of the spleen disappears, but is indicated by the presence of notches on its upper border in the adult.

The histogenesis of the spleen has attracted relatively little attention. For earlier accounts consult references (Sabin 1912, Thiel & Downey 1921, Lewis 1956, von Herrath 1958, Bloom & Fawcett 1975). The vascular reticulum is well developed at 8 to 9 weeks, with immature reticulocytes and numerous closely spaced thin-walled vascular loops. Differentiation of blood cells, macrophages, and of arteries, veins, capillaries and sinusoids has occurred by the eleventh to twelfth week. The capsule consists at first of cuboidal cells bearing cilia and microvilli (Weiss 1957).

The spleen is subject to various anomalies, including complete agenesis, multiple spleens or polysplenia, isolated small additional spleniculi and persistent lobulation. Attention has been directed to association of cardiac, pulmonary and other abnormalities with asplenia or polysplenia (Rose et al 1975).



2.109A Diagrams to show the closure of the laryngotracheal groove and its separation from the oesophagus in the latter part of the fourth week. (After Streeter.) A, B and C represent transverse sections at the levels shown in A^1, B^1 and C^1, which are outline drawings of the oesophageal region in three closely following stages. Left lateral aspect.



In A and A^1 the laryngotracheal groove communicates freely with the oesophagus.

In B^1 the lower end of the laryngotracheal groove has begun to close and to form right and left evaginations, which represent the earliest rudiments of the lung buds, seen in B.

In C^1 the separation of the laryngotracheal groove from the oesophagus has proceeded further in a headward direction, and in C the primitive lung buds are now freed from the oesophagus.

2.109B The lung buds from a human embryo, 11.8 mm long, showing commencing lobulation. Ventral aspect. (After Streeter 1948.)

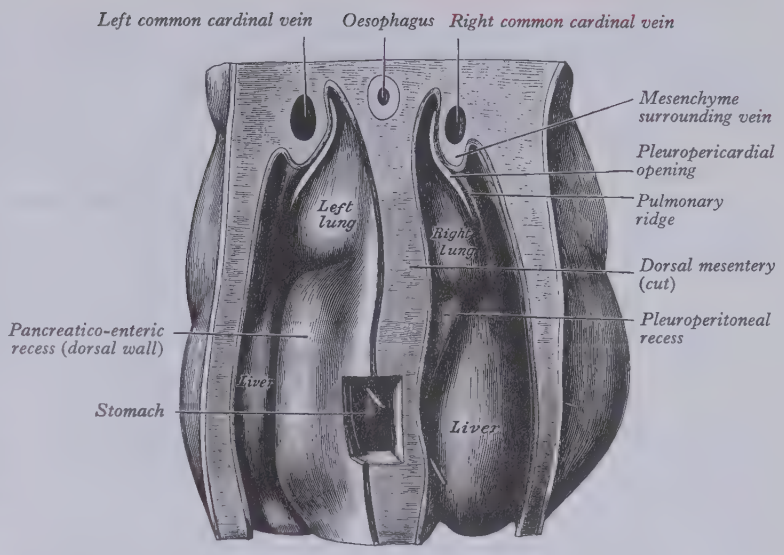
2.109C The lungs of a human embryo, 14.2 mm long, in the early part of the sixth week. (After Streeter.) Right/left differences in lobation are evident.

DEVELOPMENT OF LARYNX, TRACHEA AND LUNGS

The rudiment of the respiratory tree appears in the fourth week as a median *laryngotracheal groove* in the ventral wall of the pharynx (i.e. caudal hypobranchial eminence, or furcula, p. 228). The groove deepens and its lips fuse to form a septum, converting it into a splanchnopleuric *laryngotracheal tube* (2.109). The process of fusion commences at the caudal end of the groove and extends cranially, but it does not involve the extreme cranial end of the groove, where the lips remain separate, bounding a slit-like aperture, where the tube opens into pharynx. The tube is lined with endoderm, from which the epithelial lining of the whole respiratory tract is developed. The cranial end of the tube forms the larynx, its succeeding part the trachea, while from its caudal end two lateral outgrowths arise and form the stem bronchi of the right and left *lung buds*. These grow into the pleural coeloms and are therefore covered with splanchnic mesenchyme (2.107A), from which the fibroelastic connective tissue, cartilage, non-striated muscle and vasculature of the bronchi and lungs are developed.

The larynx, as an initial rudiment, is the cranial end of the laryngotracheal groove, bounded ventrally by the caudal part of the hypobranchial eminence (p. 228) and on each side by the ventral ends of the sixth arches. In the latter, two *arytenoid swellings* appear, one on each side of the groove (2.101A, B), and as they enlarge they approximate to each other and to the caudal part of the hypobranchial eminence (2.101A, B) from which the *epiglottis* is developed. The *opening* into the larynx, at first a vertical slit, is converted into a T-shaped cleft by the enlargement of the arytenoid swellings; the vertical limb of the T lies between the two swellings and its horizontal limb between them and the epiglottis. Soon after its appearance the epithelial walls of the cleft adhere to each other, and the primitive aperture of the larynx remains occluded until the third month when its lumen is regained. However, with rostral growth of the arytenoid swellings and the deepening of the *primitive aryepiglottic folds* forming the walls of the *vestibule*, a new *definitive aperture* is formed above the level of the primitive aperture, and the latter now corresponds to the level of the *glottis*. The arytenoid swellings differentiate into the *arytenoid* and *corniculate cartilages*, and the ridges joining them to the epiglottis become the definitive *aryepiglottic folds* in which the *cuneiform cartilages* are derived from the epiglottis. The *thyroid*

cartilage is developed from the ventral ends of the cartilages of the fourth, or fourth and fifth branchial arches; it appears as two lateral plates, each chondrified from two centres and united in the mid-ventral line by a fibrous membrane in which an additional centre of chondrification develops. The *cricoid cartilage* arises from two cartilaginous centres, which soon unite ventrally, gradually extend and ultimately fuse on the dorsal surface of the tube (see also p. 172). For a recent compilation of literature on the early development of the larynx, consult O'Rahilly and Tucker (1973).

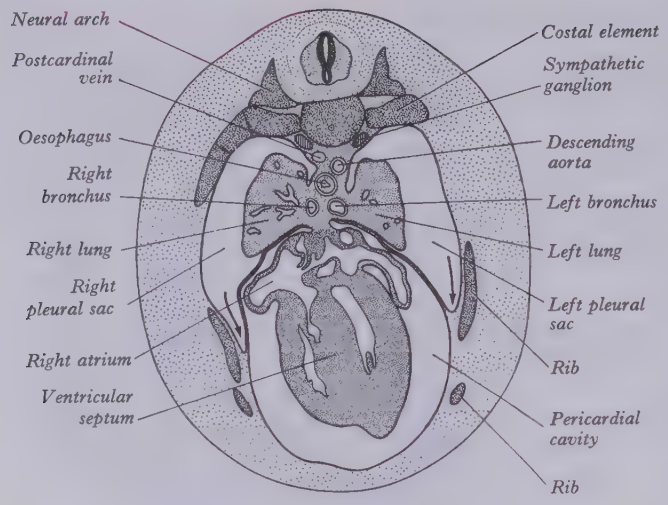


The right and left *lung buds* make their appearance before the laryngotracheal groove is converted into a tube. (An analysis of early pulmonary rudiment development in various mammals is provided by Hjortsjö 1950.) They grow out into the pleural passages caudal to the common cardinal veins where primary division of each lung bud into masses occurs. Three masses appear on the right and two on the left; these are the first indications of the corresponding lobes of the lung (2.109B,C). The buds undergo further subdivision and ramification, and ultimately end in minute expanded extremities—the *infundibula*. After the fifth to sixth month the *air sacs* begin to make their appearance as minute pouches of the infundibula. (For the detailed chronology of the branching, subdivision, phases and differentiation of the bronchial tree consult Reid 1976.) The splanchnopleuric mesenchyme surrounding the air passages and their terminals develops a dense capillary plexus. At first this receives blood directly from the aortic sac, and later from the sixth (branchial) aortic arches (future pulmonary arteries). The plexus is drained by radicles converging to form the pulmonary veins. The latter, of uncertain origin, open into, then contribute to, the walls of the cardiac left atrium (p. 210).

Three phases of differentiation—glandular, canalicular and alveolar—are described. In the *glandular phase*, the bronchial divisions are defined and differentiate; their epithelial cells have a prominent Golgi apparatus, scattered RNA granules and glycogen, but few organelles (Leeson & Leeson 1964). In the *canalicular phase* the respiratory parts are delineated and establish an intimate relation with the expanding blood vascular system. The *alveolar phase* extends from 6 months, but new bronchi and alveoli continue to be formed after birth (Wilson 1928). The mechanism of alveolar distension is uncertain; fetal respiratory movements, possibly involving aspiration of amniotic fluid into the lungs, may be involved (Duenhoelter & Pritchard 1973). The main expansion occurs with the onset of respiration at birth but is not complete for some days. During their development the lungs migrate caudally, so that by the time of birth the bifurcation of the trachea is opposite the fourth thoracic vertebra. As the lungs grow and project into the pleural passages the coelomic surface of the splanchnic mesenchyme enveloping each lung rudiment expands with it and becomes the visceral pleura. For bibliographies concerning pulmonary development consult Boyden (1972), O'Rahilly & Boyden (1973), Reid (1976).

DEVELOPMENT OF THE BODY CAVITIES

The formation of the intraembryonic coelom and its manner and route of communication with the extraembryonic coelom have already been considered (p. 132). After the formation of the head fold the median *pericardial coelom* connects dorsally with the right and left *coelomic ducts*, which open caudally into the *peritoneal coelom*. When the lung buds develop they project into the coelomic ducts, which may now be termed the *pleural coeloms*, and their communications with the pericardial and peritoneal coeloms become the *pleuropericardial* and *pleuroperitoneal canals* respectively (2.107,110). (When separation between these fluid-filled major coelomic regions is advancing towards completion, they are named the pericardial pleural and peritoneal *cavities*; the serous walls of the latter are often called *sacs*. In early embryos the cavities retain substantial volumes of fluid and their walls are separate; in later fetal and postnatal life cavities' walls are coapted, a mere microscopic film of serous fluid intervening.)



A curved elevation of tissue, the *pulmonary ridge*, develops on the lateral wall of the pleural coelom and partly encircles the pleuropericardial canal. The ridge is continuous with the dorsolateral edge of the septum transversum. The developing lung bud abuts on the ridge, which as a result divides into two diverging membranes meeting at the septum transversum. One is cranially placed and termed the *pleuropericardial membrane*; embedded within it the common cardinal vein and phrenic nerve reach the septum transversum by this route. The other membrane, caudally placed, is termed the *pleuroperitoneal membrane*. As the apical part of the lung forms it invades and *splits* the body wall and extends cranially on the *lateral aspect* of the common cardinal vein, carrying with it, or rather preceded by, an extension from the primitive pleural coelom to form part of the *secondary* or *definitive pleural sac*. In this way the common cardinal vein and the phrenic nerve come to lie medially in the mediastinum. The pleuropericardial canal, which lies medial to the vessel, is gradually narrowed to a slit, which is soon obliterated by the apposition and fusion of its margins (2.110). Its closure occurs early and is mainly effected by the growth and expansion of the surrounding viscera, heart and great vessels, lungs, trachea and oesophagus, and not by active growth of the pleuropericardial membrane across the opening to the root of the lung (2.110).

2.110 View, from the dorsal aspect, into the thoraco-abdominal part of the coelom of a human embryo 6.8 mm long, in the fifth week. Note that the dorsal body wall, including the spinal cord, developing vertebral column, the dorsal aorta and the mesonephroi, has been removed. A window has been made in the dorsal wall of the pancreatico-enteric recess to expose the posterior surface of the stomach and a wire has been passed through the epiploic foramen. (After Piper.)

In addition to its extension in a cranial direction the lung and its associated vesceral and parietal pleura also enlarge ventromedially and caudodorsally (vide infra). With the ventromedial extension, the lung and pleurae therefore excavate and split the somatopleure over the pericardium, separating the latter from the ventral and lateral thoracic walls (2.111). Thus the ventrolateral fibrous pericardium, parietal serous pericardium and mediastinal parietal pleura, although topographically deep, are *somatopleuric in origin*.

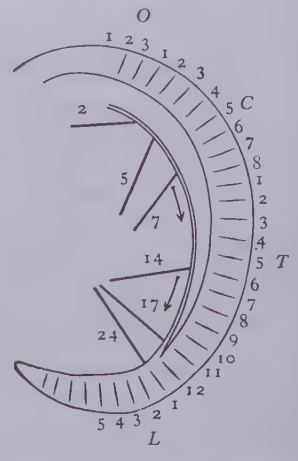
Separation of pleural and peritoneal cavities is effected by development of the diaphragm. The *septum transversum* at first forms a block of mesoderm, caudal to the pericardial cavity and extending from the ventral and lateral regions of the body wall to the foregut. Dorsal to it on each side is the relatively narrow *pleuroperitoneal canal*. The liver grows into the septum transversum, which now can be seen to consist of two parts. One, the *pars diaphragmatica*, is disposed in the transverse plane and lies over the convex cranial surface of the liver. The other, the *pars mesenterica*, lies initially in the median sagittal plane and is expanded by the developing liver. At this stage the liver is widely attached to the pars diaphragmatica and to the ventral abdominal wall. These attachments are the forerunners of the coronary and triangular ligaments and of the falciform ligament respectively. Medial to the pleuroperitoneal canals are the oesophagus and stomach with

2.111 Transverse section of a 21 mm human embryo, showing how the pleural sacs extend ventrally on each side of the pericardium and split the body wall. The arrows indicate the directions of growth of the two secondary pleural sacs.

their dorsal mesentery, and at the root of the latter the dorsal aorta. Dorsolateral to the canals are the pleuroperitoneal membranes, which remain small; dorsally are the mesonephric ridges, suprarenals and gonads. Just as the enlargement of the pleural cavity cranially and ventrally is effected by a process of burrowing into the body wall, so its caudodorsal enlargement is effected in the same way. The expanding pleural cavities extend into the mesoderm *dorsal* to the suprarenal glands, the gonads and (degenerating) mesonephric ridges. Thus somatopleuric mesoderm is peeled off the dorsal body wall to form a substantial portion of the dorsolumbar part of the diaphragm. The pleuroperitoneal canal is closed by the fusion of its edges, which are carried together by growth of the organs surrounding it and, in particular, that of the suprarenal, which carries the dorsal margin of the canal ventrally to meet the pars diaphragmatica of the septum transversum (Wells 1954). The right pleuroperitoneal canal closes earlier than the left. Hence it is on the left that an abnormal communication persisting between the pleural and peritoneal cavities more frequently is encountered.

While these changes occur, the septum transversum undergoes a progressive alteration in relative position. In a 2 mm human embryo, the dorsal border of the septum transversum lies opposite the second cervical segment but, as the embryo grows and the heart enlarges, it migrates caudally. At first the ventral border moves more rapidly than the dorsal, but after the embryo has attained a length of 5 mm it is the dorsal border which migrates more rapidly (2.112). When the dorsal border of the septum transversum lies opposite the fourth cervical segment, the phrenic nerve (C3,4 and 5) and portions of the corresponding myotomes grow into it and accompany it in its later migrations. It is not until the end of the second month that the dorsal border of the septum transversum is opposite the last thoracic and first lumbar segments, the final position occupied by some of the dorsal attachments of the diaphragm and some derivatives of the pars mesenterica. However, the main derivatives of the pars diaphragmatica lie at considerably more cranial levels (vide infra and p. 241 et seq.).

THE DEVELOPMENT OF THE DIAPHRAGM



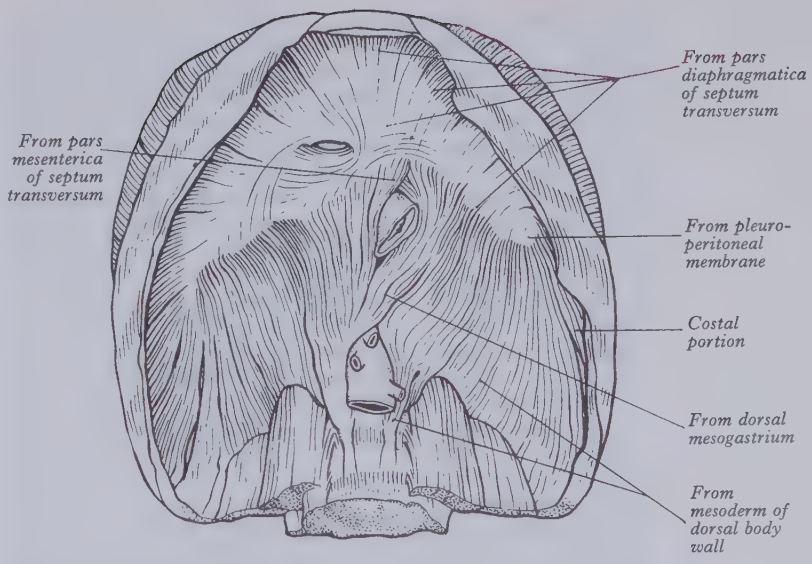
The closure of the pleuroperitoneal openings completes a mesodermal partition which thereafter separates thoracic from abdominal viscera and forms the framework for the future diaphragm. This has a composite origin. The sternal and costal parts are derived almost exclusively from the pars diaphragmatica of the septum transversum, with a small dorsolateral contribution from the pleuroperitoneal membranes and by delamination from the thoracic wall (costal part). Anterior to the oesophageal hiatus is a small contribution from the cranial oesophagophrenic continuation of the gastrohepatic part of the lesser omentum, both derived from the pars mesenterica of the septum transversum. Between the oesophageal and aortic hiatuses it is formed by the dorsal mesentery (strictly the dorsal mesoesophagus but often, less precisely, included as part of the dorsal mesogastrium). The remainder of the lumbar part of the diaphragm is formed from mesoderm around the abdominal aorta and more laterally from mesoderm of the dorsal body wall behind the suprarenal, mesonephric ridge and gonad (Wells 1954). Some authorities consider that much greater areas of the adult diaphragm are derived from the pleuroperitoneal membranes and from the chest wall. Gaps between the lumbar and costal parts of the diaphragm are usually due to under-development of the latter.

Premuscle tissue, derived principally from the fourth cervical myotomes, invades the septum transversum as already described and from there extends into the rest of the mesodermal partition, together giving rise to the muscular diaphragm (2.113) and its fibrous central tendon, or aponeurosis, with its trefoil shape, cruciform intersecting fibres and central nodal thickening.

THE PERITONEUM AND OMENTAL BURSA

Students addressing themselves de novo to topographical descriptions of the mature peritoneal cavity with its complex parietes, 'sessile' (or retroperitoneal) organs, peritonealized organs with their mesenteries (termed ligaments, folds or omenta in different locations), mesenteric contents and lines of reflexion and recesses, fossae, 'gutters', spaces, and bursae, face a formidable task. Comprehension is often lacking, and much of what is merely rote retention, quickly recedes. Preliminary study of a concise account of the development of an organ and its surroundings, or a survey of the whole region, is valuable; thus frequent cross reference should be made between any field of study of a mature organ, and its ontogeny.

The emergence of a bilaminar embryonic disc and cavitation of extraembryonic mesoderm, resulting in an exocoelom, has been reviewed (p. 131), as has proliferation, and spreading of intraembryonic mesoderm in the progressively pear-shaped, bilaterally symmetrical, trilaminar embryo (p. 132). The initial appearance of a median, rostrocaudally disposed protocardiac area, oropharyngeal membrane, notochord Hensens' node and primitive streak, is accompanied throughout the length of the notochord on both sides by intraembryonic mesodermal columns: mediolaterally—paraxial, intermediate and lateral plate. The plate is, at the disc margins, ringed by a band of extraembryonic mesoderm where somatopleure (amnion) and splanchnopleure are confluent; with growth, the band meets and fuses with the spreading lateral plate. The fusion of the three mesoderms occurs at the *junctional zone*; the latter completely encircles the early



2.112 Schema showing stages in the descent of the dorsal attachment of the septum transversum. The numerals on the heavy lines indicate the length of the embryo in mm, and the position of the occipitial, cervical, thoracic and lumbar segments is also shown. Note: straight lines ignore the true profile of the septum. (After Mall.)

embryonic plate periphery, but beyond the cranial tip of the notochord involves rostral streams of mesoderm which skirt the buccopharyngeal membrane, meet in the protocardiac area and continue into a substantial part of the junctional zone. Caudally, streams from the primitive streak skirt the cloacal membrane and blend with the connecting stalk around its contained allantoic duct (p. 140). Median cavitation in the protocardiac area and its confluence with multiple clefts in each lateral plate forming a ∩ shaped intraembryonic coelom which is bounded dorsally by somatopleure, ventrally by splanchnopleure, medially by intermediate mesoderm, and initially, rostrolaterally by the junctional zone (see pp. 131 et seq.). Loss of the junctional zone in the caudal half of the embryonic margins establishes communication between intraembryonic and extraembryonic coeloms. Head, tail and lateral folding imposes craniocaudal reversal of the headward and tailward structures, assumption of embryonic form, circumscription of an umbilicus, enfoldment of a splanchnopleuric gut tube and definition of the primary body cavities and coelomic regions. The manner of their separation into definitive pericardial, pleural and peritoneal cavities is described above: particular emphasis is placed on the invasion and splitting of the somatopleure with expansion of the secondary pleural cavities, submergence of the pericardium, also the positional changes and multiple derivations of the diaphragm. The intra-embryonic encompassing of a splanchnopleuric gut tube, its allocation into foregut, midgut and hindgut regions and a summary of their derivatives are given (pp. 231 et seq.). Also the period of extrusion of the midgut loop into the umbilical exocoelom, concomitant differential growth and varying degrees of rotation of almost all parts of the subdiaphragmatic gut, return of the midgut loop, and profound serous membrane modifications are traced (pp. 232 et seq).

Some repetition is unavoidable but, where apposite, brief summaries are appended to circumvent unacceptable degrees of cross-referencing; in other locations, further details and systematic names are given, when alternative morphogenetic events occur, but are infrequently mentioned in introductory accounts. Only those viscera developed in direct apposition to one of the primary coelomic regions, or a secondary extension of the latter, retain a partial or almost complete visceral serous cover. No coelomic cavitation occurs in the rostral and caudal ends of the embryo, i.e. the cranium, cervical vertebrae, buccal cavity, pharynx and their mural derivatives; similarly, the lower third of the rectum, anal canal, coextensive vagina and lower urinary tract. In all these cases, derived structures are embedded in unsplit *mixed somatovisceral mesenchyme*, often with accessions from the neural crest. (The possible classification of certain groups of *both* craniocervical *and* caudoperineal muscles and their nerves as 'special visceral' should be reviewed.) The cervicothoracic oesophagus is encased in prevertebral, retrotracheal and retrocardiac mesoderm and develops no true dorsal or ventral mesentery. In the lower thorax the oesophagus inclines ventrally anterior to the descending thoracic aorta; the dorsocaudally sloping midline diaphragm between oesophageal and aortic orifices may be homologized with part of a *dorsal meso-oesophagus*; in the same manner, a ventral midline diaphragmatic strip may be considered a derivative of a *ventral meso-oesophagus*. At superior and intermediate thoracic levels parts of the lateral aspects of the oesophagus come into closer relation to the secondary, mediastinal, *parietal* pleura (p. 1332).

The alimentary tube from the diaphragm to the commencement of the rectum possesses, throughout its length, initially, a sagittal dorsal mesentery; its line of continuity with the dorsal parietal peritoneum (i.e. its 'root' or 'line of reflexion') is, evidently, also midline. The abdominal foregut, from the diaphragm to the future hepatopancreatic duodenal papilla also has a ventral mesentery. The latter extends from the ventrolateral margins of the abdominal oesophagus and, as yet 'unrotated', primitive stomach and proximal duodenum, to cranially, the pars diaphragmatica of the septum transversum, anteriorly, to the ventral abdominal wall to the level of the cranial rim of the umbilicus, and caudally (between umbilicus and duodenum) presents a crescentic free border. The midgut and hindgut have no ventral mesentery; thus the pleural and supra-umbilical peritoneal cavities are initially (and transiently) bilaterally symmetrical above the umbilicus; below, the peritoneal cavity is freely continuous across the midline ventral to the gut.

2.113 Inferior surface of the diaphragm showing the derivation of the different parts of its connective tissue framework. (After Wells 1954.)

A few general developmental points may be mentioned. Some organs, e.g. the lung, despite the extensive pulmonary growth and wide cavitation of a secondary pleural cavity, retain a relatively simple visceroparietal serous membrane disposition. The lung root, with its bronchial, neurovascular and lymphatic radicles is circumscribed by a comma-shaped line of reflexion, the dependent 'tail' or pulmonary ligament accommodating calibre variations in the contained tubes. Other organs with a single dorsal mesentery may undergo changes varying from slight to profound. Thus mesenteric changes are an integral accompaniment of alterations in their visceral contents including differential, sometimes asymmetrical growth, regional or progressive degeneration, repositioning such as sequential extrusion, retrusion, rotation, spiralization and relative ascent or descent. The *parietovisceral line of reflexion* of the originally midline dorsal mesentery may become oblique (see the jejuno-ileal mesentery) or transverse (see transverse mesocolon), angular (see sigmoid mesocolon) or complex and highly curved (see dorsal mesogastrium). In other locations, the events are more pronounced, the dorsal mesentery is lost entirely and the organ becomes 'sessile' or 'retroperitoneal', connective tissue only separating its external (usually posterior) surface from the abdominal parietes or the surface of another organ; the peritoneum is limited to some or all its (usually) ventral and perhaps ventromedial and also ventrolateral surfaces. The resulting parietovisceral or intervisceral depressions or grooves are called pouches, fossae or gutters in different locations. The term *recess* has two distinct connotations, *embryological* (vide infra), and in *mature topography* where it denotes a peritonealized, blind-ended channel, extending from a major region of the peritoneal cavity, continuing in a retrovisceral or paravisceral position, and often partly enclosed by one or two vascularized (or avascular) peritoneal folds.

The movements of lines of reflexion, assumption of a retroperitoneal site and other changes, are often held to affect relatively large endodermal 'organs' encased in a *fine* layer of splanchnic mesenchyme which is continued to the parietes by an equally tenuous, but vascularized, mesentery. With growth and also shape and positional changes, part or the whole of the mesentery lies against the parietal peritoneum; their apposed surfaces fuse and are absorbed. Thus the line of reflexion is altered, or the organ becomes retroperitoneal; further, mesenteric neurovascular bundles lie ventral to structures derived primarily from the intermediate mesoderm. Such mechanisms are significant throughout the subdiaphragmatic gut, but are

predominant in the small and large intestine. However, such views fail to recognize the ability of all serous membranes to vary their thickness, lines of reflexion, disposition, 'space' enclosed and their channels of communication, by areal and thickness growth on one aspect combined with cavitation leading to expanding *embryonic recess* formation on the other. The ventral and dorsal foregut mesenterics are relatively large, thick blocks of mesoderm, compared with the slender endodermal tubes they encase. A complex series of recesses develop in these mesodermal masses, become confluent, and with foregut rotation, differential growth of stomach, liver, pancreas and spleen, and completion of the diaphragm, the territories of the greater sac and lesser sac (omental bursa) are delimited, and the mesenteric complexes of these organs (omenta and 'ligaments') are defined (vide infra).

It is convenient to first consider the mesenteries of the small and large intestine after rotation and the principal growth patterns have been achieved and the developing pancreas is becoming retroperitoneal. Most of the duodenal loop encircles the head of the pancreas and is retroperitoneal, the peritoneum covering principally its ventral and convex aspects. Exceptions are a short initial segment of the superior (first) part; this is more completely peritonealized having the attachments of the right margins of the greater and lesser omenta; peritoneum is lacking when there is close apposition of the transverse colon to the descending (second) part, or where the latter is crossed by the root of the transverse mesocolon; also where '*the*' mesentery crosses the transverse (third) part, and descends across the ascending (fourth) part from its upper extremity at the duodenojejunal flexure. In addition to the main peritoneal relations of the duodenum just mentioned, one or more of up to six different *duodenal recesses* may develop. Their variations in shape and size, their intestinal, mesenteric and vascular relations and, when adequately recorded, their frequencies and disposition of their orifices are given on p. 1344, and will not be repeated here.

The succeeding small intestine (jejunum and ileum) from the duodenojejunal flexure to the ileocaecal junction ('valve') undergoes, from a mesenteric standpoint, less modification of its embryonic form than other gut regions. Its early dorsal mesentery (no ventral component is present here, or caudally) is a continuous, single (but structurally bilaminar) sheet, with its parietal attachment—line of reflexion, or 'root'—in the midline. Usually, with development and the mechanisms mentioned above, the attachment of the root becomes an *oblique* narrow band from the left aspect of the second lumbar vertebra to the cranial aspect of the right sacro-iliac joint. Thus, from above downwards, it crosses the ascending and transverse parts of the duodenum, abdominal aorta, inferior vena cava, right psoas major and many structures related to these. For dimensions, contents and other details see pp. 233, 1344. Formal names—mesojejunum, mesoileum—are seldom used; *the mesentery* is universal.

The caecum and vermiform appendix, as stated, arise as a diverticulum from the *antimesenteric* border of the caudal limb of the midgut loop and thus the caecum possesses no primitive mesocaecum. These regions of the gut undergo long periods of growth, often asymmetrical, and their final positions, dimensions and general topography show much variation (pp. 1365, 1366). The caecum is usually quite mobile with its lateral, medial, ventral, caudal and most of its dorsal surfaces clothed with visceral peritoneum. Peritoneum may be lacking dorsally near its continuation into the ascending colon. This arrangement is, however, usually complicated by the presence of two or three *caecal recesses*, bounded on one or more aspects by *local peritoneal folds* some of which carry vascular pedicles. For further details of the recesses (*superior* and *inferior ileocaecal* and *retrocaecal*) and folds (*lateral* and *medial parietocaecal, vascular caecal* and *ileocaecal*) see p. 1345. The vermiform appendix is also almost wholly clothed with visceral peritoneum, derived from the diverging layers of its rather diminutive *mesoappendix*. The latter, of triangular profile, carrying the appendicular vessels, lymphatics and nerves, is further detailed on p. 1344; it appears as a continuation of 'the' mesentery near its ileocaecal junction. Despite the opening remarks above, therefore, the mesoappendix should perhaps be regarded as a direct derivative of the primitive dorsal mesentery; on this view, a similar status for the vascular fold of the caecum should be considered. With approaching completion of differential growth, rotation and circumabdominal displacement of the colonic gut, until the fourth month, this part of the gut retains its primitive dorsal mesentery (*mesocolon*) throughout. Its original root is still vertical, in the dorsal midline, from which it diverges widely, roughly as an incomplete, flattened pyramid to reach its colonic border (at the future taenia mesocolica). During the fourth and fifth months substantial areas of the primitive mesocolon adhere to, then fuse with, the parietal peritoneum; thus some colonic segments become sessile while others have a shorter mesocolon with an (often profoundly) altered parietal line of attachment (root). In one series of 100 specimens studied (p. 1367) the most common arrangement occurred in about 50%; in these a transverse and a sigmoid mesocolon persisted and the sessile state affected the ascending colon, right (hepatic) flexure and the descending colon. In the remainder, either the ascending or descending, or both, colonic segments also retained a mesocolon (varying from a localized 'fold' to a complete mesocolon). When sessile, the ventral, medial and lateral aspects of the ascending or descending colon are clothed with peritoneum, the protrusion of the viscus producing medial and lateral peritoneal *paracolic gutters* on each side. The multiple topographical relationships of these parts of the colon and particularly the dorsal structures, with a mere fibroareolar separation, are detailed on p. 1346. This form of apposition to underlying structures proceeds from the ascending colon to include the right colic (hepatic) flexure, and thence continuing anteroinferiorly to the left, thus involving the right-sided initial segment of the transverse colon. The right flexure is in contact with the caudal part of the ventrolateral surface of the right kidney; the colonic peritoneum passes cranially clothing this part of the kidney, sometimes reaching the rim of the right suprarenal. In either event, the peritoneum is next reflected ventrally as the lower layer of the coronary ligament to the dorsum of the right lobe of the liver: this renal peritoneum forms the floor of the *hepatorenal pouch* (of Morison). The pouch, in addition to its topographical relations with colon, kidney, suprarenal and liver, has clinically significant associations with the right lateral paracolic gutter, the epiploic foramen—its boundaries and their many contents—, the vestibule of the mature omental bursa, the gallbladder and biliary ducts. (Numerous references are made to all the foregoing in Section 8). The right extremity of the transverse colon, as mentioned, is also sessile, fibroareolar tissue separating it from the anterior aspect of the descending (second) part of the duodenum and the corresponding aspect of most of the head of the pancreas. The remainder of the transverse colon, up to and including the left (splenic) colic flexure, is almost completely peritonealized by the diverging layers of the *transverse mesocolon*. The root of the latter reaches the neck and whole extent of the anterior border of the body of the pancreas. The long axis of the definitive pancreas lies *obliquely*; also, the splenic colonic flexure is considerably more rostral than the hepatic flexure; in accord, the root of the mesocolon curves obliquely upwards as it crosses the upper abdomen from right to left. As it expands, the posteroinferior wall of the greater omental part of the bursa omentalis (vide infra) gradually covers, becoming closely applied to, the transverse mesocolon and its contained colon, finally projecting beyond the latter. Craniocaudal adherence now occurs between the omental wall and the pericolonic and mesocolonic layers. In the mature condition, therefore, a cursory examination suggests that the transverse colon is connected to the posterior abdominal structures by a single mesenteric sheet; close inspection, however, shows this to be a compound structure, quadrilaminar in nature (p. 1339).

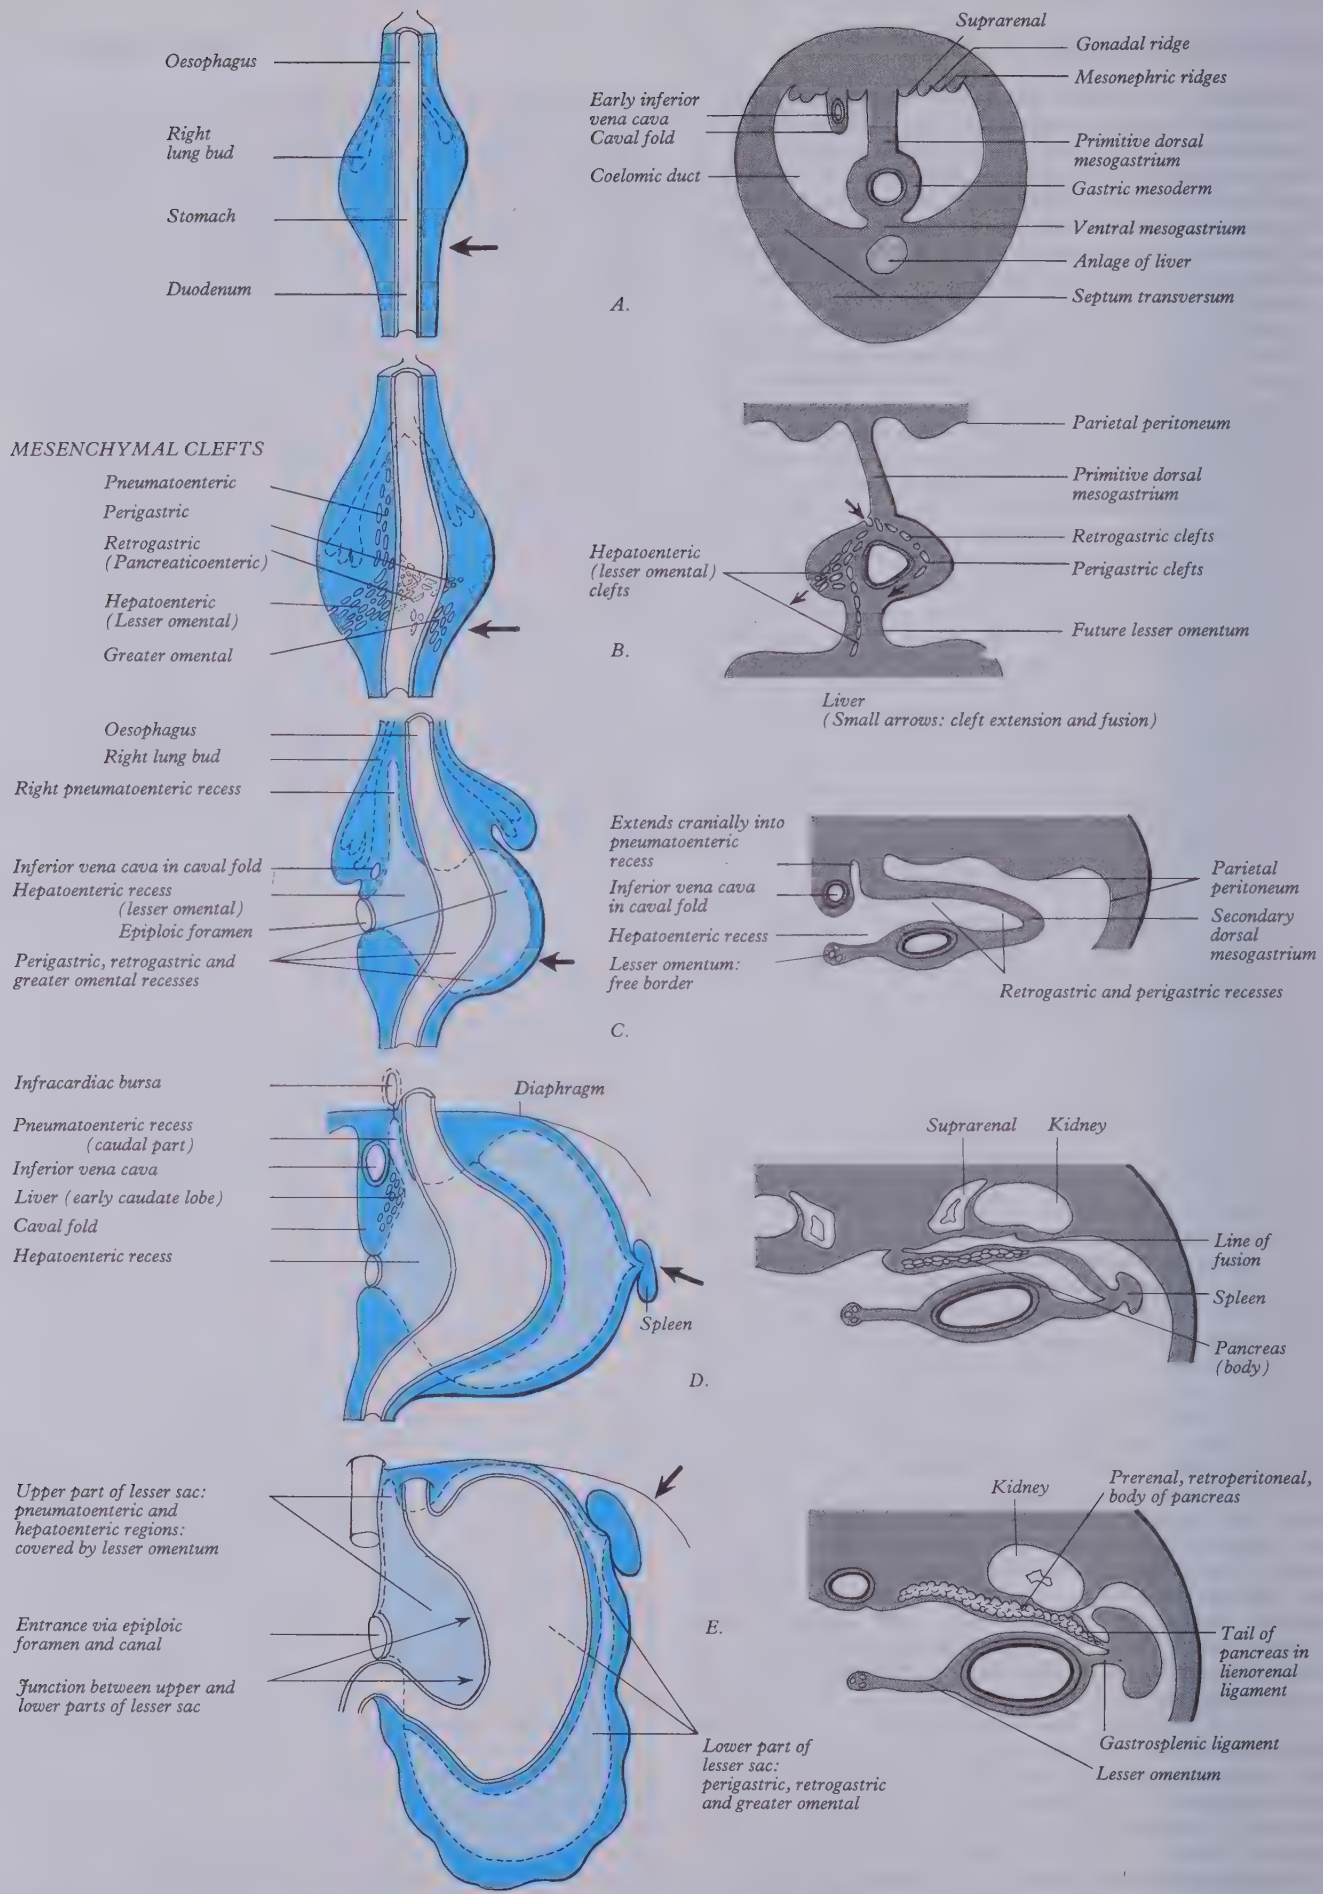
The left colic flexure receives much of its peritoneal covering from the left extremity of the transverse mesocolon; it also often is connected to the parietal peritoneum of the diaphragm over the tenth and eleventh ribs by a *phrenicocolic ligament*. The latter sometimes blends with a *presplenic fold* that radiates from the gastrosplenic ligament. The descending colon becomes sessile; it commences over the inferolateral border of the left kidney and first passes almost vertically in the depression between psoas major, quadratus lumborum and the aponeurotic origin of transversus abdominis, to the level of the iliac crest; here it inclines

inferomedially crossing iliacus and psoas major to reach the brim of the true pelvis where it continues as the sigmoid colon. The numerous structures intervening between the posterior aspect of the descending colon and its fibromuscular 'bed' are detailed on p. 1368. Contrary to often stated (but unsupported) assumptions, it has now been clearly demonstrated (Kanagasuntheram 1957) that the process of fusion and obliteration of both ascending and descending mesocolons commences laterally and progresses medially.

The sigmoid colon is ultimately most variable in its length and disposition, with numerous topographical relationships (p. 1369). It retains its dorsal mesocolon, but the initial midline dorsal attachment of its root is considerably modified in its definitive state. The latter is commonly described as an inverted V which is, however, asymmetrical, and, other than the rectal termination of its right limb, lies wholly to the left of the midline. The apex of the V lies ventral to the bifurcation of the left common iliac artery; this separates it from the cranial part of the left sacro-iliac joint. The left limb of the V is shorter than the right and, bearing the inferior left colic (sigmoidal) vessels, is almost horizontal, inclining only slightly cranially as it is traced lateromedially from its origin to the apex. The right limb carries the superior rectal vessels; it is longer than the left and about 45° to the vertical, as it extends from the apex to its midline termination (at the cranial end of the rectum) on the ventral aspect of the third sacral vertebra. For details of the relationships and contents of the sigmoid mesocolon, also the presence, form and age dependency of its associated *intersigmoid apical recess*, see pp. 233, 1344, 1345.

The rectum continues from the ventral aspect of the third sacral vertebra to its anorectal (perineal) flexure antero-inferior to the tip of the coccyx, the distance, of course, changing with age. All aspects are encased by mesoderm; the early dorsally placed mass being named, by some authorities, the *dorsal mesorectum*. The latter does not form a true mesentery, however, but with progressive skeletal development it reduces to a woven fibro-areolar sheet with patterned variations in thickness and fibre orientation. The sheet is closely applied to the ventral concavity of the sacrum and coccyx, with numerous fibromuscular and neurovascular elements enclosed (p. 1369). Thus, the rectum becomes sessile, visceral peritoneum being restricted to its lateral and ventral surfaces. With the disappearance of the post-anal gut by the end of the fifth week, the ventrolateral peritoneum reaches the superior surface of the pelvic floor musculature, and this persists until late in the fourth month. In this period the ventral rectal peritoneum of the male is reflected to cover the posterior surface of the prostate and bladder trigone and associated structures; the female initially receives a reflexion covering almost the whole posterior aspect of the vagina, thence continuing over the uterus. Subsequently, the closely apposed walls of these deep peritoneal pouches fuse over much of their caudal extent, their mesothelia are lost, and the organs have an intervening, bilaminar, (surgically separable) fibrous stratum. The latter is the masculine recto-vesical fascia and posterior wall of the prostatic sheath; its female homologue is the posterior part of the fibrous envelope of the vagina, that intervenes between its middle two-fourths, and the rectum. Thus the proximal third of the rectum has a peritoneal tunic ventrolaterally; the lateral extensions are triangular—deep proximally and tapering to an acute angle when the middle third of the rectum is reached. Thereafter, the middle third has peritoneum restricted to its ventral surface where it forms the posterior wall of the shallower rectovesical or rectovagino-uterine pouch. The remaining rectum and anal canal are subperitoneal.

The many additional peritoneal eminences, ridges, folds, grooves, fossae and pouches, that on varying time scales characterize the true pelvis and lower abdomen, simply reflect the growth patterns of the subjacent viscera, vessels, some nerves or features of the parietes. They are mentioned either in the following pages, or with the appropriate organ under *Splanchnology*.



Subdiaphragmatic foregut peritoneum is complex in its definitive topography and, whilst having relatively simple symmetrical origins, becomes progressively more complicated during development. The latter involves rapidly changing three-dimensional arrays of serosal visceral surfaces, mesodermal masses and mesenteric sheets. Difficulties are compounded by the (rather surprising) paucity of structural ontogenetic accounts, the obligatory absence of human experimental data, some slackening of surgical interest in topographical minutiae and the adoption of simplified basic instructional courses. Here a few paragraphs offer scant justice to the topic and space limitations permit only brief allusion to the (often 'investigator specific') variations in terminology commonly encountered. Classic investigations, reviews and bilbiographies are found in Broman (1904, 1938); these may be contrasted with Kanagasuntheram (1957).

Some features have already been mentioned in other contexts, but will be summarized here to allow addition, deletion, criticism and suggested alternatives to the nomenclature and causal mechanisms invoked. (Throughout these and previous sections, reference should be made to **2**.106A-H, and **2**.114A-E.)

The subdiaphragmatic foregut includes, sequentially, the presumptive short terminal oesophagus, stomach and proximal duodenum (as far as, and including, the hepatopancreatic anlage). These subregions of the foregut initially (3–4 mm CR length) constitute a continuous endodermal tube of roughly uniform calibre (but slightly flattened laterally in the gastric region), encased in a *thick* stratum of visceral mesoderm. The latter is linked from *both* its *dorsal* and *ventral* aspects with substantial blocks of mesoderm that blend, respectively, with a wide dorsal midline strip of the body wall and diaphragm and the ventrolateral body wall and diaphragm including the caudal base of the pericardium. Thus, at this early stage, the abdominal foregut with its associated mesodermal masses comprises a thick sagittal septum dividing the peritoneal coelom into right and left symmetrical halves down to the level of the umbilicus. Until closure (p. 239), each half communicates with a pleural coelom via a small pleuroperitoneal canal. With the appearance of recognizable subregions of the foregut, and of the liver, pancreas and spleen, and the hepatopancreatic duct systems, each undergoes asymmetrical differential growth (sometimes interpreted as physical 'rotation' of the whole organ—vide infra), expansion and relative displacement. Concurrently, the thick mesoderm that encases each organ forms most of its mural tissues, connective tissue framework and, where present, its visceral peritoneal surfaces (serosa). The mesoderm *between* organs (e.g. between stomach and liver, stomach and pancreas, stomach and spleen, spleen and left kidney) and the mesoderm extending from a viscus to the parietes increases in area and becomes relatively thinner, while its visceroparietal lines of attachment are altered, as are, necessarily, their topographical planes. These events follow the development of *multiple small clefts* within the thick mesoderm, their coalescence and secondary opening into the primitive peritoneal cavity rapidly follows and then further expansion of the *developmental recess* so formed. (The sequence of events closely mimics the formation of the primary intraembryonic coelom in the protocardiac area and lateral plate mesoderm. It is *not*, as commonly described (e.g. p. 232), a simple depression followed by excavation into one of the thick mesodermal strata from the primary peritoneal cavity. These morphogenetic changes result in a marked asymmetry of the upper abdominal viscera, their mesenteries and associated subregions of the peritoneal cavity. The latter, although increasingly complex topographically, remains a single cavity with numerous intercommunicating regions, pouches and recesses. (The only small peritoneal sacs to separate completely from the main cavity are the *infracardiac bursa*—vide infra and p. 1332—and the *tunica vaginalis testis*.)

The human definitive peritoneal cavity (there are extreme species specializations) is commonly described as comprising **lesser sac** and a **greater sac** of peritoneum.

The lesser sac (or *definitive bursa omentalis*) is compounded of a series of confluent recesses, mainly situated in the left, superior quadrant of the abdomen; however, it extends beyond the boundaries of the quadrant, crossing the median plane about 4 cm to the right, and a quite variable extent ventro-inferiorly. Briefly, it is intimately related to the retro-peritoneal organs of the 'stomach bed', the transverse colon and its mesocolon, the posteroinferior surface of the stomach and mesenteries (omenta and ligaments) attached to its greater and lesser curvatures, the spleen and its ligaments, the caudate lobe and process of the liver and the

2.114 The development of the subdiaphragmatic foregut, its associated visceral and somatovisceral mesoderm and coelom, with particular reference to the terminal oesophagus, stomach, duodenum, spleen, the lesser sac of peritoneum and omenta. Seen in semicoronal section (left column) and transverse section at the levels indicated (right column). This differs in some important respects from traditional accounts. The text furnishes further definitions, details and discussion.

diaphragm. (Vide infra and p. 1339 for details, also p. 1340 for a discussion of the use of terms 'ligament' and 'omentum' in relation to peritoneal features.) A little above the centre of its right margin, the cavity of the lesser sac connects with that of the greater sac, i.e. the whole remainder of the peritoneal cavity, through a vertical slit, with apposed but easily separable walls, the *epiploic foramen* (p. 1339).

The greater sac is, for practical convenience, often allocated into a number of subregions, or 'spaces': all, except two, are peritonealized, and all connect with neighbouring spaces, either by a wide direct, or a more circuitous route. (In an overall peritoneal classification, as here, the cavity of the lesser sac and two extraperitoneal spaces are included.) The abdominal peritoneal cavity is (incompletely) divided by the transverse colon and its mesocolon into a *supracolic space* containing the foregut, its derivatives and mesenteries, and into an *infracolic space* containing the midgut and hindgut with derivatives and mesenteries, already described. The supracolic space is subdivided into six: *right* and *left subphrenic*, *subhepatic* and *extraperitoneal* spaces. (The left subhepatic space is a rather inappropriate name for the omental bursa; the right extraperitoneal space is the 'bare area' of the liver; the left extraperitoneal space surrounds the left suprarenal and upper pole of left kidney.) The infracolic space is divided by the mesentery of the small intestine into *right* and *left* moieties, while external to the ascending and descending colon lie the *right* and *left lateral paracolic gutters*. All the latter are more or less directly continuous with the fossae and pouches of the lesser pelvis. (For further details of these various spaces see p. 1346 and throughout the account of the peritoneum in *Splanchnology*.)

Abdominal foregut—associated mesoderm has an ontogenetic history too complex to receive more than a brief summary here; also the origin, admixture and final fate of some masses remain uncertain in the absence of experimental data. However, the nomenclature employed is, in some cases, a misleading simplification merely handed on in successive accounts over many decades. Sometimes, unproven mechanisms are held to operate which, on close examination, could not result in the well-known definitive topography. Some additional terms and divergences from current morphogenetic accounts are included.

Early embryonic nomenclature is often confined to the mesodermal masses lying dorsal and ventral to the foregut. However, the thick mesodermal strata of the wall of the gut itself are equally prominent morphogenetically. Although continuous with, they cannot be allocated quantitatively, as parts of the dorsal and ventral masses. It is useful, therefore, to refer to them simply as *oesophageal*, *gastric* and *duodenal mesoderms*. Some of the latter areas are *compound* in the sense that by cavitation and cleavage they may provide part of their thickness as *secondary extensions* of surrounding primary mesenteries with new lines of visceral attachment and areal expansion. These processes also result in modification of parietal lines of reflexion and related peritoneal cavity.

The septum transversum is the somewhat inappropriate name (but deeply ingrained in embryological literature) denoting all the mesoderm that extends from the ventral aspect of the caudal foregut to the ventrolateral aspects of the supra-umbilical abdominal and lower thoracic walls; its rostral surfaces reach, and contribute to the caudal 'bases' of the pericardium and secondary pleural cavities; its caudal free surface arches from the duodenum to the cranial rim of the umbilicus. Dorsally it borders the pleuroperitoneal canals, is continuous with the foregut mesoderms mentioned above, and contributes to the *caval fold* (vide infra). Some of these features have been encountered elsewhere (e.g. pp. 133, 140, 207, 239, 240) and will only receive a brief summary here. After head fold formation the most rostral part of the septum transversum has the common sinuatrial chamber of the heart embedded in it, each sinual horn of which receives the transeptal terminals of a vitelline, umbilical and common cardinal vein (for their fate see p. 222). As the pericardial cavity expands and the sinuatrial chamber 'rises' into it, septal mesenchyme follows (*pars pericardialis*) and condenses as the fibroserous diaphragmatic aspect of the pericardium. The intermediate stratum of septal mesenchyme (*pars diaphragmatica*) makes substantial contributions to the framework of the sternocostal parts of the diaphragm (**2**.113). Additional extensions occur into the mesenchymatous bed in which the subhepatic-hepatic-hepatocardiac parts of the inferior vena cava develop (p. 225) and in relation to the expanding liver. Thus the pars diaphragmatica alone truly merits the name septum transversum and even this is both incomplete (until closure of the pleuroperitoneal canals) and also, with expansion of the lungs, secondary pleural cavities, liver and stomach, soon becomes less 'transverse' as it develops a marked convexity towards the thorax. Strong fibrous continuity between the perinodal area of the central tendon of the diaphragm and the overlying fibrous pericardium persists. Midline strips of diaphragm ventral and dorsal to the oesophageal hiatus are held by some to be mesenteric in origin (vide infra): in the writers' view this merely adds confusion to an already complex terminology. Since this is their normal fate it seems preferable to term these the ventral and dorsal pars diaphragmatica of the oesophageal mesoderm from the outset.

The remaining subdiapragmatic part of the septum 'transversum', as indicated, is designated the *pars mesenterica* and initially forms a sagittally placed ventral 'mesentery' for the foregut. Although a continuous sheet, thick subregions are recognized: a brief *ventral meso-oesophagus*, continuing into a more extensive *ventral mesogastrium*, the latter merging into a *ventral mesoduodenum* that has a caudal free border. Many (the majority of) accounts ignore these subregions and simply equate all derivatives of the ventral pars mesenterica as those of *the* ventral meso*gastrium*. Some confusion may occur, however, particularly with respect to the development and definitive courses of the main biliary ducts, hepatic artery, portal vein and attendent lymphatics and nerves, and to the hepatic and gastric serosae and mesenteries. As indicated, the mesenchymal modifications are correlated with the asymmetrical growth patterns of the stomach, duodenum and liver (see pp. 232, 237 and below).

The abdominal foregut dorsal mesoderm commences rostrally as an oesophageal *dorsal pars diaphragmatica* which, as indicated, contributes a narrow midline strip extending between the oesophageal hiatus and the aortic orifice. The remainder, the *dorsal pars mesenterica*, again initially forms a midline sagittal dorsal septum of thick mesenchyme; its subregions (corresponding to the ventral ones) and parts of one continuous mesenchymal block are: a brief *dorsal meso-oesophagus*, a more extensive *dorsal mesogastrium* and a *dorsal mesoduodenum*. Their modifications are even more extensive than those of the ventral mesenteries and also have the additional complications of the developing pancreas and spleen. Further, many accounts ignore the subregions and collectively dub them *the* dorsal meso*gastrium*. This may lead to (perhaps minor) misplacement of the anlage of certain organs; however, the siting of the initiation of the lesser sac of peritoneum in the dorsal mesogastrium is both incorrect and confusing.

The caval fold is a linear eminence with divergent rostral and caudal ends, that passes from the upper abdominal to the lower thoracic region, and protrudes from the dorsal wall of the pleuroperitoneal canal. Cranially it becomes continuous, lateromedially, with the root of the pulmonary anlage and pleural coelom, the pars pericardialis of the septum transversum and the retrocardiac mediastinal mesenchyme. Caudally it forms an arch with *dorsal* and *ventral horns*; the dorsal merges with the primitive dorsal mesentery and the mesonephric ridge (and associated gonad and suprarenal); the ventral horn is confluent with the dorsal surface of the septal mesenchyme. Thus the fold is a zone where intestinal, mesenteric, intermediate, hepatic, pericardial, pulmonary and mediastinal mesoderms meet and blend, and may justifiably be compared with the junctional zones of mesoderm described elsewhere (p. 131, **2**.27). Contributions from septal mesenchyme are considered of particular importance by some authorities (Kanagasuntheram 1957). It provides a mesenchymal route for the upper abdominal, transdiaphragmatic and transpericardial parts of the inferior vena cava; it is also prominent in the development of parts of the liver, lesser sac of peritoneum and certain mesenteries. The left fold regresses whereas the right fold enlarges rapidly.

The lesser sac (*definitive bursa omentalis*) has already been mentioned in terms of its general disposition and communication

with the greater sac. Unfortunately considerable variation exists between the terminologies adopted by different authors, both during ontogeny and in adult topography. Development of the lesser sac is so intimately interlocked with additional ontogenetic features, particularly of the liver and stomach, their mesenteries, and secondary extensions of the greater sac, that these must receive brief mention.

Invasion of the ventral pars mesenterica by the hepatic and (transiently) the ventral pancreatic rudiment, followed by trifurcation of the primary hepatic anlage into right and left submasses and a caudal pars cystica, has been described (p. 237). Hepatic growth on the two sides is approximately equal in early fetal months, and the liver mass almost fills the ventral mesoderm; but thick, short blocks of mesoderm intervene between the liver and the foregut, diaphragm and supra-umbilical ventral body wall. Removal of the viscera at these symmetrical stages reveals the cut edges of the mesothelium bordering the coelom and enclosing the wide areas of mesenchymal continuity. The latter has a large roughly circular central area with numerous tapering projections towards the abdomen: the obliquely cut mesenteries, caval folds, mesonephric and attendant ridges and the lateral rim of the pleuroperitoneal canals. The whole bears some resemblance to an inverted coronet, hence the name coronary ligament of the liver. (With growth and maturity the restricted use of the name is much less apposite.) Much of the mesodermal mass surrounding the liver develops cavities that coalesce and open into the general coelomic cavity as extensions of the greater (and lesser) sacs of peritoneum. Thus almost all the ventrosuperior, visceral and some of the posterior aspects of the liver become peritonealized. The process involving the greater sac continues over the right lobe and ceases when the future superior and inferior layers of the coronary ligament and the right triangular ligament are defined. Those, plus a medial boundary provided by an extension of the lesser sac, enclose the 'bare area' of the liver where loose areolar tissue of septal origin persists. Due to asymmetrical liver growth the same processes affecting the left lobe result in the smaller left triangular ligament. Where the superior layers of the coronary and left triangular ligaments meet they continue as a (bilaminar) ventral mesentery attached to the ventrosuperior aspects of the liver; its parietal attachment has a slight inclination to the right as it crosses the ventral diaphragm and then descends to the umbilicus. Its umbilico-hepatic free caudal border, somewhat arched, carries the left umbilical vein (or, postnatally, the fibrous obliterated vein or *ligamentum teres*, with fine calibre para-umbilical veins); the whole structure constitutes the *falciform ligament*. Most of the latter may be considered the final ventral part of the ventral mesogastrium; its free border, however, has a ventral mesoduodenal origin.

As stated, the endodermal subdiaphragmatic foregut of the early embryo is a tube of almost uniform calibre, but with a slight fusiform gastric dilatation with a minimal degree of side-to-side flattening, encased in thick gastric mesoderm. The latter is continuous with the primitive ventral and dorsal mesogastria and these indicate the sagittal positions of the *primitive* ventral and dorsal borders of the stomach. Many accounts state that the development of a ventrally directed concave *lesser curvature* and a more rapidly growing dorsocranially directed convex *greater curvature* and incipient *fundus* occur while the anlage is still sagittal. Thereafter, the whole miniature organ and attached mesogastria are supposed to physically rotate through almost 90° (see p. 232). On this view the original left surface becomes ventrosuperior and the primitive dorsal border is directed to the left as the greater curvature. The interpretation of various mesenteric and neurovascular sequelae were based on these assumptions. Inspection of closely-spaced series of embryos (Kanagasuntheram 1957, 1960) led to the suggestion that the morphogenetic changes in both stomach and duodenum and their attendant mesenteries were mainly, if not wholly, due to patterned differential growth rates and mesodermal cleft formation and cleavage. Thus the stomach, initially a tube with slight lateral flattening, developed a linear zone of high proliferation along the length of the central part of its (original) left lateral wall. At first it became triangular *in transverse section*, with rounded angles and apex pointing to the left; further growth resulted in an elliptical profile. The ends of the sectional ellipse corresponded to the curvatures; the end directed to the right, and a little ventrally, the lesser curvature and justifiably regarded as a modified primitive ventral border; the left end, or greater curvature is an entirely *new formation*. For a while the two primitive mesogastria are *both* attached near the emerging lesser curvature (the sites of the primitive dorsal and ventral borders). The profound changes involved in reaching the definitive state only supervene with the development of the lesser sac.

The lesser sac is first indicated by the appearance of multiple clefts in the para-oesophageal mesenchyme on both left and right aspects of the oesophagus. Although they may become confluent, the left clefts are transitory and soon atrophy. The right clefts merge to form the *right pneumato-enteric recess* that extends from the oesophageal end of the lesser curvature as far as the caudal aspect of the right lung bud. At its gastric end it communicates with the general peritoneal cavity and lies *ventrolateral* to the gut; more rostrally it lies directly *lateral* to the oesophagus. It is *not*, as commonly stated, a simple progressive excavation of the right side of the *dorsal* mesogastrium. The right pneumato-enteric recess undergoes further extension, subdivision and modification mentioned below. From its caudal end a second process of cleft and cavity formation occurs producing the *hepato-enteric recess* that thins and expands the mesoderm between the liver and the stomach and proximal duodenum, and also reaches the diaphragm. The resulting, structurally bilaminar mesenteric sheet is the *lesser omentum* and is derived from the small mesoesophagus, the major part from the ventral mesogastrium, and the reduplicated strip including the free border from the ventral mesoduodenum. As differential growth of the duodenum occurs, the biliary duct is repositioned and most of the duodenum becomes sessile; the duodenal attachment of the free border and a continuous neighbouring strip of the lesser omentum becomes confined to the upper border of a short segment of its superior part. The free border, with contrasting growth and positioning of its attached viscera, gradually changes from the horizontal to the vertical. It carries the bile duct, portal vein and hepatic artery, and its hepatic end is reflected around the porta hepatis; an alternative name for this part of the lesser omentum is the *hepatoduodenal ligament*, and it forms the anterior wall of the epiploic foramen. The floor of the foramen is the initial segment of the superior part of the duodenum mentioned above, its posterior wall is the peritoneum covering the immediately subhepatic part of the inferior vena cava, and its roof the peritonealized caudate process of the liver. That major part of the lesser omentum from the lesser gastric curvature, passes in an approximately coronal plane to reach the floor of the increasingly deep groove for the ductus venosus (postnatally the ligamentum venosum) on the hepatic dorsum. This part is sometimes called the *hepatogastric ligament*.

The pneumato-enteric recess continues to expand to the right into the substance of the caval fold, ceasing near the left margin of the hepatic part of the inferior vena cava; the latter remains extraperitoneal, crossing the base of the now roughly triangular bare area of the liver (encompassed by coronary and right triangular ligaments) and this new expanded line of reflexion. With closure of the pleuroperitoneal canals the rostral part of the right pneumato-enteric recess is sequestered by the diaphragm but often persists as a small serous sac in the right pulmonary ligament. The remaining caval fold mesenchyme to the left of the inferior vena cava, and forming the right wall of the upper part of the lesser sac, becomes completely invaded by embryonic hepatic tissue and is transformed into the caudate lobe of the liver. This smooth, vertically elongate mass projects into the cavity of the lesser sac, and both its posterior and much of its anterior surfaces are peritonealized because of the increasing depth of the groove for the ductus venosus and the attachment of the lesser omentum to its *floor*. The narrow isthmus of the *caudate process* connects its right inferior angle to the rest of the right lobe (and is the roof of the epiploic foramen). The parts of the lesser sac thus far described above and to the right of the lesser curvature of the stomach have received a plethora of names by different investigators; sometimes these stem from changing or contrasting views of ontogeny. A few prominent ones will be mentioned. Some regard the right rim only of the structures already listed as constituting the boundaries of the epiploic foramen. The narrow

channel, a few centimetres long, passing to the left, and coextensive with the caudate process and peritonealized part of the initial duodenal segment, is called the *vestibule* of the lesser sac (but vide infra). The remaining, much more extensive part above the lesser curvature is termed, variously, the *upper (superior) part* (recess) of the lesser sac, the *hepatic part* of the lesser sac or finally the *hepato-enteric part of the pneumato-enteric recess*. Some authorities group all the foregoing under the general term *vestibule*; they are intimately related to the diaphragm, caudate lobe of the liver, and coextensive with the lesser omentum. Varying use of the name vestibule partly reflects earlier, mistaken views of the ontogeny of the upper and lower parts of the lesser sac (about to be described). Much of the upper part was considered to be merely a part of the general peritoneal coelom 'captured' by differential growth and omental changes of plane, whereas fundamentally different mechanisms of excavation were considered to apply to the lower part, the '*true' omental bursa* of some authors. Current evidences suggest that the *same* array of developmental mechanisms, with only quantitative regional differences, apply to *all* coelomic regions. The general name omental bursa should be used with caution; both upper and lower parts have walls that are partly omental (lesser and greater omenta respectively); also neither part is functionally more nor less bursal than other coelomic regions —peritoneal, pleural or pericardial. Confusion stemming from the term 'recess' firmly established in embryology but, with different connotations, used sporadically in adult topography has been mentioned (p. 241). Thus, the upper (superior) and lower (inferior) parts of the lesser sac seem preferable terms. Ultimately the junction between upper and lower parts is oblique, curving upwards as it passes from right to left; ventrally lies the gastric lesser curvature, dorsally the body of the pancreas. The left limit is a curved ridge of mesenchyme (future *left gastropancreatic fold*) carrying the left gastric artery and the right a curved ridge (future *right gastropancreatic fold*) carrying the common hepatic artery.

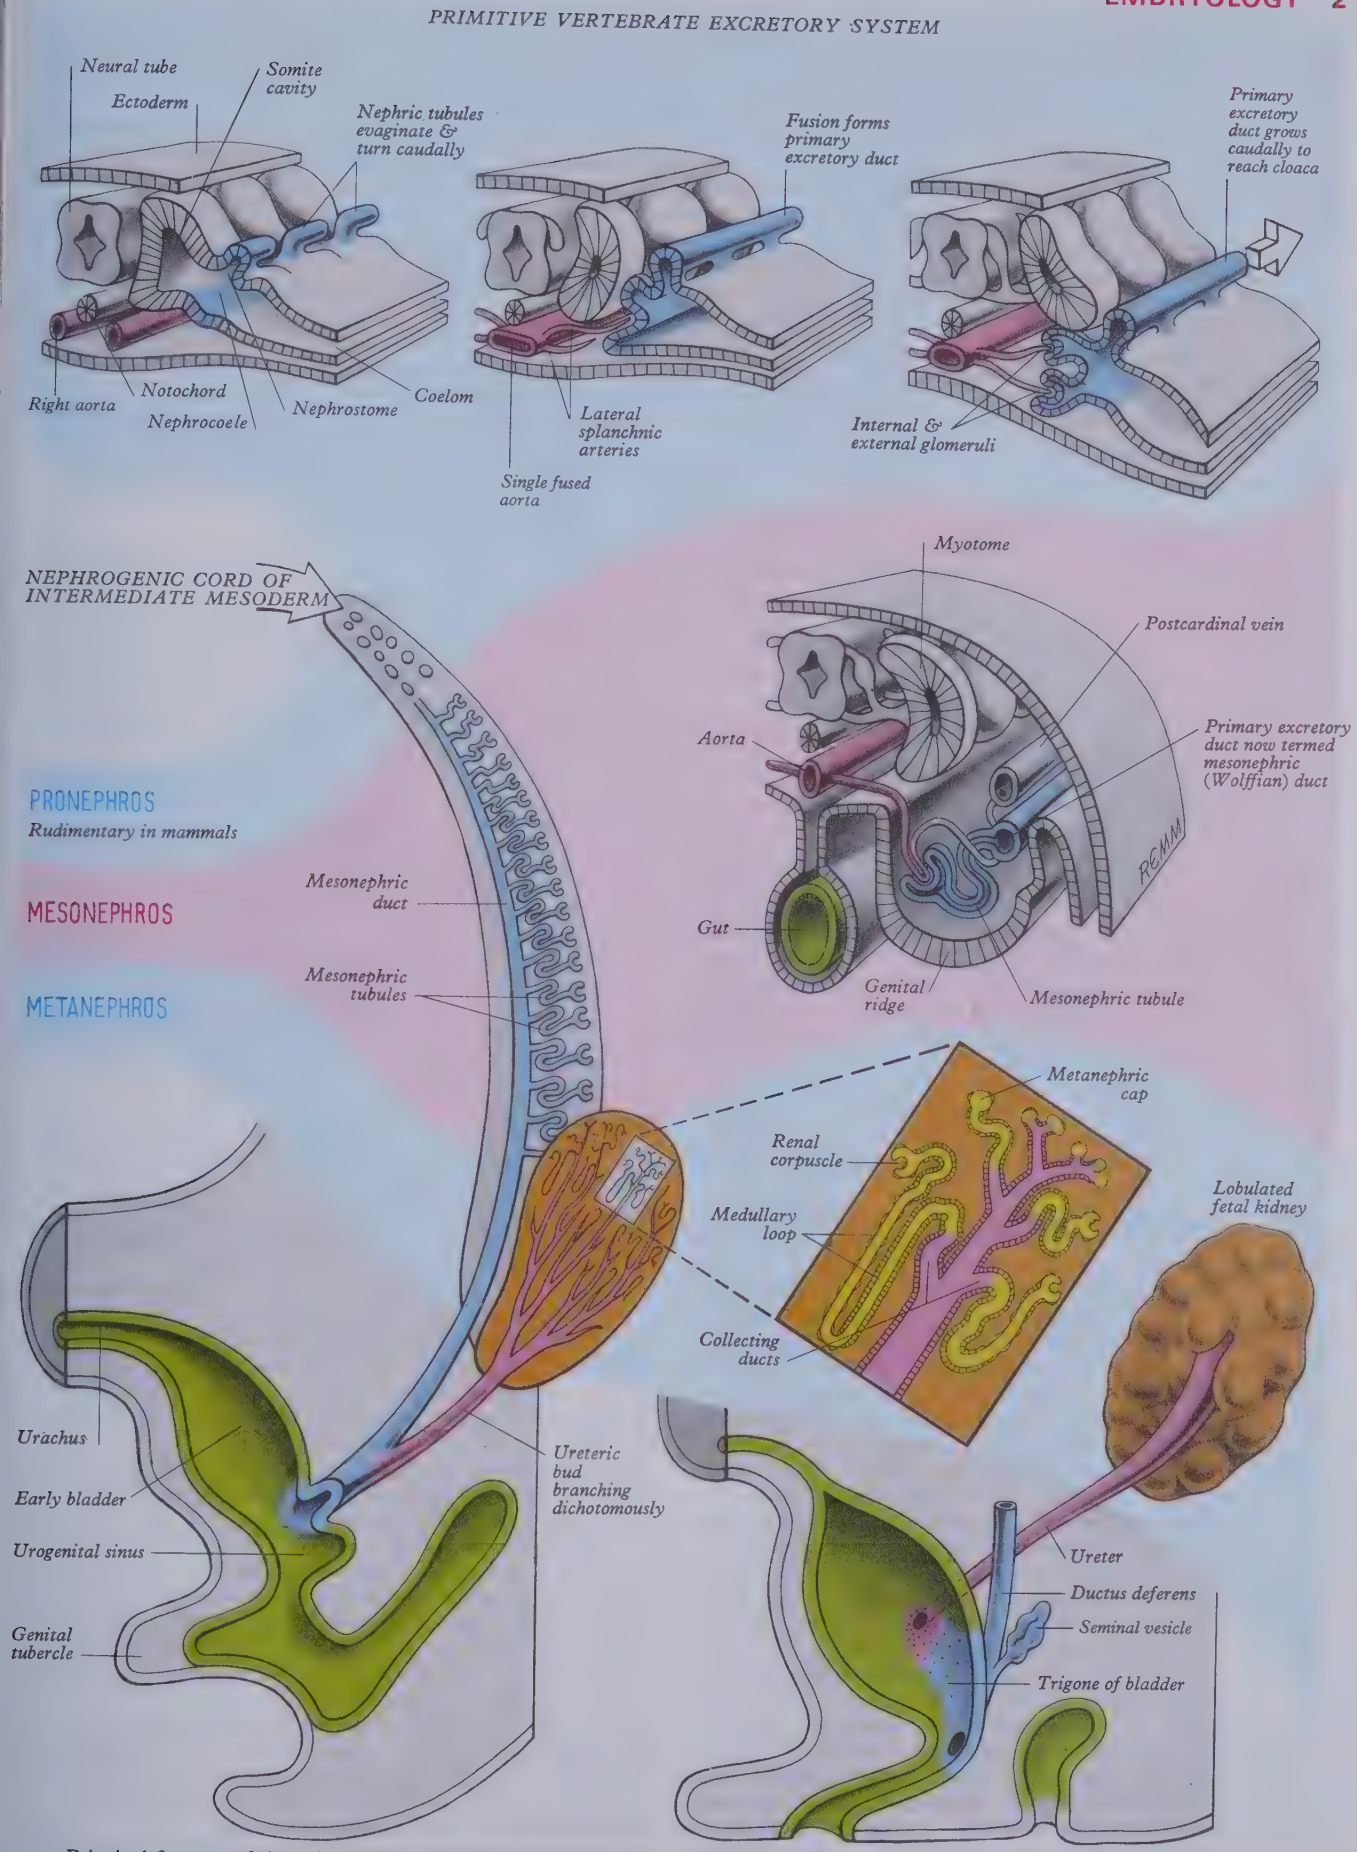
The lower (inferior) part of the lesser sac commences development at about 8–9 mm CR length—at this stage the early pneumato-enteric and hepato-enteric recesses are well established. Differential gastric growth is progressing (p. 246) giving an elliptical transverse sectional profile, with a right sided lesser curvature, corresponding to the original ventral border of the gastric tube, and to which the lesser omental gastric part of the ventral mesogastrium remains attached. As indicated, the greater curvature is a new formation, rapidly expanding, with its convex profile projecting mainly to the left, but also rostrally and caudally. It was emphasized that the original dorsal border of the gastric tube now traverses the dorsal aspect of the expanding rudiment, curving along a line near the *lesser* curvature; here, transiently, the *primitive* dorsal mesogastrium is attached. The latter blends with the thick layer of compound gastric mesoderm clothing the posterior aspect and greater curvature of the miniature stomach; because of its thickness, the mesoderm projects rostrally, caudally, and particularly to the left, beyond the 'new' greater curvature of the endodermal lining of the stomach. (It may be noted that during these stages the geometries, and hence sectional profiles, of tissue strata and cavities are complex and change rapidly with varying levels of histological section and with time. Thus only a brief summary of some salient points can be attempted here. For details consult e.g. Kanagasuntheram 1957.) The processes already described in relation to the ventral mesenteries now supervene. Multiple clefts appear at various loci in the mesoderm; each group of clefts rapidly coalesce to form (transiently) isolated closed spaces. The latter, by a continuation of the mechanism, soon join with each other and with the preformed upper part of the lesser sac. The initial loci involve firstly the compound posterior gastric mesoderm nearer the lesser curvature and along its zone of blending with the primitive dorsal mesogastrium; secondarily in the dorsal mesoduodenum; thirdly, independently in the caudal rim where greater curvature mesoderm and dorsal mesogastrium blend. As these cavities become confluent and their 'reniform' expansion follows, matches and then exceeds that of the gastric greater curvature, there are some major sequelae. The primitive dorsal mesogastrium increases in area not only by intrinsic growth but, as cavitation proceeds, by substantial additions from the dorsal lamella separated by cleavage of the posterior gastric mesoderm: together these may conveniently be called the *secondary dorsal mesogastrium*. The *gastric attachment* of the latter changes as a set of somewhat spiral lines, longitudinally disposed, that move, with time, from near the lesser curvature towards, and finally reaching, the definitive greater curvature. The *parietal* mesogastrial and (cleaving) mesoduodenal *attachment* remains, for a time, in the dorsal midline, but subsequently undergoes profound changes. With the confluence of the cavities that collectively form the lower part of the lesser sac, its communication with the upper part, corresponding to the lesser gastric curvature and right and left gastropancreatic folds, becomes better defined. *Ventral* to the lower part of the cavity lies the post-cleavage mesoderm covering the posteroinferior surface of the stomach and a short proximal segment of the duodenum. This ventral wall is continued beyond the greater curvature and duodenum as the mesodermal strip of visceral attachment of the secondary dorsal mesogastrium and mesoduodenum. The radial width of the strip is relatively short rostrally (gastric fundus) and gradually increases along the descending left part of the greater curvature; it is longest throughout the remaining perimeter of the greater curvature as far as the duodenum, and this prominent part shows continued marginal (caudoventral and lateral) growth with extended internal cavitation (its walls constituting the expanding *greater omentum*). The *margins* of the cavity of the inferior part of the lesser sac are limited by the reflexed edges of the ventrally placed strata derived from the secondary dorsal mesogastrium just described. These converge, forming the mesodermal *dorsal wall*, which is initially 'free' throughout except at its midline dorsal root. At roughly mid-gastric levels is where, encased in this dorsal wall, the pancreatic rudiment grows obliquely, its tail ultimately reaching the left limit of the lesser sac at the level of the junction between gastric fundus and body. (It may be mentioned that many earlier accounts held that the lower part of the lesser sac stemmed from a simple excavation of the dorsal mesogastrium —the *pancreatico-enteric recess*—with subsequent further extensions. This view has been discarded here.)

Centred on the dorsal mesogastrial region towards which growth of the pancreatic tail is directed, the anlage of the spleen appears in the coelomic epithelium and subjacent mesenchyme. As it expands into the upper left hypochondriac part of the *greater* sac, it retains its neurovascular pedicle and serous tunic, both of dorsal mesogastrial origin (p. 238, **2**.114).

The greater omentum and its contained extension of the lesser sac continue to grow both laterally, but particularly caudoventrally, covering and closely applied to the transverse mesocolon, transverse colon and inframesocolic and infracolic coils of small intestine. At this stage the quadrilaminar nature of the dependent part of the greater omentum is most easily appreciated. It will be recalled that 'simple' mesenteries, e.g. *the* mesentery of the jejuno-ileum, are bilaminar in that they possess two mesothelial surfaces enclosing a connective tissue core which bears blood and lymphatic vessels, lymph nodes, nerves, adipose tissue and other cell varieties. In the greater omentum, the gastric serosa covering its postero-inferior surface (single mesothelium) and the anterosuperior serosa (single mesothelium) converge, meeting at the greater curvature (and initial segment of the duodenum). The resulting bilaminar mesentery continues as the anterosuperior (or 'descending') stratum of the omentum which, on reaching the omental margins, is reflexed and 'returns' (or 'ascends') as its posterior bilaminar stratum to its parietal root. The two bilaminar strata are initially in fairly close contact caudally, but separated by a fine, fluid-containing, cleft-like extension of the lower part of the lesser sac. The posterior mesothelium of the posterior stratum makes equally close contact with the anterosuperior surface of the transverse colon (starting at its *taenia omentalis*) and with its transverse mesocolon.

At this stage, and subsequently, it is convenient to designate the lower part of the lesser sac as consisting of three *subregions: retrogastric, perigastric,* and *greater omental*. The names are self-explanatory but their confines are all modified by various factors. Two phenomena are particularly prominent—gastric 'descent' relative to the liver, and fusion of peritoneal layers with altered lines of reflexion, adhesion of surfaces and loss of parts of cavities.

After the third month the hepatic growth diminishes, particularly the left lobe, and the whole organ recedes into the upper abdomen; meanwhile the stomach elongates and some descent occurs, despite its relatively fixed cranial and caudal ends. This causes the angular flexure of the stomach that persists postnatally: the concavity of the lesser curvature is now directed more precisely to the right, the lesser omentum is more exactly coronal and its free border vertical ventral to the liver; the free border of the ligamentum falciformis passes steeply rostrodorsally from umbilicus to liver. The mesodermal dorsal wall of the lower part of the lesser sac, crossed obliquely by the growing pancreas, has hitherto remained free, with its original dorsal midline root. Substantial areas now fuse with adjacent peritonealized surfaces of retroperitoneal viscera, the parietes, or another mesenteric sheet or fold. In the latter case there occurs a variable loss of their apposed mesothelia and some continuity of their mesodermal cores, but they remain surgically separable and no vascular anastomosis develops across the interzone. Above the pancreas the posterior secondary dorsomesogastrial wall of the sac becomes closely applied to the peritoneum covering the posterior abdominal wall and its sessile organs—the diaphragm, much of the left suprarenal gland, the ventromedial part of the upper pole of the left kidney, the initial part of the abdominal aorta, the coeliac trunk and its branches, and other vessels, nerves, and lymphatics (pp. 1339, 1340). Their peritoneal surfaces fuse and, with some tissue loss, a single mesothelium covering these structures remains, intercalated as a new secondary dorsal wall for this part of the lesser sac. The pancreas, as indicated (p. 237), grows from the duodenal loop, penetrating the substance of the dorsal mesoduodenum and secondary dorsal mesogastrium, their mesoderms and mesothelia initially clothing its whole surface, except where there exist peritoneal lines of reflexion. Its posterior peritoneum becomes closely applied to that covering all the posterior abdominal wall structures it crosses (prominently—the inferior vena cava, abdominal aorta, splenic vein, superior mesenteric vessels, inferior mesenteric vein, portal vein, left renal vessels, the caudal pole of the left suprarenal, a broad ventral band on the left kidney and various muscles etc., see p. 1382). The intervening peritoneal mesothelia fuse and atrophy, the mesodermal cores forming fascial sheaths and septa. The pancreas is now sessile and the peritoneum covering the upper left part of its head, neck and anterosuperior part of its body forms the central part of the dorsal wall of the lesser sac. The pancreatic tail remains peritonealized by a persisting part of the secondary dorsal mesogastrium as it curves from the ventral aspect of the left kidney towards the hilum of the spleen. (The infracolic parts of the pancreas are covered with greater sac peritoneum.) In the greater omental subregion of the lower part of the lesser sac two contrasting forms of mesenteric adhesion occur. The posterior 'returning' bilaminar stratum of the omentum undergoes partial fusion with the peritoneum of the transverse colon (at the taenia omentalis) and with its mesocolon. (They provide a great increase in the functional area of the stomach 'bed'—p. 1349; also they remain surgically separable and no anastomosis occurs between omental and colic vessels.) In fetal life the greater omental cavity extends to the internal aspect of the lateral and caudal edges of the omentum. However, postnatally a slow but progressive fusion of the internal surfaces occurs with obliteration of the most dependent part of the cavity; this proceeds rostrally and, when mature, the cavity does not usually extend appreciably beyond the transverse colon. (The other fusions described above follow different patterns.) Transverse mesocolon-greater omental fusion commences early while the umbilical hernia of the midgut has not returned; it is initiated between the right margin of the early greater omentum and near the root of the *presumptive* mesocolon, later spreading to the left. The pancreas becomes sessile mediolaterally i.e. head, followed by neck and body from right to left. Paradoxically, in the suprapancreatic region, the direction of the process of fusion is reversed, progressing lateromedially from left to right. These events are wholly in accord with the numerous variations and anomalous visceral positioning and mesenteric arrangements that have been observed and recorded.



Correlated with the many facets of development of the lesser sac and its associated viscera, the original dorsal midline attachment to the parietes of the foregut dorsal mesentery is profoundly altered. However, despite the extensive areas of fusion, virtually the whole of the gastric greater curvature (other than a small suboesophageal area) and its topographical continuation, the inferior border of the first 2–3 cm of the duodenum, retain true mesenteric derivatives of the secondary dorsal mesogastrium and its continuation, the dorsal mesoduodenum. Thus, although regional names are given to assist identification and description, it must be emphasized that they are merely subregions of one continuous sheet; a short description of their 'root' or parietal line of reflexion is also given.

The upper (oesophagophrenic) part of the *lesser* omentum arches across the diaphragm and as this bilaminar mesentery approaches the oesophageal hiatus its laminae diverge, skirting the margins of the hiatus. They then descend for a limited distance and variable inclination, to enclose reciprocally-shaped areas on the dorsum of the gastric fundus and diaphragm. The area may be roughly triangular to quadrangular; it contains areolar tissue and constitutes the *bare area of the stomach* or, when large, the *left extraperitoneal space*. Its right lower angle is the base of the left gastropancreatic fold; its left lower angle reconstitutes the bilaminar mesentery. The root of the latter arches downwards and to the left across the diaphragm and suprarenal and gives the *gastrophrenic ligament* to the gastric fundus. Continuing to arch across the ventral surface of the upper part of the left kidney, its layers part to receive the pancreatic tail and initially extend to the hilum of the spleen as the *splenorenal (lienorenal) ligament*. The left half of this bilaminar 'ligament' provides an almost complete peritoneal tunic for the spleen (as indicated, projecting into the greater sac) then, reuniting with its fellow at the opposite rim of the splenic hilum, continues to the next part of the gastric greater curvature as the *gastrosplenic ligament*. The remaining major (perhaps two-thirds) of the gastric greater curvature and its short duodenal extension are the visceral attachment of the anterior, 'descending', bilaminar stratum of the greater omentum. Its returning, posterior, bilaminar stratum continues to its parietal root; the latter extends from the inferior limit assigned to the splenorenal ligament, continuing to curve caudally and to the right along the anterior border of the body of the pancreas, immediately cranial to the line of attachment of the transverse mesocolon. Crossing the neck of the pancreas, the same curve is followed for a few centimetres on to the glands' head; the omental root then is sharply recurved cranially and to the left, soon to reach the inferior border of the duodenum. Thus it reaches that part of the lesser sac provided by cleavage of the dorsal mesoduodenum from the greater sac, entering the epiploic foramen and traversing the epiploic canal between the caudate hepatic process and proximal duodenum, the lower right angle of the hepatoenteric recess, and crossing the right gastro- pancreatic fold, then descending behind the proximal duodenum to enter the right marginal strip enclosed by the greater omentum.

DEVELOPMENT OF UROGENITAL ORGANS

The urinary and reproductive organs are developed from the mesoderm of the *intermediate cell mass* (p. 133) and they are intimately associated with one another especially in the earlier stages of their development. Typically in lower vertebrates, the intermediate cell mass develops serial segmental *nephrotomes* (2.115), each enclosing a cavity, the *nephrocoele*, which communicates with the coelom through a *peritoneal funnel*. The dorsal wall of each nephrotome evaginates as a *nephric tubule* communicating with the nephrocoele via a *nephrostome*. The dorsal tips of the (cranial) earlier developed nephric tubules bend caudally and fuse forming a longitudinal *primary excretory duct*, which grows caudally and curves ventrally to open into the cloaca. The more caudally placed and successively later developed tubules open secondarily into this duct or into tubular outgrowths from it. *Glomeruli* arise from the ventral wall of the nephrocoele (*internal glomeruli*) or the roof of the coelom adjacent to the peritoneal funnels (*coelomic* or *external glomeruli*), or in both situations (2.115). External glomeruli are usually transitory.

It has been customary to regard the renal excretory system as three organs, the *pronephros*, *mesonephros* and *metanephros*,

2.115 Principal features of the primitive vertebrate nephric system for comparison with the development of the human nephric system. It should be appreciated that a considerable period of embryonic and fetal life has been necessarily compressed into a single, static diagram. (Modified from Williams et al 1969.)

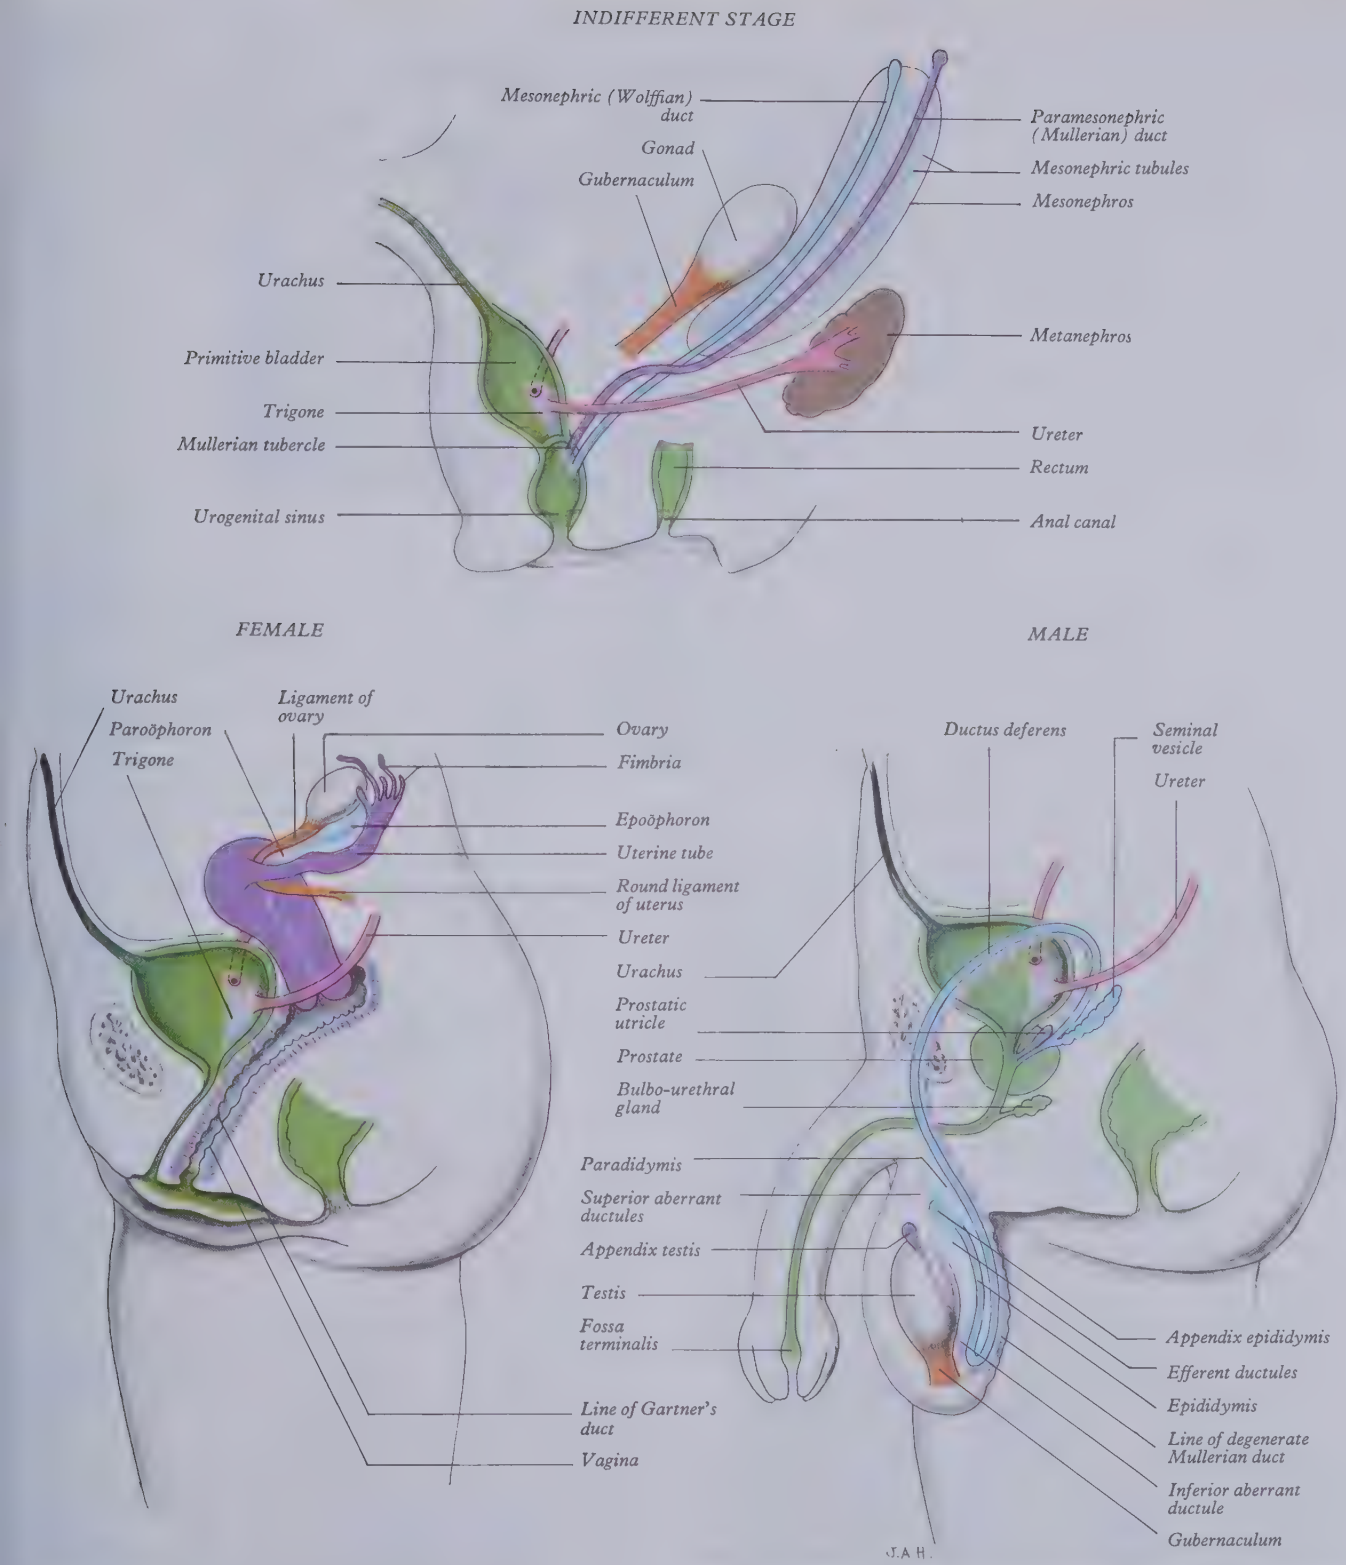
succeeding each other in time and space. The last to develop is retained as the permanent kidney. It is, however, difficult to provide reliable criteria that distinguish them as individual organs or to define their precise limits in the embryos of all animals. A pronephros cannot be distinguished as a separate organ in man; the earliest and most cranially situated nephric tubules are rudimentary, transient and regarded as marking the pronephric region, and the latter merges caudally without clear demarcation into the mesonephros.

Human nephrotomes, with cavitation to form nephrocoeles which communicate with the coelom, are restricted to a few segments bordering the rostral limit of the intraembryonic coelom. Cranial to this (pronephric region) the intermediate mesoderm develops irregular, transient, solid or vesicular balls of cells. Caudal to the level of the eighth to tenth somites the mesoderm of the intermediate mass is fused into an unsegmented *nephrogenic cord*. This is connected at irregular intervals with the coelomic epithelium. No nephric tubules are developed at the most cranial levels.

The *primary excretory duct* begins in embryos of about 14 somites (23–24 days) as a solid rod of cells in the dorsal part of the nephrogenic cord. Its cranial end is about the level of the ninth somite and its caudal tip merges with the undifferentiated mesoderm of the cord. It differentiates before any nephric tubules; when the latter appear it is at first unconnected with them. In older embryos the duct has lengthened and its caudal end becomes detached from the nephrogenic cord to lie immediately beneath the ectoderm. From this level it grows caudally, independently of the nephrogenic cord, and then curves ventrally to reach the wall of the cloaca. It becomes canalized progressively from its caudal end to form a true duct which opens into the cloaca in embryos of 4–5 mm length (about 28 days). (Clearly, up to this stage, the name 'duct' is scarcely appropriate.)

The pronephros is first indicated as clusters of cells (rudimentary nephric tubules) in the nephrogenic cord (**2**.115). In regions cranial to the primary excretory duct these clusters develop no further. More caudally similar groups of cells appear and these become vesicular. The dorsal ends of the most caudal of these vesicles join the primary excretory duct, their central ends being connected with the coelomic epithelium by cellular strands probably representing rudimentary peritoneal funnels. Glomeruli are not developed in association with these cranially situated nephric tubules, which ultimately disappear. It is doubtful whether external glomeruli develop in the human embryo. These rudimentary nephric tubules constitute the pronephros described by earlier workers.

(For an overview and bibliographies concerning the early development of the human nephros consult Torrey 1954, O'Rahilly & Muecke 1972.)

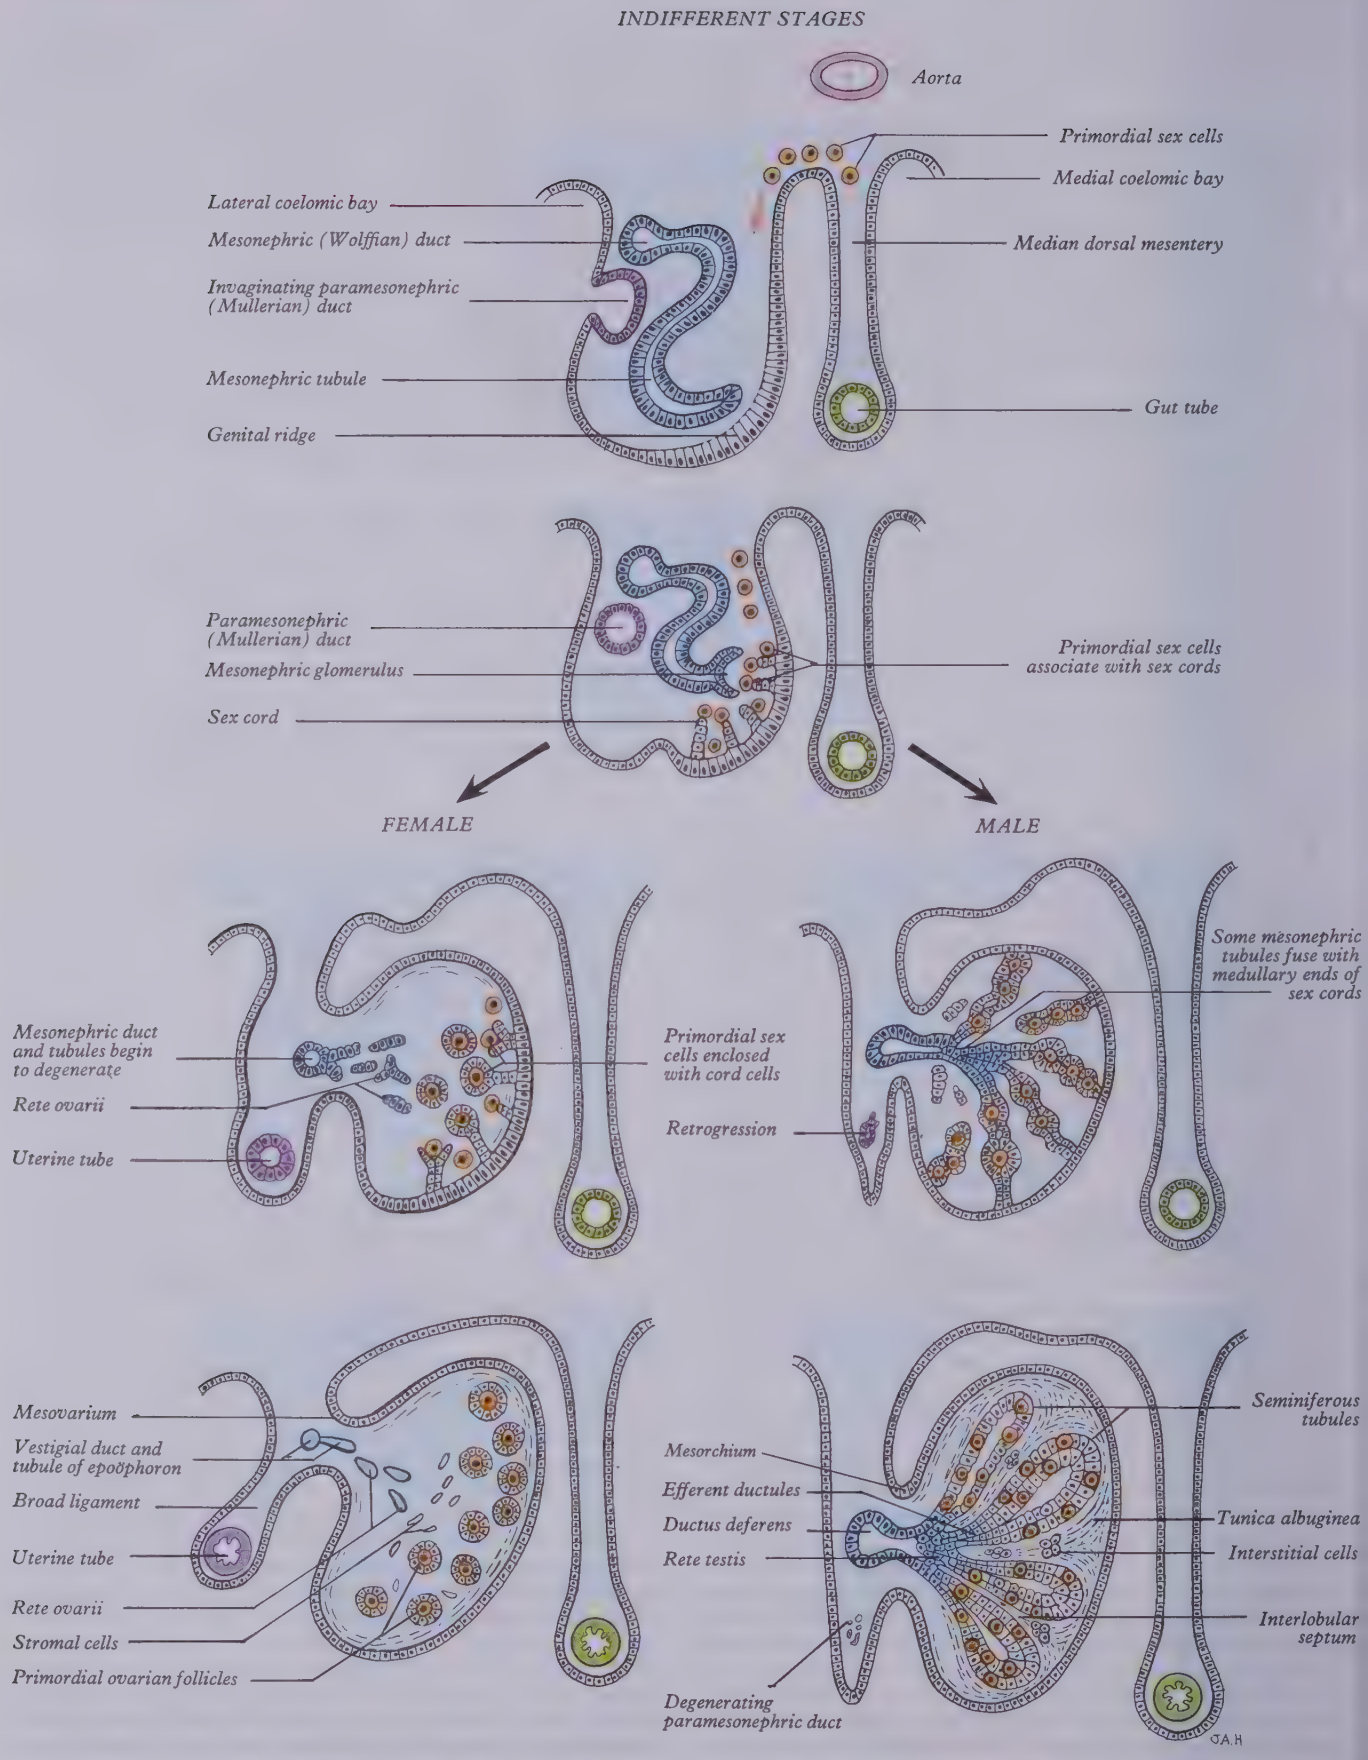


The mesonephros develops caudal to the foregoing rudiments (**2**.115–117). It extends caudally to the level of the third lumbar segment, its nephric tubules are more completely differentiated and distinct internal glomeruli are formed. As in the more cranial region, each tubule first appears as a mass of cells which becomes hollow. One end of the vesicle grows towards and opens into the primary excretory duct, which is now termed the *mesonephric duct*, whilst the other forms the internal glomerulus. This dilates and invaginates; the outer stratum forms the *glomerular capsule*, the invaginated segment tissue from which the glomerular capillaries differentiate, with their enclothing cell varieties. These are supplied with blood through a lateral branch of the aorta (Streeter 1945). It is estimated that about 70–80 mesonephric tubules and a corresponding number of glomeruli develop, but these are *not* segmental in arrangement. These tubules, however, are not present at the same time and it is rare to find more than 30–40 in an individual embryo, for the cranial tubules and glomeruli develop then atrophy before the development of those situated more caudally. By the end of the sixth week each mesonephros is an elongated spindle-shaped organ which projects into the coelomic cavity, one on each side of the dorsal mesentery from the septum transversum to the third lumbar segment. This whole projection is the *mesonephric ridge* (Wolffian body); it develops subregions (vide infra), and the gonad is developed on its medial surface. There are striking similarities in structure between the mesonephros and the permanent kidney or metanephros, but the former's nephrons lack a segment corresponding to the descending limb of the loop of Henle (Leeson 1957, Davies & Routh 1957).

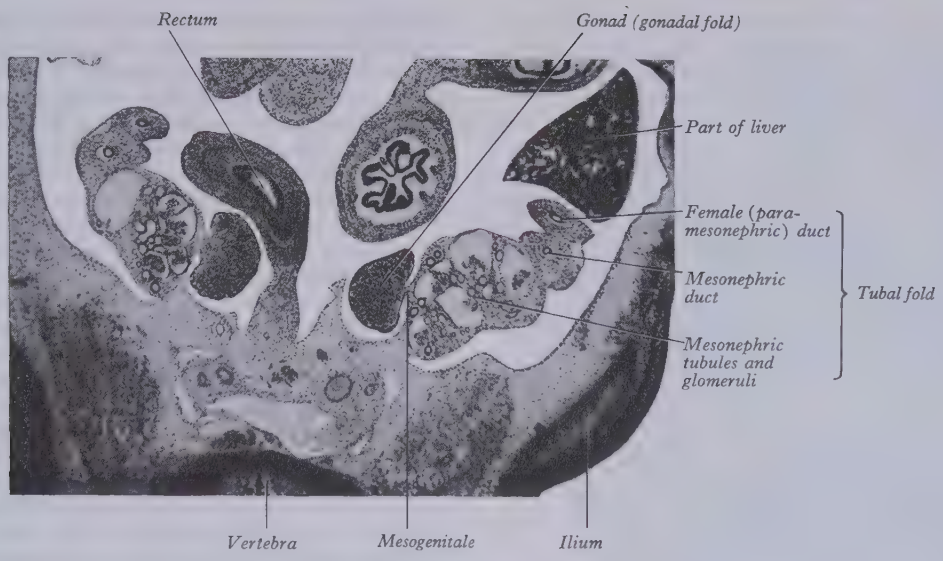
In both sexes the cranial end of the mesonephros atrophies; in embryos of 20 mm length the organ is found only in the first three lumbar segments, although it may still possess as many as 26 tubules. (This massive degeneration of the more cranial tubules appears to have no parallel in other mammals.) The most cranial one or two tubules persist as the *rostral aberrant ductules*; the succeeding five or six tubules develop into the *efferent ductules of the testis* and the *lobules of the head of the epididymis* in the male, and the tubules of the *epoöphoron* in the female; the caudal tubules form the *caudal aberrant ductules* and the *paradidymis* in the male, and the *paroöphoron* in the female.

The mesonephric duct runs caudally in the lateral part of the mesonephric ridge, at the caudal end of which it projects into the cavity of the coelom in the substance of a mesodermal *mesonephric fold* (**2**.118–122). (Subsequently, with the neighbouring formation of the paramesonephric duct, they form the *tubal fold* — vide infra.) As the mesonephric ducts approach the urogenital sinus the two folds fuse with each other, between the bladder ventrally and the rectum dorsally, forming across the cavity of the pelvis a transverse partition which is somewhat inaptly termed the *genital cord* (**2**.120A,B). In the male the peritoneal fossa between the bladder and the genital cord becomes obliterated, but it persists in the female as the uterovesical pouch. The mesonephric duct itself becomes the canal of the *epididymis*, *ductus deferens* and *ejaculatory duct*. The *seminal vesicle* and the ampulla of the ductus deferens appear as a common swelling at the termination of the mesonephric duct during the end of the third and into the fourth month. This coincides with degeneration of the paramesonephric ducts, though no causal relation between the two is apparent. Separation into two rudiments occurs at about 125 mm crown-heel length. The seminal vesicle elongates, its duct is delineated and hollow diverticula bud from its wall. About the sixth month (300 mm crown-heel length) the growth rate of both vesicle and ampulla is greatly increased; the cause is uncertain but may result from increased secretion of prolactin by the fetal or maternal hypophysis, or the effects of placental hormones. The tubules of the prostate show a similar increase of growth rate at the same time. In the female the mesonephric duct is vestigial, becoming the longitudinal duct of the epöophoron.

The metanephros, or permanent kidney, has a double origin (**2**.115). At about the 5 mm stage an outgrowth forms from the dorsomedial aspect of the mesonephric duct, near the cloaca. This is the *metanephric (ureteric) diverticulum* and it grows dorsally, then cranially. Its blind extremity grows into the caudal end of the nephrogenic cord, becomes expanded and the adjoining mesoderm condenses around it to form the *metanephrogenic mass* or *cap* (**2**.115, 121). The presence of the actively growing extremity of the diverticulum provides unidentified factors determining the differentiation of the mesoderm and, where the ureter fails to develop, no metanephrogenic cap is formed. The stalk of the diverticulum becomes the *ureter*, and its expanded cranial end gives origin not only to the *pelvis* of the kidney and its *calices* but also to the *collecting tubules* of the kidney. The secreting and convoluted tubules and the renal corpuscles are all derived from the metanephrogenic cap in a manner similar to the development of the mesonephric tubules and glomeruli. The blood vessels of the glomeruli develop in situ from mesenchyme in the concavity of the glomerular capsule (Lewis 1958a,b) and extend by repeated splitting of the lumina of the first-formed capillaries (Zamboni & De Martino 1968). (For details of the tubulo-vascular relationships in the developing kidney consult Speller & Moffat 1977.)



From the expanded extremity of the ureter arise four collecting tubules of the first order and it itself forms the primitive renal pelvis. Each of the tubules ends in an ampullated extremity, from which collecting tubules of the second order bud out. These, in turn, give rise to collecting tubules of the third order and so on. In some animals the four collecting tubules of the first order are absorbed into the renal pelvis, which then presents a single renal papilla and no subdivision into calices. In man, however, the collecting tubules of the first and second order persist and

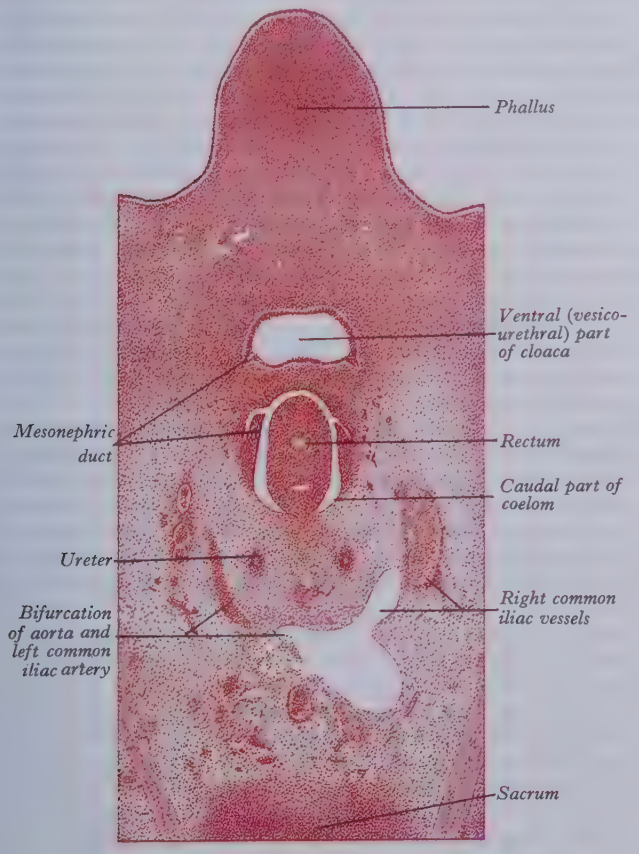


2.116 Disposition and fate of the mesonephric and paramesonephric ducts, mesonephric tubules, gonads and gubernaculum, primitive bladder and urogenital sinus, and ureters, as seen in the transformation from the indifferent stage to the definitive condition in the two sexes. (Modified from Williams et al 1969.)

constitute, respectively, the major and minor calices, while the tubules of the third and fourth orders are taken into the minor calices which, therefore, directly receive the openings of the collecting tubules of the fifth order.

When it first appears, the metanephric renal rudiment is sacral but, as the ureteric outgrowth lengthens, it grows cranially and when the embryo has a length of some 13 mm its expanded pelvis lies on a level with the second lumbar vertebra. During this period the ascending kidney receives its blood supply *sequentially* from arteries in its immediate neighbourhood, the middle sacral and common iliac arteries; the definitive *renal artery* is not recognizable until the beginning of the third month. It arises from the most caudal of the three suprarenal arteries, all of which represent persistent mesonephric or lateral splanchnic arteries (p. 218). Additional renal arteries are by no means uncommon. They may enter at the hilum or at the upper or lower

2.117 Schema of the development of the gonads and associated ducts as seen in transverse section. Note fate of primordial sex cells, mesonephric duct and tubules and paramesonephric duct in the two sexes.

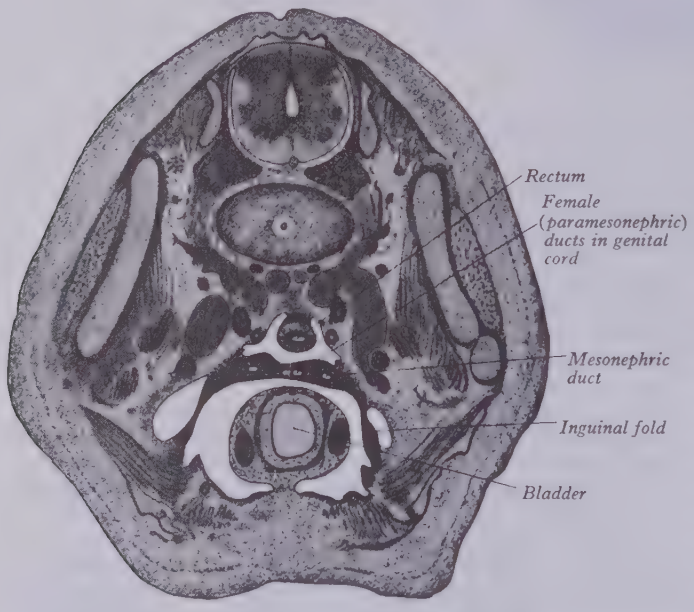


2.118 Transverse section through the lower part of the abdomen of a human fetus, nine weeks old, showing the connections and relative positions of the structures derived from the mesonephric ridge.

pole of the gland, and they also represent persistent mesonephric arteries.

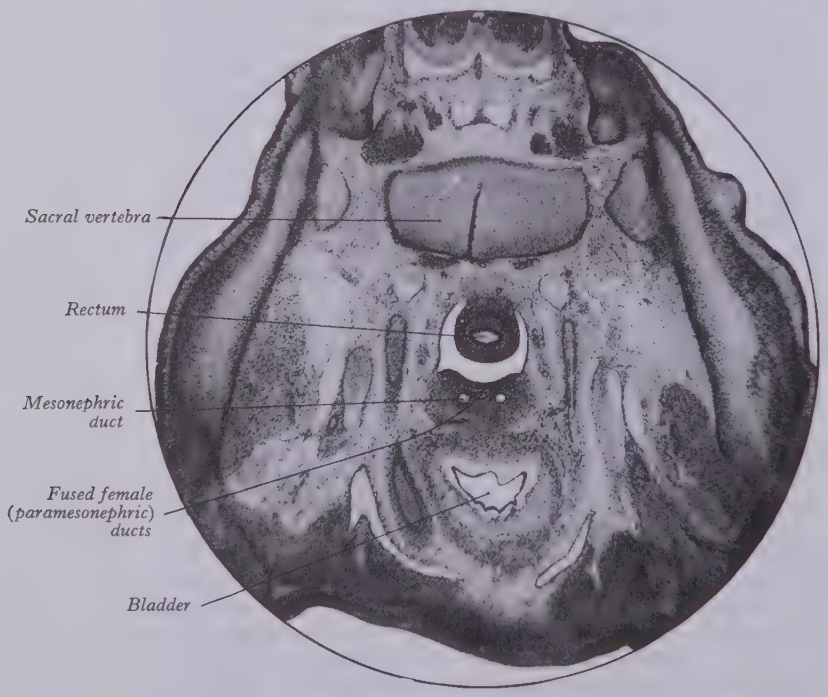
At an early stage the metanephric kidney is lobulated, a condition which persists through fetal life but disappears during the first year after birth. Varying degress of lobulation, however, on occasion persist throughout life.

There occur many varieties of cystic renal disease, and a number of different classifications proposed (see Chisholm & Williams 1982). For long it has been held that renal cysts in most, if not all instances, result from vesicular cell clumps retained after failure of fusion between the tips of branches from the ureteric diverticulum on the one hand, and metanephrogenic cap tissue on the other. Such a view is no longer tenable. It has been demonstrated, convincingly, that the cyst-like formations are wide dilatations of a part of otherwise continuous nephrons (Moffat 1982). *Adult polycystic renal disease*, the commonest form, is inherited as an autosomal dominant; in this the dilatations may affect any part of the nephron, from Bowman's capsule to collecting tubule. Less common is *infantile cystic renal disease*, inherited as a recessive trait; the proximal and distal tubules are dilated to some degree but the collecting ducts are grossly affected.



2.119 Transverse section of the tail end of a human embryo in the eighth week. CR length 22 mm. The projection from the dorsolateral aspect of the ventral portion of the cloaca marks the entry of the mesonephric duct. Stained with haematoxylin and eosin. Magnification × *c.*20.

Further development of the ureter has attracted less attention but one series included 45 human embryos (5–55 mm). It was claimed that the ureteric wall was highly permeable at an early stage (5 mm). Its lumen then becomes obliterated (13–22 mm), to be subsequently recanalized. Both processes were observed to begin at intermediate levels of the ureter and to proceed in both directions. The recanalization was not associated with metanephric function, but possibly with the rapid elongation of the ureter in conformity with embryonic growth. Two fusiform enlargements appear subsequently, affecting its lumbar and pelvic levels. The lumbar enlargement appears during the fifth month, the pelvic not until the ninth month, the latter being inconstant. As a result the ureter shows a constriction at its upper end (pelviureteric junction) and another as it crosses the pelvic brim. A third narrowing is always present at its lower end and is related to the growth of the bladder wall.



At first the caudal connection of the ureter is to the dorsomedial aspect of the mesonephric duct but, owing to differential growth, the connection becomes lateral to the duct. Thereafter the caudal end of the duct becomes incorporated in the developing bladder, and the orifice of the ureter opens separately into the bladder on the lateral side of the opening of the duct. Later the two orifices become separated still further and, although the ureter retains its point of entry into the bladder, the mesonephric duct opens into that part of the urogenital sinus which subsequently becomes the prostatic urethra.

The paramesonephric (Mullerian) ducts initially develop in embryos of both sexes, but become dominant in the development of the *female* reproductive system; they are not detectable, however, until the embryo reaches a length of 10–12 mm (early sixth week). Development in the 'indifferent' period is followed by further details of the female duct maturation and finally brief notes of the limited male derivatives. Each commences as a linear invagination of the coelomic epithelium (the *paramesonephric*

groove) on the lateral aspect of the mesonephric ridge near its cranial end, and its blind caudal end continues to grow caudally into the substance of the ridge as a solid rod of cells which acquires a lumen as it lengthens. Throughout the extent of the mesonephros it is *lateral* to the mesonephric duct. At the caudal end of the mesonephros (which it reaches in the eighth week), the paramesonephric duct turns medially (**2**.116) and crosses *ventral* to the mesonephric duct to enter the genital cord (**2**.120A,B), where it bends caudally in close apposition with its fellow of the opposite side. The two ducts reach the dorsal wall of the urogenital sinus during the third month, and their blind ends produce an elevation on it termed the *Mullerian (sinus) tubercle* (**2**.116,122F). Each duct consists, at the end of the indifferent stage, of vertical cranial and caudal parts with an intermediate horizontal region.

2.120A Transverse section through the pelvic part of a human fetus shows the formation of the genital cord and the inguinal folds.

2.120B Transverse section through the pelvis of a nine-week-old male human fetus, showing the approximation of the genital cord to the dorsal wall of the urogenital sinus.

In the female the cranial part forms the uterine tube, and its original coelomic invagination remains as the pelvic opening of the tube, the fimbriae becoming defined as the cranial end of the mesonephros degenerates. The caudal vertical parts of the two ducts fuse with each other (**2**.122F) to form the *uterovaginal primordium*. This gives rise to the lower part of the uterus and, as it enlarges, it takes in the horizontal parts to form the fundus and most of the body of the adult uterus. The stroma of the endometrium and the uterine musculature (myometrium) are developed from the surrounding mesoderm of the genital cord.

At about 60 mm CR length an epithelial proliferation (the *sinuvaginal bulb*) arises from the dorsal wall of the urogenital sinus in the region of the sinus tubercle, and its origin marks the site of the future hymen. Whether the epithelium involved in the proliferation is from the sinus (Bulmer 1957) or epithelium of the mesonephric duct which has extended over the Mullerian tubercle (Vilas 1932, Meyer 1938, Forsberg 1963) is uncertain. The proliferation gradually extends cranially as a solid, anteroposteriorly flattened plate, inside the tubular mesodermal condensation of the uterovaginal primordium which will eventually become the fibromuscular vaginal wall. The caudal tip of the paramesonephric duct epithelium recedes until, at about the 140 mm stage, its junction with the sinus proliferation lies in the cervical canal.

Commencing from its caudal end, and gradually extending cranially through its whole extent, the solid plate formed by the sinus proliferation enlarges into a cylindrical structure; thereafter the central cells desquamate to establish the vaginal lumen. According to one view, the paramesonephric ducts do not directly contribute to the formation of the vagina (Frutiger 1969) but it has also been suggested that mesonephric and paramesonephric ducts are both concerned (Linkevich 1969). As the upper end of the vaginal plate enlarges it grows up into the mesoderm to embrace the cervix, and then is excavated to produce the vaginal fornices. As the lower end enlarges it invaginates the dorsal wall of the urogenital sinus around the hymeneal orifice, trapping a thin layer of mesoderm around the orifice to form the hymen (**2**.123). The hymen is lined on its superior surface by vaginal epithelium which, despite its origin, is clearly distinct from the sinus epithelium on the inferior surface. In the later stages, however, the lower surface of the hymen and a large part of the vestibule become lined by an epithelium indistinguishable from that of the vagina (Bulmer 1959). The urogenital sinus undergoes relative shortening craniocaudally to form the vestibule, which opens on the surface through the cleft between the genital folds.

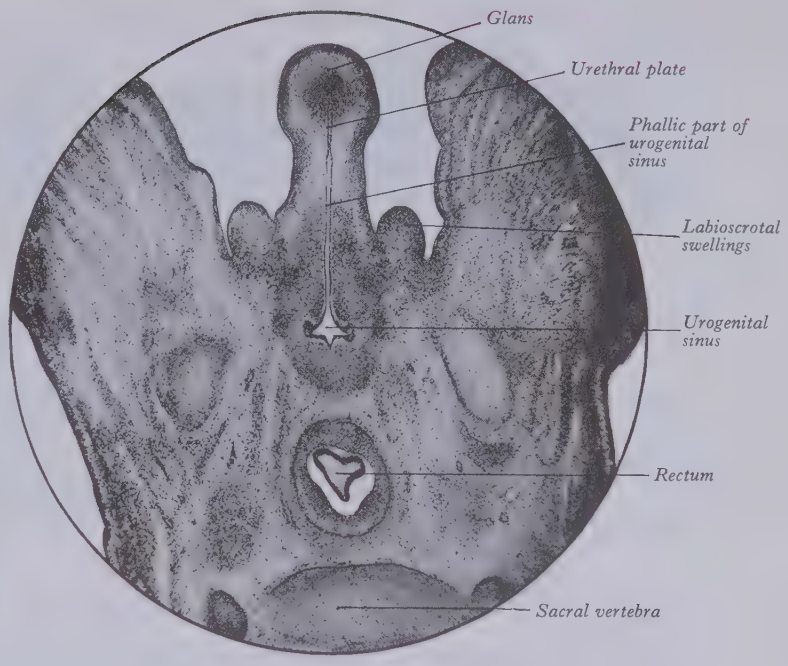
During the later months of fetal life the vaginal epithelium is enormously hypertrophied, apparently under the influence of maternal hormones, but after birth it assumes the inactive form of childhood (Fraenkel & Papanicolaou 1938).

The differing embryonic origins of the vaginal epithelium and uterine epithelium have been correlated with their dissimilar responses in adult life to stimulation with oestrogenic hormones (Zuckerman 1940).

In the male the paramesonephric duct mostly atrophies, but a vestige of its cranial end persists as the *appendix testis* (p. 1424). The fused caudal ends of the two ducts are connected to the wall of the urogenital sinus by a solid *utricular cord* of cells. In this position it soon merges with a proliferation of sinus epithelium, the *sinu-utricular cord*, similar to, but less extensive than, the sinus proliferation in the female. This proliferating epithelium is claimed to be an intermingling of the endoderm of the urogenital sinus with the lining epithelia of the mesonephric and paramesonephric ducts, which have extended on to the surface of the sinus tubercle. As the sinu-utricular cord grows, so the utricular cord recedes from the tubercle. In the second half of fetal life the composite cord acquires a lumen and dilates to form the *prostatic utricle*, the lining of which consists of hyperplastic stratified squamous epithelium. The sinus tubercle becomes the *colliculus seminalis* (Vilas 1933, Glenister 1962).

The primordial germ cells, origin of the definitive germ cells, are segregated very early. This has been demonstrated at the 2-somite stage in the chick (Clawson & Domm 1969). They are large cells, in comparison with most somatic cells, being from 12 to 20 μm in diameter, and characterized by vesicular nuclei with

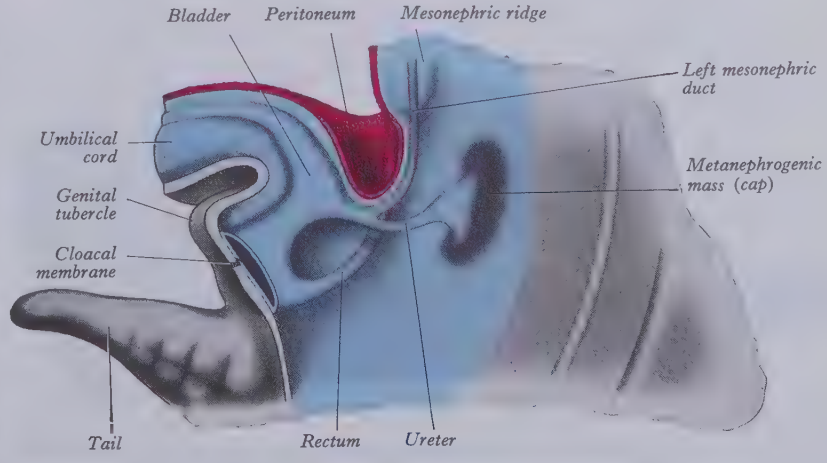
well-defined nuclear membranes and by a tendency to retain yolk inclusions long after these have disappeared from somatic cells. (For the ultrastructure of human primordial germ cells consult Fukuda 1976.) It is not yet established whether the primordial germ cells are derived from particular blastomeres during cleavage, if they constitute a clonal line from a single blastomere or are the product of a progressive concentration of the germinal plasma of the fertilized ovum by unequal partition of this at successive mitoses (Bounoure 1939).



The germ cells can be identified in human embryos at the 13-somite stage (fourth week) in the endoderm at its caudal end and in the adjacent part of the yolk sac (Witschi 1948). At this stage the number of cells is probably not more than 20 to 30 (Hardisty 1967). When the tail fold has formed they appear in the endoderm and the splanchnic mesoderm of the hindgut as well as in the adjoining region of the wall of the yolk sac. By amoeboid movements and by growth displacement they migrate dorsocranially in the mesentery, passing around the dorsal angles of the coelom (medial coelomic bays) to reach the medial sides of the mesonephric ridges—the developmental sites of the gonads. In most vertebrates mitosis in the germ cells is arrested after their early segregation, to be renewed only when they reach the genital primordia. However, in mammals there is no such arrest and the cells proliferate both during and after migration to the mesonephric ridges; cells which do not complete this migration degenerate. After segregation the primordial germ cells are often termed *primary gonocytes*, which in turn divide to form *secondary gonocytes*. The distinction between the two generations is clear in most vertebrates, but the absence of mitotic arrest in mammals leads to a merging of the two stages.

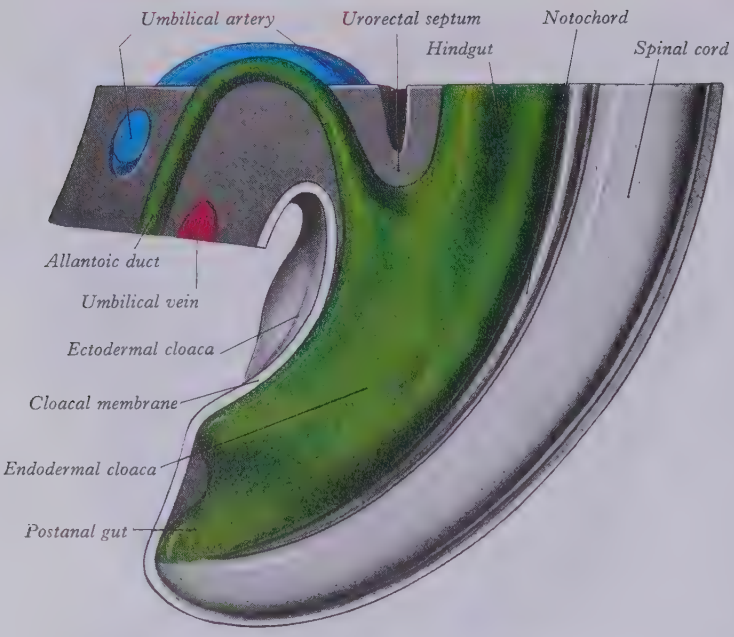
The early association of primordial germ cells with the endoderm suggests that they are in fact derived from primitive endodermal cells or perhaps from common stem cells. Alternatively, the endoderm may exert an inductive effect on their site, proliferation and differentiation without being their actual source. For a discussion of this problem and citation of pertinent references consult Carlon & Stahl (1973).

While sexual differences in germ cell numbers occur in some vertebrate species, it is uncertain whether this represents an original difference at segregation or results from earlier and more rapid proliferation in one sex. No connection between numbers of primordial germ cells and fertility has been detected, but there is evidence that gross deficiency in number may affect individual fecundity (Hardisty 1967).

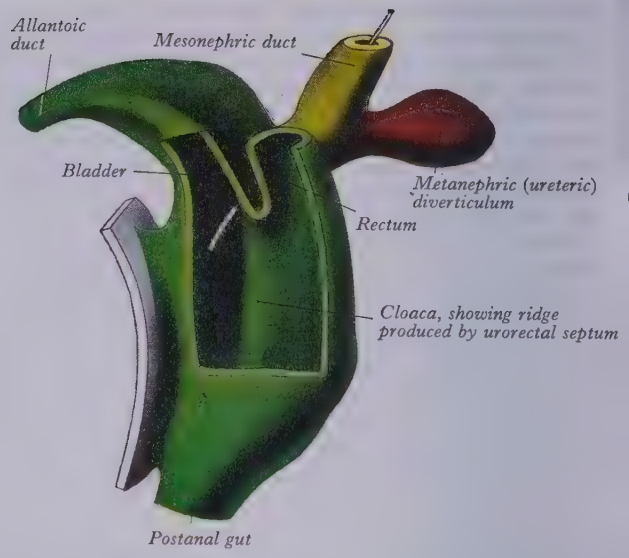


The formation of the gonads is first indicated by the appearance of an area of thickened epithelium on the medial side of the mesonephric ridge in the fifth week (**2.117**). Elsewhere on the surface of the ridge the coelomic epithelium is one or two cells thick, but over this genital area it becomes many-layered. The thickening rapidly extends in a longitudinal direction until it covers nearly the whole of the medial surface of the ridge. The thickened epithelium continues to proliferate, displacing the renal corpuscles of the mesonephros in a dorsolateral direction and forming a projection into the coelomic cavity, the *gonadal ridge*. Surface depressions form along the limits of the ridge which is thus connected to the mesonephros by an originally broad mesentery, the *mesogenitale*. In this way the mesonephric ridge becomes subdivided into a lateral part containing the mesonephric and paramesonephric ducts, which may be termed the *tubal fold*, and a medial part, termed the *gonadal fold*. The tubal fold also contains the nephric tubules and glomeruli at its base.

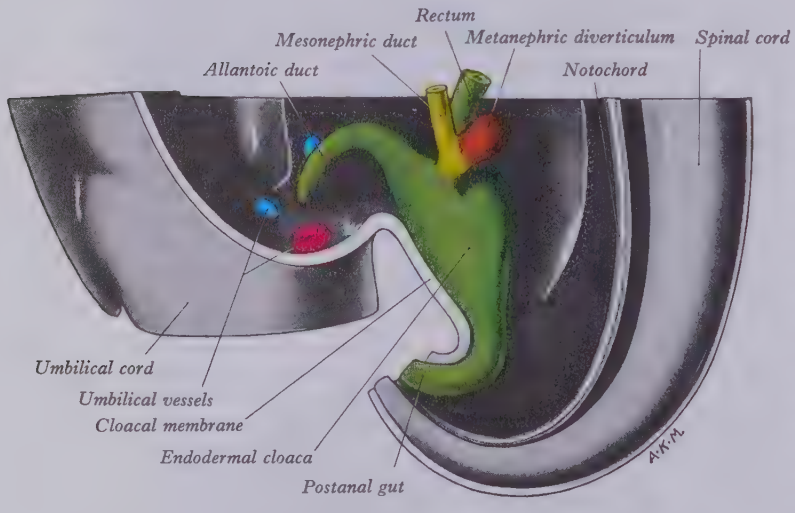
Up to the seventh week the gonad possesses no sexually differentiating feature. The proliferating epithelium now forms a number of cellular *gonadal cords*, separated by mesenchyme. These cords remain at the periphery of the primordium to form a cortex; more centrally a proliferation and labyrinthine cellular condensation of the mesenchyme of the mesonephros constitute a medulla. In the male all the progenitors of the definitive gonocytes become incorporated in the cords, but in the female a large number remain behind under the surface epithelium. At this stage in the male, an extension of the mesenchyme separates the gonadal cords from the surface and rapidly thickens to form the primitive *tunica albuginea*. This also develops in the female but to a lesser extent and at a later stage.



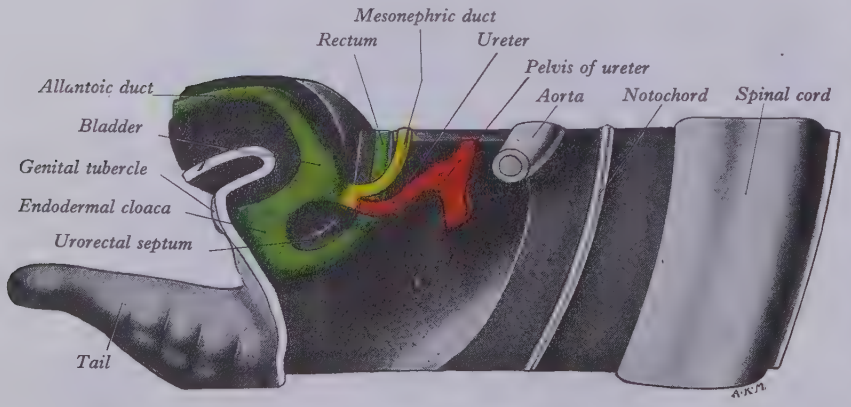
2.120C Transverse section through the lower part of the pelvis of a nine-week-old human fetus.



The testis (**2.117**). The cellular cords lengthen partly by additions from the coelomic epithelium and encroach on the medulla, where they unite with the network derived from the mesenchyme which ultimately becomes the *testicular rete*. The primordial germ cells are incorporated in the cords, which later become enlarged and canalized to form the *seminiferous tubules* (see Fukuda & Hedinger 1975). The cells derived from the surface of the early gonad form the *supporting cells* (of Sertoli). The *interstitial cells* of the testis are derived from the mesenchyme and possibly also from coelomic epithelial cells which do not become incorporated into the tubules. The cords of the testicular rete, which canalize later, become connected to the glomerular capsules in the cranial end of the (caudal) persisting part of the mesonephros and their associated glomerular tufts atrophy. The rete cords thus become connected to the mesonephric duct by the five to twelve most cranial *persisting* tubules and these become exceedingly convoluted and form the lobules of the head of the epididymis. The mesonephric duct, which was the primitive 'ureter' of the mesonephros, becomes the canal of the *epididymis* and the *ductus deferens* of the testis. The seminiferous tubules do not acquire lumina until the seventh month, but the tubules of the testicular rete somewhat earlier.



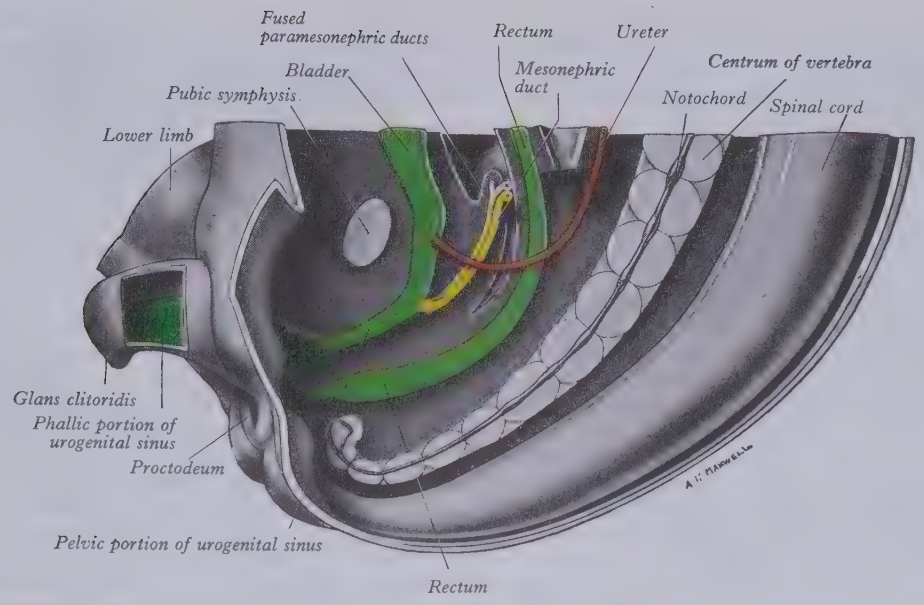
2.121 Schema, based on **2.122D**, to show the formation of the pelvis of the kidney and the metanephrogenic mass or cap.



2.122A The tail end of a human embryo, about 4 weeks old. The model has been dissected to show the left lateral aspects of the spinal cord, notochord and endodermal cloaca. (After Keibel.)

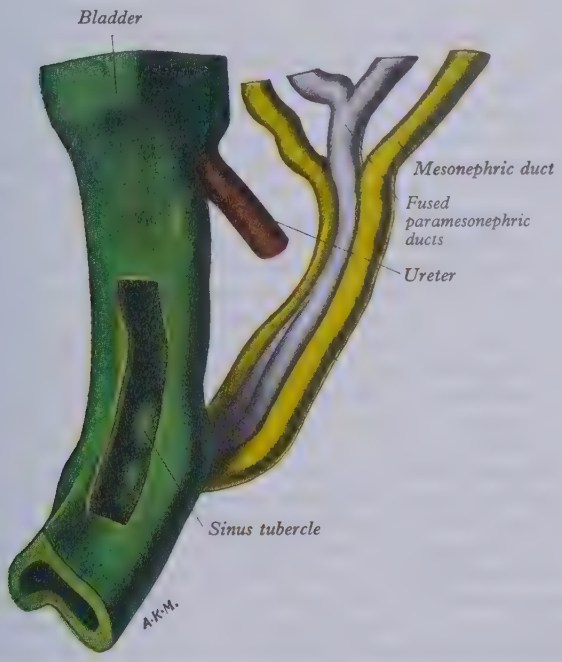
2.122B The endodermal cloaca of a human embryo, near the end of the fifth week. A wire has been passed along the right mesonephric duct into the cloaca, and a part of the left wall of the cloaca, including the left mesonephric duct, has been removed, together with the adjoining portions of the walls of the developing bladder and rectum. A piece of the ectoderm around the cloacal membrane has been left *in situ* and is uncoloured. (After Keibel.)

2.122C The caudal end of a human embryo, about 5 weeks old. (Drawn from a model by Keibel.)



2.122D Part of the caudal end of a human embryo, about 6 weeks old. (Drawn from a model by Keibel. The model, which has been partly dissected, is seen from the left side.)

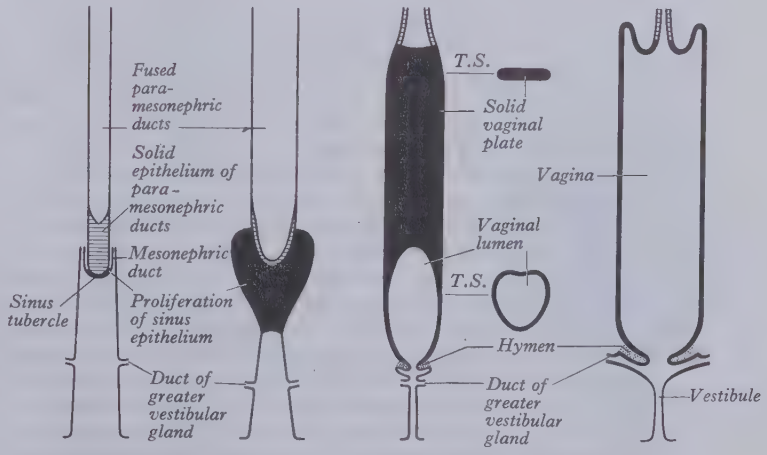
The ovary (2.117). In its earliest stages, the ovary closely resembles the testis, although it is slower to differentiate its characteristically female features. Few, if any, of the gonadal cords invade the medulla, the majority remaining in the cortex, where they may be joined by a second proliferation from the epithelium covering the gonad. In sections of the ovary in the third and subsequent months the cords appear as clusters of cells which may or may not contain primitive germ cells. These clusters are separated by fine septa of undifferentiated mesenchyme. An *ovarian rete* condenses in the medullary mesenchyme and some of its cords may form a junction with mesonephric glomeruli. The medulla subsequently regresses, and connective tissue and blood vessels from this region invade the cortex to form the stroma of the ovary. During this invasion the cell clusters break into individual groups which surround the *primordial 'ova'*, now *primary oöcytes*, which have entered the prophase of the first meiotic division. These cells were derived from a mitotic division of the primordial germ cells (*naked oögonia*). Their epithelial capsules consist of flattened *pregranulosa cells* derived from proliferations of coelomic epithelium (Gillman 1948). The ovary now has its full complement of primary oöcytes. The majority undergo atresia at various stages during their development, but the remainder resume development by completing the first meiotic division shortly before ovulation (Zuckerman 1951, 1956). The capsular cells at the same time enlarge and multiply to form the stratum granulosum, and as they do so they become surrounded by thecal cells which differentiate from the stroma.



Organ culture of human fetal ovaries confirms the above, but it was considered that the primary oöcytes had progressed to the leptotene stage. Strands of epithelial cells containing oögonia developed during culture (Baker & Neal 1974).

Only the middle part of the gonadal ridge produces the ovary. Its cranial part is sterile and becomes the *suspensory ligament of the ovary* (infundibulopelvic fold of peritoneum). Its caudal region, also sterile, is incorporated in the *ovarian ligament*.

The descent of the testis is *not* merely a simple migration. At first it lies on the dorsal abdominal wall, but, as it enlarges, its cranial end degenerates and the remaining organ therefore occupies a more caudal position. It is attached to the mesonephric fold by a peritoneal fold, the *mesorchium* (2.118) (the *mesogenitale* of the undifferentiated gonad), which contains the testicular vessels and nerves and a quantity of undifferentiated mesenchyme. In addition, it acquires a secondary attachment to the *ventral* abdominal wall, which has a considerable influence on its



2.122E The tail end of a female human fetus, $8\frac{1}{2}$–9 weeks old. The model has been dissected from the left side to show the structures in and near the median plane. Note that the cloaca has now been separated into urogenital and intestinal segments. (After Keibel.)

2.122F Part of the vesico-urethral portion of the endodermal cloaca of a female human fetus, $8\frac{1}{2}$–9 weeks old. (Drawn from a model by Keibel.)

subsequent movements. At the point where the mesonephric fold bends medially to form the genital cord (p. 250), it becomes connected to the lower part of the ventral abdominal wall by an *inguinal fold* of peritoneum (2.120A). The mesenchymal cells occupying the core of the inguinal fold condense as another cord, the *gubernaculum*, extending from the skin which will later form the scrotum, through the inguinal fold and the mesorchium to the caudal pole of the testis. It traverses the site of the future inguinal canal, which is formed around it by the muscles of the abdominal wall as they differentiate. At the end of the second month the caudal part of the ventral abdominal wall is horizontal but, after the return of the intestines to the peritoneal cavity (p. 233), it grows in length and progressively becomes vertical. As a result the umbilical artery pulls up a falciform peritoneal fold, as it runs ventrally from the dorsal to the ventral wall, and this forms the medial boundary of a peritoneal fossa into which the testis projects. This fossa is the *saccus vaginalis* or *lateral inguinal fossa* (p. 1339) and its lower end protrudes down the inguinal canal along the ventrosuperior aspect of the gubernaculum, as the *processus vaginalis*. The caudal pole of the testis is *retained* in apposition with the deep inguinal ring by the gubernaculum until the seventh month, when it abruptly and rapidly passes through the inguinal canal and gains the scrotum. As it descends it is necessarily accompanied by its peritoneal covering, and the adjoining peritoneum from the iliac fossa is drawn down into the processus vaginalis. The distal end of the processus vaginalis, into which the testis projects, forms the *tunica vaginalis testis* but the portion associated with the spermatic cord in the scrotum and in the inguinal canal normally becomes obliterated, usually leaving a fibrous remnant. Sometimes the remnant atrophies completely. Alternatively, its original cavity may persist, in whole or in part and any location. These variations may form the walls of hernial sacs or encysted fluid sites. The fascial coverings of the testis and spermatic cord, including the cremaster, are developed from the gubernaculum testis (Backhouse & Butler 1958).

The actual mechanism of the descent of the testis is still uncertain. It has been ascribed, by different investigators, to shortening and active contraction of the gubernaculum, to increased intra-abdominal pressure, to a simple growth process and to the effect on the convex surface of the gland of the active contraction of the lower fibres of the internal oblique muscle, squeezing it through the canal. None of these explanations is entirely convincing.

2.123 Diagrams to show the successive stages in the development of the uterus and vagina.

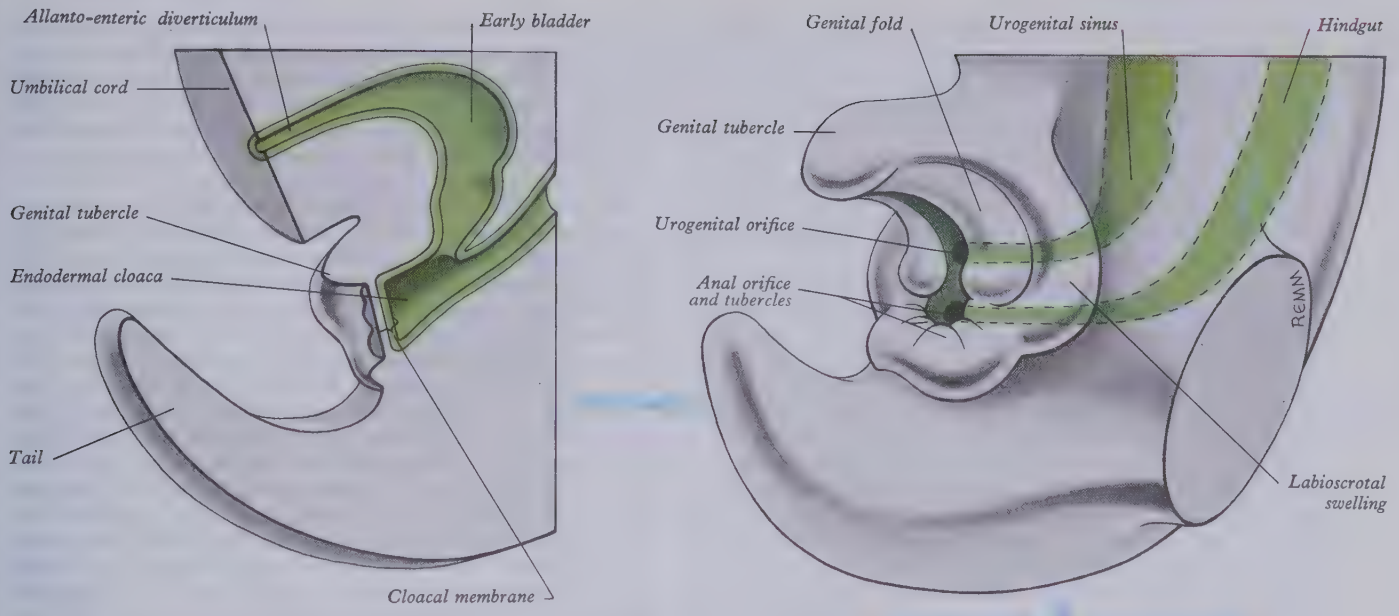
Whatever contribution the gubernaculum makes to the process, it cannot be by muscular contraction, because it contains no muscle, remaining a soft, mesenchymatous mass through its existence (Forssner 1928, Backhouse & Butler 1960). It precedes the testis both spatially and in rate of growth, forming a tapering column of soft tissue with the diminutive testis at its cranial pole. It continues to grow until the seventh month, by which time its caudal part has filled the future inguinal canal and has begun to expand the developing scrotum. In this it also precedes the processus vaginalis, but does not develop attachments to skin; nor is there any evidence that it produces the radiating extensions into the suprapubic, perineal and femoral sites, which are often used as explanations for the various forms of ectopia testis. By its soft consistency the gubernacular tissue may offer a route of low resistance to the descending testis, and the cessation of its growth in the last two months of gestation, coupled with an accelerating rate of growth in the testis and epididymis, may also be a factor in testicular descent as far as the inguinal canal. The mechanism of final, rapid descent into the scrotum remains unidentified. Endocrine effects seem certain, but this does not explain the actual agency. This account is based principally upon events as observed in porcine material by Backhouse & Butler (1960). A subsequent discussion of the problems of testicular descend and maldescent by Backhouse (1964) should be consulted. He has reviewed the literature since Hunter's original description (1762). Apparently the cremaster muscle develops in gubernacular mesenchyme and this may explain the development of the concept of the gubernaculum as a 'fibromuscular' ligament. The processus vaginalis also develops in close association with the soft, mucoid tissue of the gubernaculum and follows it into the genital swelling. Ultimately, as the testis and epididymis fill the scrotum, or genital swelling, the gubernacular mesenchyme is incorporated into the associated connective tissues.

Various abnormalities may occur in connection with testicular descent and obliteration of the processus vaginalis (p. 1424). The testis may remain in the abdomen, or it may fail to reach the scrotum and may then lie in any of the following situations: (1) in the perineum, (2) at the root of the penis, (3) at the superficial inguinal ring (p. 1377), (4) in the upper part of the thigh. These malpositions have been traditionally associated with certain additional extensions of gubernacular tissue. The largest extension normally passes to the scrotum while lesser extensions have been described as gaining attachment to the perineum, the root of the penis, the pubis, the inguinal ligament and the neighbourhood of the saphenous opening. The testis must follow the processus vaginalis and, should the latter for any reason follow any but the scrotal extension of the gubernaculum, malposition of the testis will result. It should be appreciated, however, that considerable doubt has now been expressed concerning these lesser expansions (previously the so-called 'tails of Lockwood'): possibly they reflect premature and abnormal fibrous partitioning of the gubernacular mesenchyme.

As noted, the processus vaginalis may remain completely patent, or its obliteration may be incomplete. When it retains a connection with the general peritoneal cavity it provides a preformed sac for a potential oblique inguinal hernia. It may be occluded at its upper end and may be shut off from the tunica vaginalis and yet remain patent in the intervening section. The patent portion may become distended with fluid, an *encysted hydrocoele* of the spermatic cord.

The descent of the ovary is less extensive. Like the testis, the ovary ultimately reaches a lower level than it occupies in the early months of fetal life but it does not leave the pelvis to enter the inguinal canal, except in certain anomalies. Connected to the medial aspect of the mesonephric fold by the *mesovarium* (homologous with the mesorchium), the ovary is also attached to the ventral abdominal wall through the medium of the inguinal fold. In this fold a mesenchymatous gubernaculum also develops but, as it traverses the mesonephric fold, it acquires an additional attachment to the lateral margin of the uterus near the entrance of the uterine tube. Its lower part, caudal to this uterine attachment, becomes the *round ligament of the uterus* and the part cranial to this, *the ovarian ligament*, these structures together being homologous with the gubernaculum testis in the male. This new uterine attachment may be correlated with the restricted ovarian descent. At first the ovary is attached to the medial side of the mesonephric fold but, in accordance with the manner in which the two mesonephric folds form the genital cord (p. 250), its connection is finally to the posterior layer of the broad ligament of the uterus. The gubernaculum thus persists in the female, unlike the male, as *two* fibrous bands or ligaments on each side.

The *saccus vaginalis* also appears in the female; its prolongation into the inguinal canal (sometimes termed the *canal of Nuck*) normally undergoes complete obliteration, but may remain patent and form the sac of a potential oblique inguinal hernia (p. 1377). At birth the ovary and the lateral end of the corresponding uterine tube lie above the pelvic brim, and they do not sink into the lesser pelvis until the latter enlarges sufficiently to contain both of them and the other pelvic viscera, including the bladder.



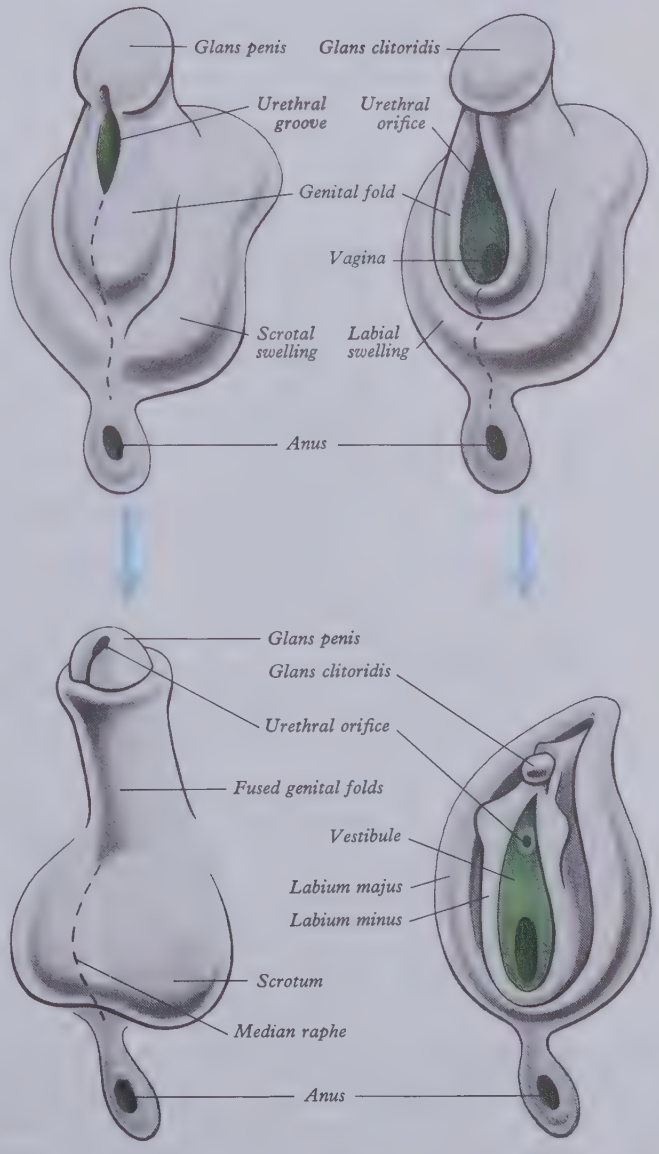
The urinary bladder (2.122A-F) is derived partly from the so-called endodermal cloaca and partly from the caudal ends of the mesonephric ducts (2.116,119,122A-F). The walls of the cloaca involved are splanchnopleure, i.e. an endodermal lining encased in visceral mesenchyme. In contrast the mesonephric ducts are wholly mesodermal. After the separation of the rectum from the cloaca (p. 233), the ventral part of the latter becomes divided into three regions: (1) a cranial *vesico-urethral canal*, continuous with the allantoic duct—into this the mesonephric ducts open; (2) a middle, narrow channel, the *pelvic portion*; and (3) a caudal, deep, *phallic* section, closed externally by the *urogenital membrane* (2.122A-E). The second and third parts together constitute the *urogenital sinus*. The ureter and the mesonephric duct come to open separately into the vesico-urethral part (p. 250). The termination of the mesonephric duct then moves caudally to open into that part which will form the prostatic urethra. This occurs by the formation of a caudally directed loop of the duct behind the urogenital sinus, followed by absorption of the apposed walls. In this way the mesonephric duct contributes to the trigone of the bladder and dorsal wall of the proximal (superior) half of the prostatic urethra, i.e. as far as the opening of the prostatic utricle and ejaculatory ducts (or its homologue the *whole* female urethral dorsal wall). The remainder of the vesico-urethral part forms the body of the bladder and urethra; its apex is prolonged to the umbilicus as a narrow canal, the *urachus*. In postnatal life the urachus is drawn downwards as the bladder descends, but its upper end remains connected to one or both of the obliterated umbilical arteries. Its lumen persists throughout life and its lower end frequently communicates with the bladder near its apex (Begg 1930).

The prostate arises during the third month from the proximal part of the urethra. The earlier outgrowths, some 14–20 in number, arise from the endoderm around the whole circumference of the tube, but mainly on its lateral aspects and excluding the dorsal wall above the utricular plate. These outgrowths give rise to the *outer* glandular *zone* of the prostate (p. 1433). Later outgrowths from the dorsal wall above the mesonephric ducts arise from the epithelium of mixed urogenital, mesonephric and possibly paramesonephric origin covering the cranial end of the sinus tubercle. These produce the *internal zone* of glandular tissue. The outgrowths, which are at first solid, branch, become tubular and invade the surrounding mesenchyme, which is differentiating into non-striated muscles, associated blood and lymphatic vessels and connective tissues, and is invaded by autonomic nerves.

Similar outgrowths occur in the female but remain rudimentary. The urethral glands correspond to the mucosal glands around the upper part of the prostatic urethra and the paraurethral glands to the true prostatic glands of the external zone (Glenister 1962).

The *bulbo-urethral glands* in the male, and *greater vestibular glands* in the female, arise as diverticula from the epithelial lining of the urogenital sinus.

The external genital organs, like the gonads, pass through an indifferent state before distinguishing sexual characters appear (2.124). A surface elevation, the *genital tubercle*, appears at the cranial end of the cloacal membrane and lengthens to form the *phallus* (2.119). Within it is a longitudinal endodermal mass, the *urethral plate* (2.120,124), which grows forwards from the walls of the cloaca and urogenital sinus towards the tip of the organ. The



2.124 The development of the external genitalia from the indifferent stage to the definitive male and female conditions.

lower aspect of the plate is in contact with ectoderm lining a median groove, the *primary urethral groove*, which has meanwhile developed along the caudal surface of the phallus. The raised margins of the groove are the *genital folds* (**2.124**). Proximally they surround the urogenital membrane and terminate in a transverse ridge immediately ventral to the anus. The rupture of the urogenital membrane provides a common perineal orifice for the genital and urinary organs at the base of the phallus, bounded at the sides by the genital folds. Meanwhile disintegration of the cells of the urethral plate and contiguous ectoderm occurs, commencing at the base of the phallus and resulting in a deepening of what is now the *definitive urethral groove*.

While these changes are in progress two *labioscrotal (genital) swellings* have appeared, one on each side of the base of the phallus; these extend caudally, separated from the genital folds by distinct grooves (**2.124**).

The male phallus enlarges to form the penis, its apex being the glans. The genital swellings meet each other ventral to the anus and unite to form the scrotum. The genital folds fuse with each other from behind forwards enclosing the phallic part of the urogenital sinus behind to form the bulb of the urethra; similarly, the folds close the definitive urethral groove in front to form the greater part of the spongiose urethra. Fusion of the folds results in the formation of a median raphe and occurs in such a way that the lining of the postglandular urethra is mainly, perhaps wholly, *endodermal* in origin (Glenister 1954). Thus, as the phallus lengthens, the urogenital orifice is carried onwards until it reaches the glans. From the tip of the glans an ingrowth of a vertical plate of surface ectoderm has occurred to meet the anterior extremity of the urethral plate, and the disintegration of this gives rise to a glandular continuation of the urethral groove; closure of this completes the terminal part of the urethra contained within the glans, which is entirely *ectodermal* in origin.

The glans and shaft of the penis are hence recognizable by the third month. The prepuce also begins to develop in the third month, when the urethra still has its primary external orifice at the base of the glans. A ridge consisting of a mesodermal core covered by epithelium appears proximal to the neck of the penis and extends forwards over the glans. Deep to this ridge is a solid lamella of epithelium which extends backwards to the base of the glans. The ventral extremities of the ridge curve backwards to become continuous with the genital folds at the margins of the urethral orifice. As the urethral folds meet to form the terminal part of the urethra, the ventral horns of the ridge fuse to form the frenulum. Over the dorsum and sides of the glans, the epithelial lamella breaks down to form the preputial sac and thus free the prepuce

from the surface of the glans. Thereafter the prepuce grows as a free fold of skin covering the terminal part of the glans. The preputial sac may not be complete until 6 to 12 months or more *after birth* and, even then, the presence of some connecting strands may still interfere with the retractability of the prepuce.

The mesodermal core of the phallus is comparatively undifferentiated in the first two months, but during the third month the blastemata of the corpora cavernosa become defined. Nerves are present in the differentiating mesenchyme from the seventh week (Dail & Evan 1974).

The female phallus, which exceeds the male in length in the early stages, becomes the clitoris. The genital swellings remain separate as the labia majora and the genital folds also remain separate, forming the labia minora. The perineal orifice of the urogenital sinus is retained as the cleft between the labia minora, above which the urethra and vagina open. The prepuce of the clitoris develops in the same way as its male homologue.

The urethra, in the *female*, is derived entirely from the vesico-urethral region of the cloaca (p. 258), including the dorsal region derived from the mesonephric ducts. It is homologous with the part of the prostatic urethra proximal to the orifices of the prostatic utricle and the ejaculatory ducts.

In the *male*, the prostatic urethra proximal to the orifice of the prostatic utricle is derived from the vesico-urethral part of the cloaca and the incorporated caudal ends of the mesonephric ducts. The remainder of the prostatic part, the membranous part and probably the part within the bulb, are all derived from the urogenital sinus (p. 258). The succeeding section, as far as the glans, is formed by the fusion of the genital folds, while the section within the glans is formed from ectoderm (vide supra).

Homologies of the parts of the urogenital system in male and female (**2**.116,124) can be summarized:

Undifferentiated	*Male*	*Female*
Gonad	Testis	Ovary
Gubernacular cord	Gubernaculum testis	Ovarian and round ligaments
Mesonephros (Wolffian body)	Appendix of epididymis (?)	Appendices vesiculosae (?)
	Efferent ductules	Epoöphoron
	Lobules of epididymis	
	Paradidymis	Paroöphoron
	Aberrant ductules	
Mesonephric duct (Wolffian duct)	Duct of epididymis	Duct of epoöphoron
	Ductus deferens	
	Ejaculatory duct	
	Part of bladder and prostatic urethra	Part of bladder and urethra
Paramesonephric (or Mullerian) duct	Appendix of testis	Uterine tube
		Uterus
	Prostatic utricle	Vagina (?)
Allantoic duct	Urachus	Urachus
Cloaca: dorsal part	Rectum and upper part of anal canal	Rectum and upper part of anal canal
ventral part	Most of bladder	Most of bladder and the urethra
	Part of prostatic urethra	
urogenital sinus	Prostatic urethra distal to utricle	
	Bulbo-urethral glands	Greater vestibular glands
	Rest of urethra to glands	Vestibule
Genital folds	Ventral penis	Labia minora
Genital tubercle	Penis	Clitoris
	Urethra in glans	

Congenital anomalies. Defects of the urethra, due to arrests of development, are not uncommon in the male. The urethra may open on the ventral (perineal) aspect of the penis at the base of the glans, and the part of the urethra which is normally within the glans is absent. This constitutes the simplest form of *hypospadias*. In more severe cases the genital folds fail to fuse, and the urethra opens on the ventral aspect of a malformed penis just in front of the scrotum. A still greater degree of this malformation is accompanied by failure of the genital swellings to unite with each other. In these cases the scrotum is divided and, since the testes are also frequently undescended, the resemblance to the labia majora is very striking. Male children suffering from this deformity are often mistaken for girls.

Maldevelopment of the cloacal or urogenital membranes is a less common condition, but two varieties can be distinguished. (1) In *extroversion of the bladder* (ectopia vesicae) the lower part of the anterior abdominal wall is occupied by an irregularly oval area, covered with mucous membrane, on which the two ureters open (Wyburn 1937). Around its periphery this extroverted area, covered by urothelium, becomes continuous with the skin. (2) In *extroversion of the cloaca* the condition is very similar, but is complicated by the presence of intestinal openings in the median plane. In (2) the cloacal membrane is probably abnormally elongated and ruptures prematurely and throughout its whole extent, prior to the formation of the urorectal septum. In (1) the maldevelopment occurs after the separation of the ventral from the dorsal part of the cloaca. The urogenital membrane extends further cranially than it does in normal cases and the genital tubercle forms at its *caudal* limit. Rupture of the membrane throws the bladder open to the exterior.

In *epispadias* the urethra opens on the dorsal aspect of the penis at its junction with the anterior abdominal wall. No satisfactory explanation has yet been suggested for this anomaly. For a genetic and epidemiological study of urinary tract malformations consult Bois et al (1975).

Differentiation of the genital organs (Moore 1947, Burns 1955) is primarily directed by genetic factors many of which may mediate their effects through endocrine controls, notably the cortex of the suprarenal gland. The differentiation of the gonad may be modified by several factors including chromosomal constitution (p. 48), degree of ripeness of the ovum at fertilization, the number and distribution of the primordial germ cells and endocrine influences. A reduction in the number of primordial germ cells, believed to be associated with over-ripeness of the ovum at fertilization, exercises a masculinizing effect on genetic females. It is suggested that this is due to a failure of normal development of the superficial or cortical zone of the ovary, thus allowing the deep or medullary zone, which is the essentially male element, to dominate subsequent differentiation. The zones are not well marked in man but it is considered that they play an important role in the differentiation not only of the gonad but also of the genital ducts, mesonephric and paramesonephric, cloaca, external genitalia and eventually of the secondary sexual characters. During their development the accessory sexual organs also pass through an indifferent or potentially bisexual stage.

The part played by hormones in the differentiation of the reproductive organs is not clear, but both androgens and oestrogens profoundly modify this process, as instanced by work on the freemartin in cattle (Jost 1961). In twin pregnancy, where the fetuses are of opposite sex and their placental circulations anastomose, the male often exerts a masculinizing effect on its female twin. This has been attributed to the action of hormones elaborated in the interstitial tissue of the medullary zone in the testes of the male fetus. The gonad in turn affects the differentiation of the genital ducts, cloaca and external genitalia. It seems that the fate of the accessory organs, and particularly of the ducts, is determined largely by the presence or absence of a male factor, possibly hormonal, elaborated by the testes. The different parts of the accessory genital organs are most susceptible to this masculinizing effect over limited but differing periods.

Prenatal Growth in Form and Size

The absolute size of neither embryo nor fetus affords a reliable indication of either its true age or stage of structural organization, even though graphs based on large numbers of observations have been constructed to provide averages. All such data suffer from the difficulty of equating dimensions and degree of differentiation with the actual time of conception, which can rarely, if ever, be

established with complete exactness. The life of the individual really commences with fertilization, but the date of this cannot be exactly determined in mankind. It has long been customary to compute the age, whether in a normal birth or an abortion, from the last menstrual period of the mother but, since ovulation usually occurs near the fourteenth day of a period, this 'menstrual age' is about two weeks too much. Where a single coitus can be held to be responsible for conception, a 'coital age' can be established and the 'fertilization age' cannot be much less than this, because of the limited viability of both gametes; but it is usually held that the difference may be several days—a highly significant interval in the earlier stages of embryonic development. Even if the time of ovulation and coitus were known in instances of spontaneous abortion, not only would some uncertainty still persist with regard to the time of fertilization but there would also remain an indefinable period between the cessation of development and the actual recovery of the conceptus. With the legalization of abortion in some countries the latter source of inaccuracy may be expected to become less important.

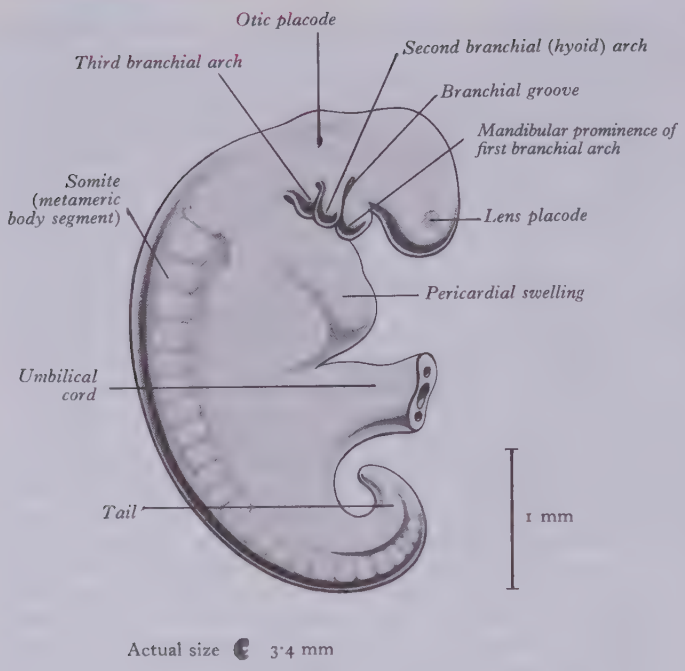
To overcome these difficulties early embryos have been graded or classified, on the basis of both internal and external features, into developmental stages or 'horizons' (**2**.125A-H). Classic contributions in this field have been made by Lillie (1917), Streeter (1942-49), Hamilton (1944), Hertig et al (1956), Heuser & Corner (1957), and O'Rahilly et al (1966-75). Although it has become customary to describe these developmental levels as *stages*, the earlier descriptions are still accepted. However, Stages 1 to 9, covering the first three weeks of development, have been given a more reliable basis by O'Rahilly (1973), who has also gathered together the pertinent literature.

Stages 1 to 3 occupy the first 4–5 days after fertilization of the öocyte in the ampulla of the uterine tube. The initial 24 hours (Stage 1) are occupied by fertilization, the dominant feature of which is the fusion of the male and female pronuclei. This is followed by the first mitotic division, which is the onset of segmentation, or cleavage, and is arbitrarily regarded as the transition from Stage 1 to Stage 2. Stage 2 is characterized by the continuation of cleavage, starting with two blastomeres and ending with about 12. During this stage the developing morula moves along the uterine tube, by mechanisms still not wholly understood, a journey occupying about 4 days. During the fourth day a segmentation cavity appears within the morula and this is taken as initiating Stage 3, which thus corresponds to the establishment of a free blastocyst.

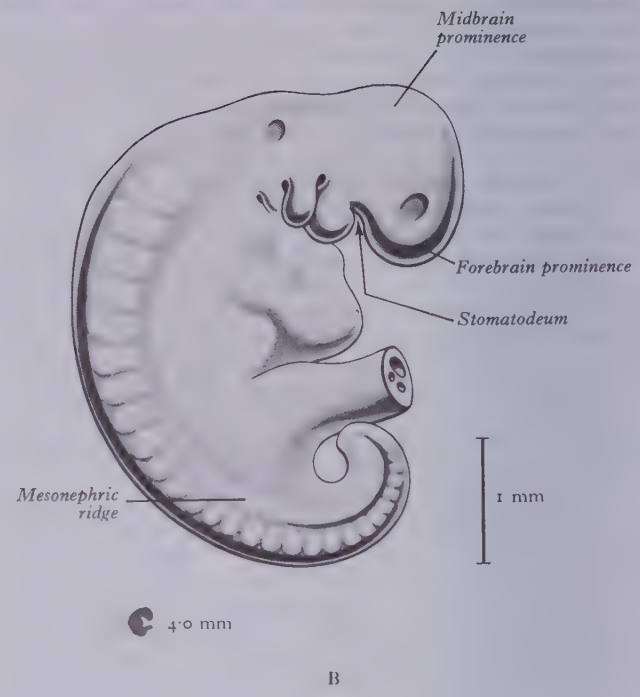
Although comparatively few human embryos representing Stages 1 to 3 have been recovered (see pp. 124–7 and consult O'Rahilly 1973), a considerable degree of agreement exists and, moreover, current observations of in vitro fertilization between human spermatozoa and ova (**2**.20A-H) support the earlier descriptions.

Stages 4 to 6 are concerned with the endometrial attachment of the blastocyst, trophoblastic development, implantation, further development of the blastocyst and the appearance of the primitive streak (**2**.20-24). Stage 4 corresponds to the fifth and sixth post-fertilization days. The blastocyst, now in the uterine cavity, loses its zona pellucida and it begins the rapid but complex activities of orientation in respect of the endometrium—adhesion, penetration and the cellular proliferation of trophoblastic growth. This establishment of dependence on the maternal circulation for nutritional requirements is far more rapid in primates than in other mammals. Stage 5 is reached when implantation has occurred, occupying the seventh to twelfth days; syncytiotrophoblastic and cytotrophoblastic strata have differentiated, the proamniotic cavity has appeared and a labyrinthine system of intercommunicating trophoblastic lacunae through which the maternal blood ebbs and flows, has developed. A little later in Stage 5 the exocoelomic membrane has been identified. In Stage 6 chorionic villous stems become defined and begin to develop side branches almost at once, producing an increasingly complex intervillous space. A little later the primitive streak becomes apparent and differentiation of the embryonic area has commenced and may now be distinguished from the various extraembryonic tissues.

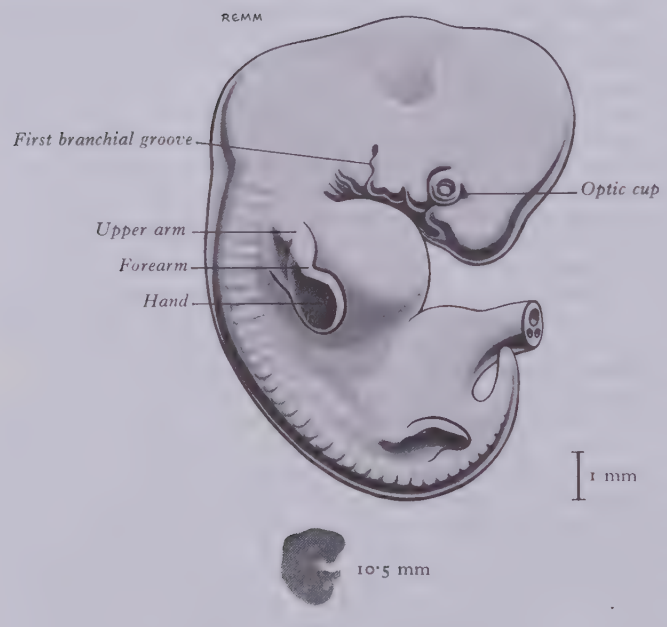
Because of the complexity of the events in Stages 5 and 6, both have been subdivided by some authorities. A much greater number of human embryos have been recovered which represent Stages 4 to 6.



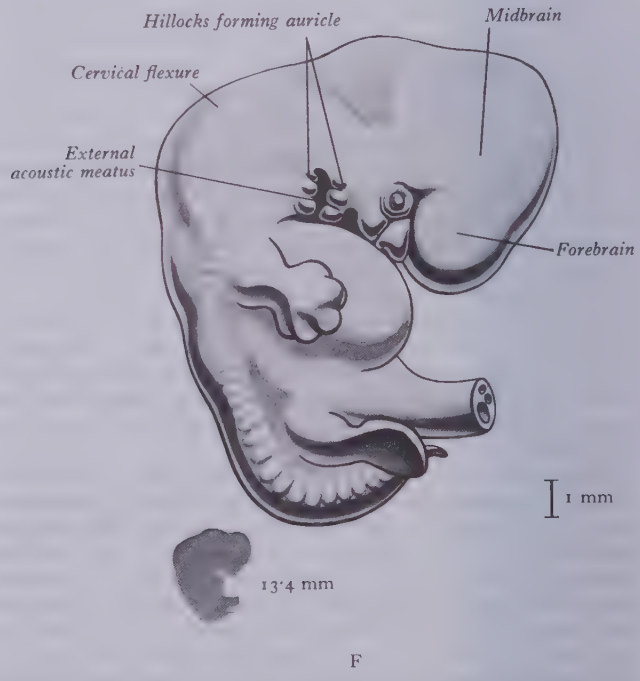
Stages 7 to 9 are characterized by basic embryogenic changes. During Stage 7 (sixteenth to eighteenth days) the primitive streak develops further and the notochordal ('head') process appears, together with the other mesodermal strata. The chorion and amnion continue to develop, villous stems being generally distributed over the former but more pronounced at the embryonic pole. Haemopoetic foci appear in the wall of the definitive yolk sac, and the cloacal membrane and allanto-enteric diverticulum are defined. Associated with the latter primordial germ cells have been noted. In Stage 8 (eighteenth to twentieth days) the prechordal plate, primitive pit, neural groove and notochordal and neurenteric canals are all definable. By Stage 9 (twentieth to twenty-second days) the neural groove is deepening and the first somites begin to appear about midway along it. The cranial half of the groove, representing developing brain, begins to develop a cephalic flexure, optic primordia become visible and early head and tail folds have appeared, as Stage 10 is approached. The foregut is becoming defined, and early pharyngeal pouches may be identified. The embryo is now 1.5–2.0 mm in length.



Stages 10 to 12, occupying days 22 to 26, feature continued formation of somites and, during this, the fourth week, head and tail folds are completed, the neural groove closes and primary cerebral vesicles appear. The cervical flexure can now be recognized, the optic vesicles form and the lental and otic placodes appear and become vesicular. The branchial arches are appearing, lateral folds are more clearly defined and the cloacal membrane and hindgut are becoming distinct. Rudimentary limb buds appear and the heart tubes fuse into a common loop in which contractile activity commences. The primordia of the thyroid gland, lungs, liver, pancreas and mesonephric tubules are all identifiable. The embryo is about 4.0 mm in length.

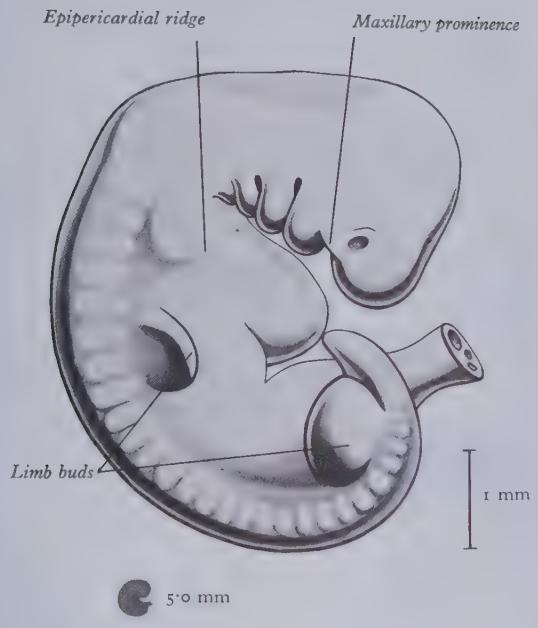


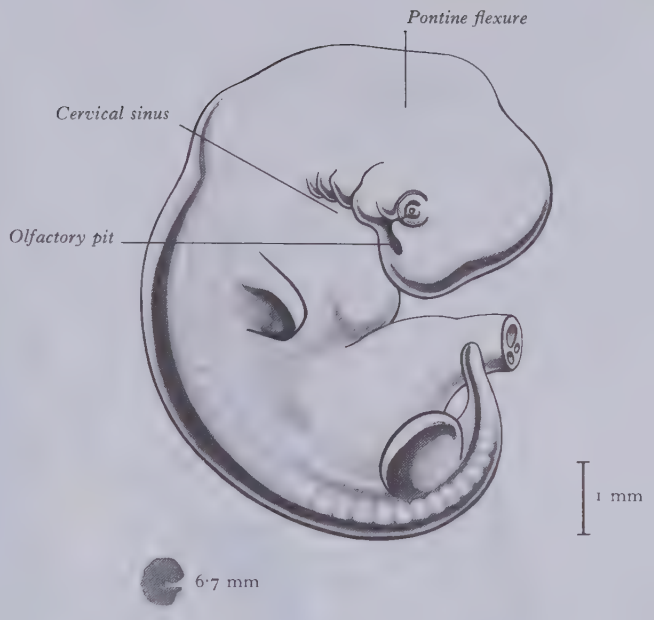
Stages 13 to 16 correspond approximately to the fifth week of development and the embryo grows from about 4 mm to 8 mm. It becomes markedly curved and its junction with the yolk sac relatively constricted. The cervical flexure is increased and the mesencephalic flexure is appearing. The dorsolateral (alar) and ventrolateral (basal) laminae are differentiating, and the emerging corpus striatum, thalamus epithalamus and hypothalamus are loci of proliferating cells. The cranial and spinal nerves are developing, together with their ganglia, from the associated placodes and neural crest elements. The limb buds are elongating, displaying joint flexures; the rudimentary hands and feet are differentiating. The olfactory placodes, maxillary, mandibular and frontonasal prominences, tongue primordia and the hypophysial pouch (of Rathke) are all appearing. The tubotympanic recesses are defined and the primordia of the thymus and parathyroid glands can be identified. In the developing heart the septum primum appears and its cornua define the foramen primum. The mesonephric ducts reach the cloaca and subsequently the metanephric (ureteric) buds appear and extend to the metanephrogenic masses of mesoderm in the sacral nephrogenic cord. The gonadal ridges, urorectal septum and genital tubercle are also developing.



Stages 16 to 20 are roughly equivalent to the sixth week, by the end of which the embryo has a length of about 13–15 mm. Its curvature has further increased and its head and relatively long tail are in contact with the developing umbilical stump. The pontine flexure, cerebral hemispheres and cerebellum are developing. The upper limbs and the facial region are growing and differentiating rapidly; the palatal processes and primitive nasal prominences are apparent and the oronasal membrane ruptures. The liver produces a surface prominence between the cardiac region and the umbilical cord. Into the latter the midgut loop herniates and the appendix and caecum become distinguishable in it. The spleen develops, as do the paramesonephric (Mullerian) ducts. The foramen primum in the heart closes, with simultaneous opening of the foramen secundum and septation of the bulbus cordis occurs. Cardiac muscle is differentiating. Haemopoiesis commences in the liver. Chondrification of many skeletal elements begins and ossification commences in mesenchymatous bones, the mandible and clavicles.

Stages 21 to 23 complete the series, extending to about day 47. This represents the major part of the seventh week and, with the

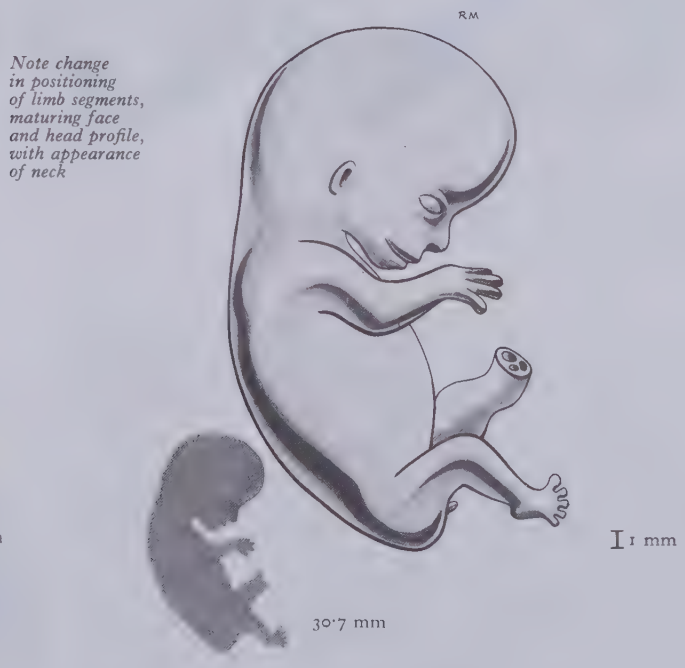




2.125 Series showing the development of the principal external features of embryos ranging from 3.4 to 30.7 mm CR length ($3\frac{1}{2}$–$9\frac{1}{2}$ weeks). To assist comparison a 1 mm scale is included in each case; the small silhouette is actual size.

eighth week, the *formative* or *embryonic period* is regarded as coming to an end (**2.125**A–H). This is a period during which *patterned differentiation* with consequent *organogenesis* tends to overshadow the growth which accompanies these events. Very considerable increase in size has, however, occurred; from a single cell about 0.14 mm in diameter the embryo has become a most complex and functioning creature, consisting of millions of cells and with a length of about 30 mm or more, and it has increased in weight many thousands of times. During the *fetal period*, which occupies the third to tenth lunar months (**2.126,127**), the accent is upon growth rather than differentiation but, of course, the latter continues through this period and to a lesser degree after birth (and in some tissues, throughout life). During this period the overall rate of growth in length is greater, but not markedly so; from the fourth to sixth weeks the rate is about 1 mm per day, with a maximum of about 2 mm during the fourth month. The increase in length in the fetal period is from 30/40 to about 500 mm, and the increase in weight from perhaps 2 or 3 g to more than 3000 g.

During the *seventh* and *eighth weeks* there is a remarkable change in the external appearance of the embryo, for at the beginning of this period the individual still appears markedly 'embryonic', though clearly a primate, whereas at the end the form is



C

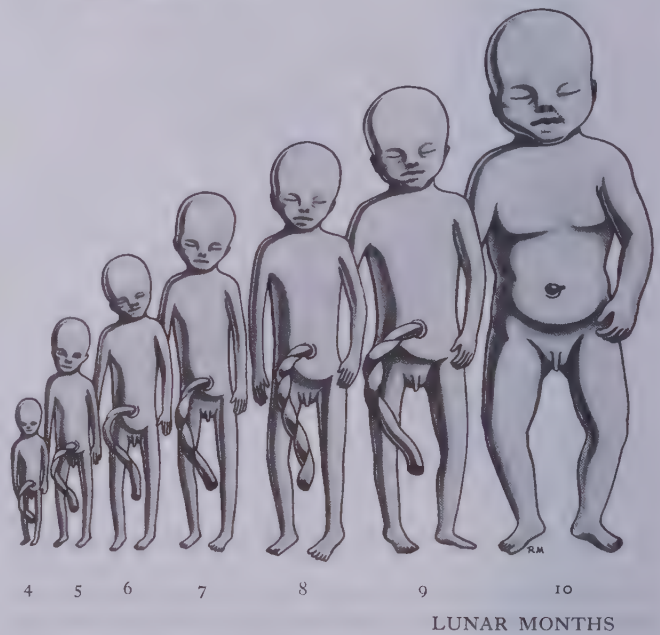
D

G

H

most definitely human. The head is less flexed and the neck longer and clearly defined. The development of the face proceeds much further, with completion of the upper lip and nostrils, although the latter are plugged and the palate still incomplete. Enamel organs are developed from the dental laminae. The external ears and the eyelids are developing and the limbs elongate considerably, approaching much nearer their ultimate proportions and displaying well-formed hands and feet with separated digits. Early in this period the interventricular septum is completed. Skeletal and visceral muscle tissues begin to differentiate about this time, and generalized ossification occurs in enchondral bones. In the metanephrogenic mass vesicles appear and the remainder of the nephrons and the collecting tubules of the kidneys are defined. The ovaries or testes are distinguishable and the paramesonephric (Mullerian) ducts are fusing to form the primordia of uterus and vagina. The external genitalia are further advanced and show sexual differentiation by the beginning of the eighth week. The cloacal membrane becomes perforate and the tail is retrogressing. By the end of the period the embryo possesses almost all the structural features, internal and external, characteristic of the human mammal and it now passes into the fetal period. During this there is much growth in the dimensions of the established organs, extensive changes in proportions brought about by variations of growth rate and widespread maturation in differentiating cells.

During the *third month* head flexion decreases further and the neck becomes proportionately longer. The eyelids meet and fuse



2.126 The progressive changes in fetal size and proportions during the third, fourth and fifth months.

and will remain temporarily united until the sixth lunar month. Nails appear on the digits and the upper limbs in general are comparatively accelerated in development. The umbilical protrusion of the gut is reduced accompanying a proportionate augmentation of abdominal volume.

During the *fourth month* the covering of primary hair appears —the *lanugo* (see p. 91). As in the previous month, the head and upper limbs are still disproportionately large and, although the trunk and lower limbs begin to catch up by increased rates of growth during the rest of uterine life, the same disproportion is present after birth and to a diminishing degree throughout childhood and on into the years of puberty. By the end of the fourth month the eyes have moved even further into an anteriorly directed position, but are still relatively wide apart. The external ear is approaching its characteristic form and is nearer its ultimate position, at the side of the head and no longer in the upper part of the neck. The total fetal length, including the lower limb, is now of the order of 230 mm. Its weight at the end of the *fifth month* is about 300 g, which will be increased more than tenfold during the second half of intrauterine life. Towards the end of this period sebaceous glands become active, and the sebum secreted blends with desquamated epidermal cells to form a cheesy covering to the skin, the *vernix caseosa*, usually considered to protect the former from maceration by the amniotic fluid. During this month the mother becomes conscious of fetal movement—so-called 'quickening'.

The *sixth month* witnesses a further general change of bodily proportions and facial appearance towards those of the infant at birth. The lanugo darkens and the skin becomes markedly wrinkled, presumably through a disparity in the growth rates of

2.127 Changes in *relative* size and bodily proportions at the fetal ages indicated.

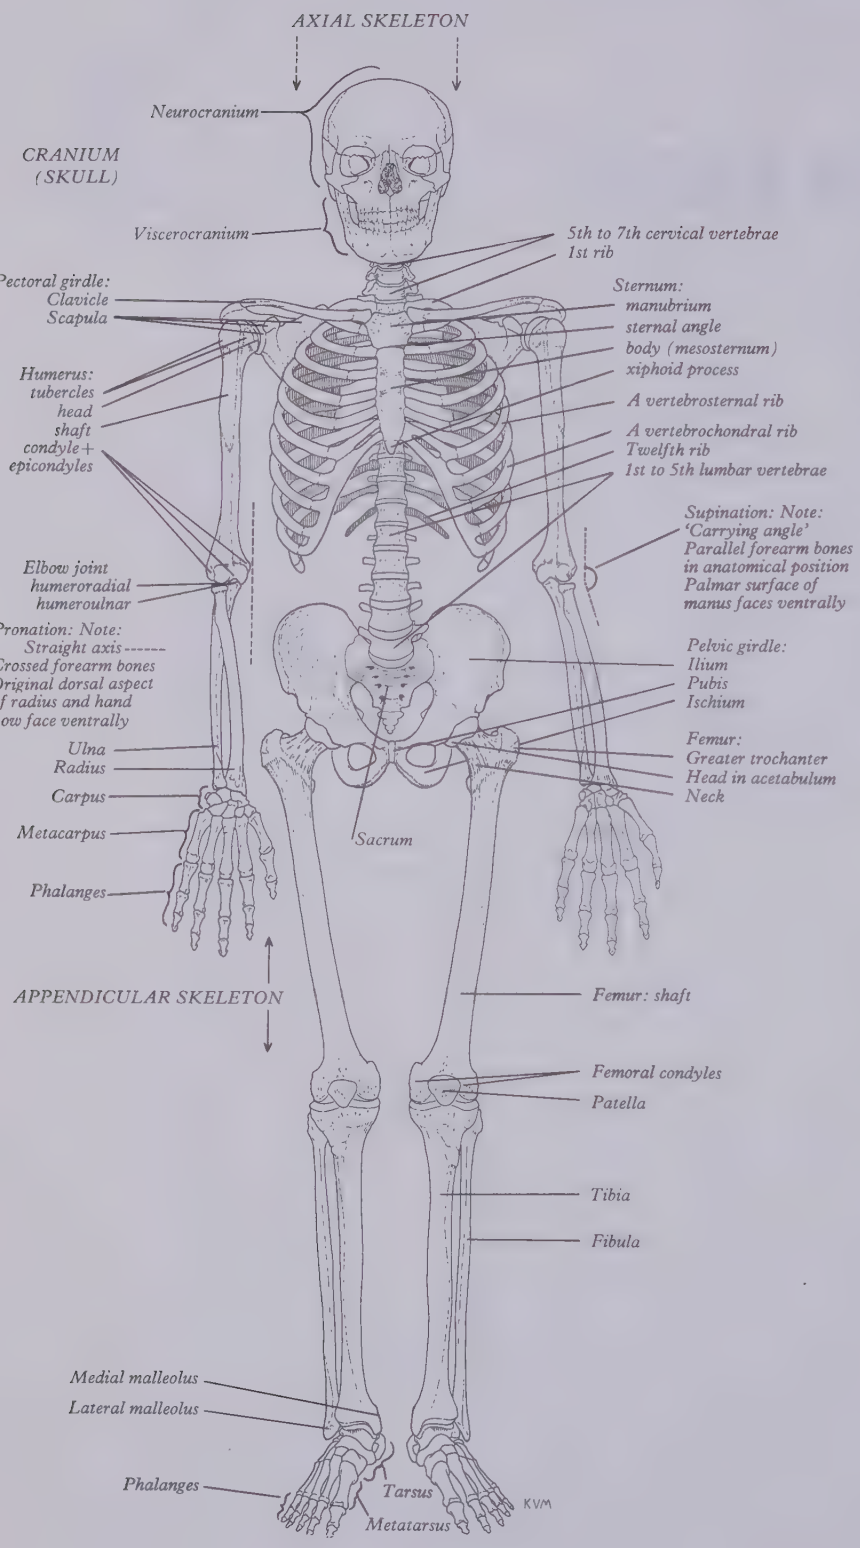
cutaneous and subcutaneous tissues. The eyelids and eyebrows are now well developed. The vernix caseosa is more abundant. The length of the fetus is about 300 mm by the end of this month.

During the *seventh month* the hair of the scalp is lengthening and the eyebrow hairs and the eyelashes are well-developed. The eyelids themselves separate and the pupillary membrane

disappears. The body becomes more plump and rounded in contour and the skin loses its wrinkled appearance due to increased deposition of subcutaneous fat. Towards the end of this month the fetus is viable and may in fact be successfully raised if born prematurely. Its length has increased to about 350 mm and it weighs about 1.5 kg.

Throughout the remaining three lunar months of normal gestation the covering of vernix caseosa is prominent. There is a progressive loss of lanugo, except for the hairs on the eyelids, eyebrows and scalp. The bodily shape is becoming more infantile, but despite some acceleration in its growth the leg has not quite equalled the arm in length proportionately even at the time of birth. The thorax broadens relative to the head, and the infra-umbilical abdominal wall shows a relative areal increase, so that the umbilicus gradually becomes more centrally situated. Average lengths and weights for the eighth, ninth and tenth months are 40, 45 and 50 cm and 2, 2.5 and 3 to 3.5 kg.

At the end of the *tenth lunar month*, just before birth, the lanugo has almost disappeared, the umbilicus is central and the testes, which begin to descend with the vaginal process of peritoneum during the seventh month and are approaching the scrotum in the ninth month, are usually scrotal in position. The ovaries are not yet in their final position at birth; although they have attained their final relationship to the uterine folds, they are still above the level of the pelvic brim.



The length of the *period of gestation* is regarded as 9 calendar months in obstetric practice—approximately 270 days. It is usually about 266 days—10 lunar months less 14 days. Legally, the infant is regarded as viable if born after the end of 7 calendar months but considerably more premature infants have been successfully reared.

GRAY'S ANATOMY

OSTEOLOGY

3

MORPHOLOGY OF THE HUMAN SKELETON

3.1 Adult male skeleton: anterior (ventral) view.

Introduction

The human skeleton is bilaterally symmetrical (3.1,2,4), with the typical vertebrate pattern of an axis, divided into segments for flexibility, and of two pairs of limbs, pectoral and pelvic, also divided into jointed parts for locomotion, grasping, etc. The skull is the expanded and modified cranial end of the axis. Osseocartilaginous sesamoid bones develop in some tendons and ligaments. All these elements are collectively termed the 'skeleton'.

The human skeleton, as in other vertebrates, is internal to the muscles with which it has evolved. It is an *endoskeleton*, unlike the *exoskeleton* of many invertebrates, such as *Insecta*, whose muscles are attached to the internal aspects of jointed elements of chitin, a rigid material also offering protection. Many features of the human endoskeleton are also deemed defensive, with an excess of emphasis sometimes sufficient to obscure its primary association with muscle and hence with movement. Perhaps only in the vault of the skull and spinal column is the protective role paramount, but even here muscle attachments appear. Cranially, its superficial situation reflects its evolutionary origin, as generally accepted, from the dermal bony armour of earlier vertebrates, including fish, amphibians and reptiles, extinct and extant. The ossified dermal carapace of the tortoise is a familiar example. The maxilla, mandible, clavicle and dentine of teeth are also dermal derivatives; all are vestiges of more extensive assemblies of dermal bones from which they have been modified to form a human 'exoskeleton'.

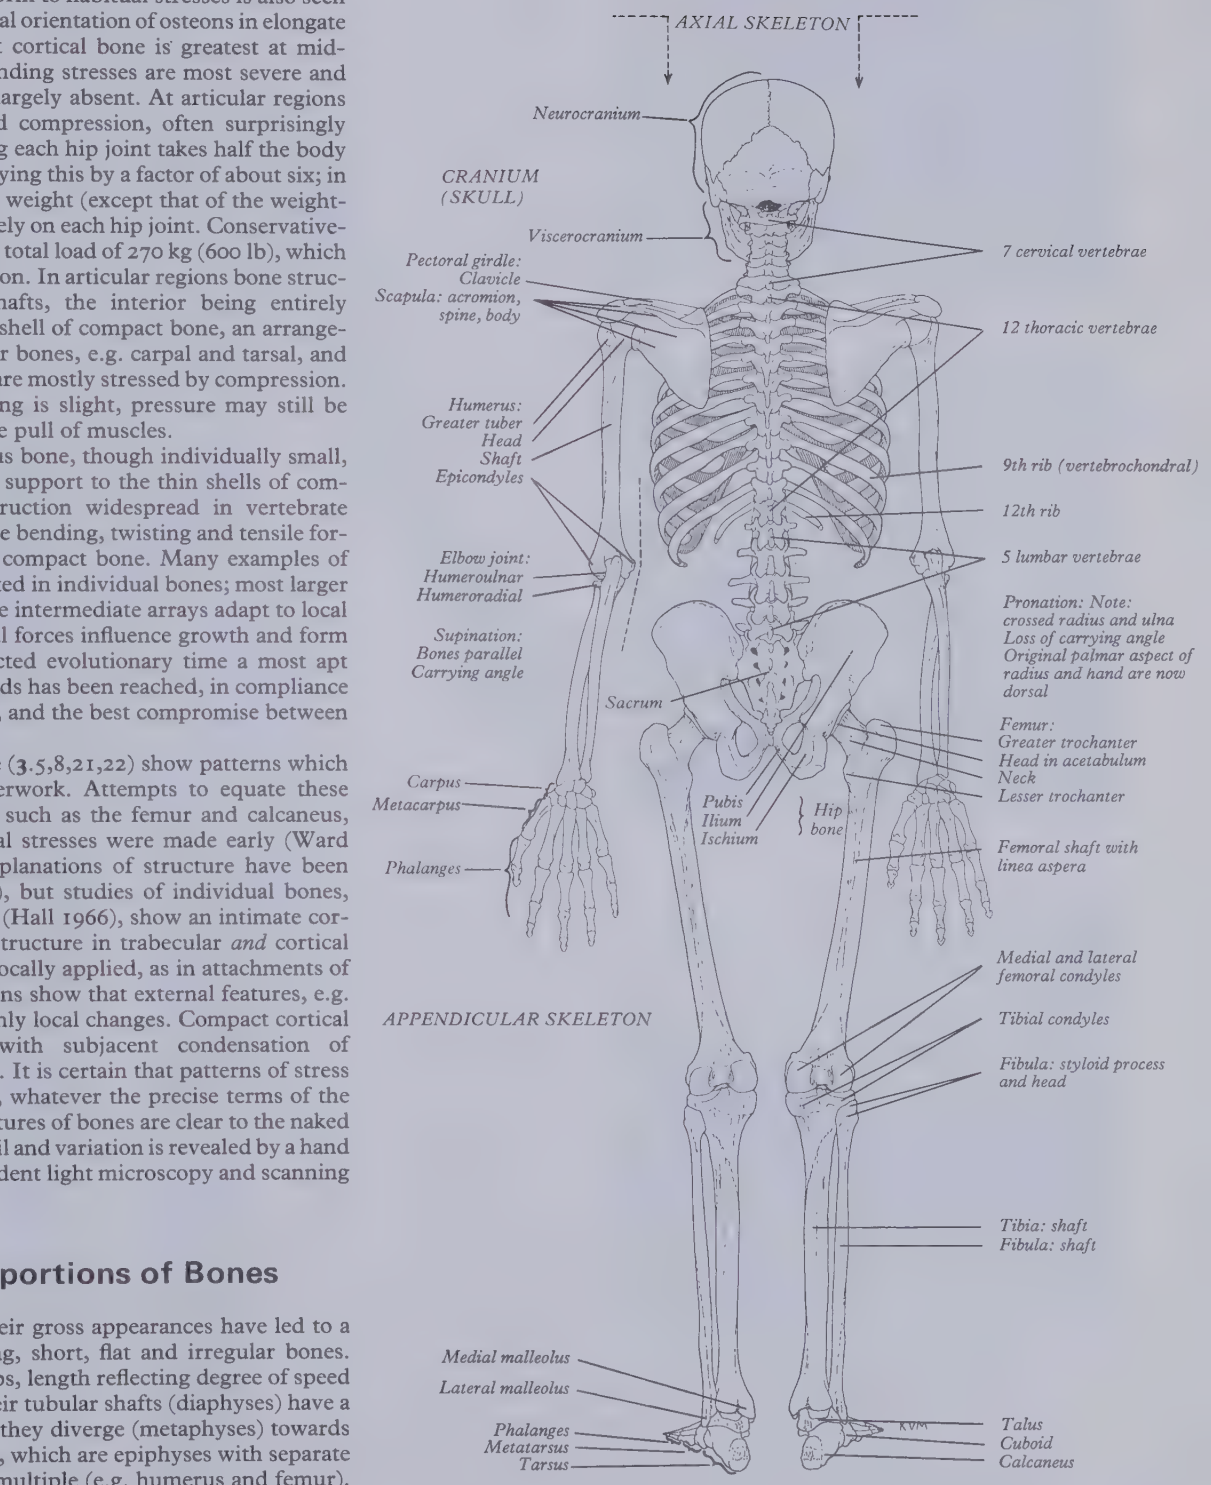
Homologues of the branchial skeleton of fish also contribute a *visceral* component in higher vertebrates, including man. Much modified, these elements appear as ear ossicles, part of the mandible, maxilla, styloid process and hyoid bone. Some caudal branchial arches persist as the cartilaginous larynx, not customarily included in the human skeleton; supportive tracheal and bronchial cartilages maintain the larger respiratory lumina, much as do bones and cartilages of nasal cavities. In some ungulates bone develops in cardiac connective tissue as an *os cordis*, and an *os penis* occurs in many mammals. The human skeleton is thus a complex, derived from original endoskeleton, exoskeletal dermal elements, modified branchial arches, and ossification in structures such as tendons.

The Skeleton in Life

The living skeleton also includes other, non-osseous structures which are lost when bones are preserved for study since attached muscles, ligaments, periosteum and cartilages are all removed. Costal cartilages are of course grouped with the skeleton; but articular cartilages, functionally prominent parts of most living bones, are by custom excluded, as are ligaments, menisci and intervertebral discs. A macerated skeleton, therefore, is completely disjointed into elements which, while convenient for examination, have lost most of their functional implications. The bone marrow also disappears, and mechanical properties, such as elasticity, proper to living bone, are lost (Smith & Walmsley 1959).

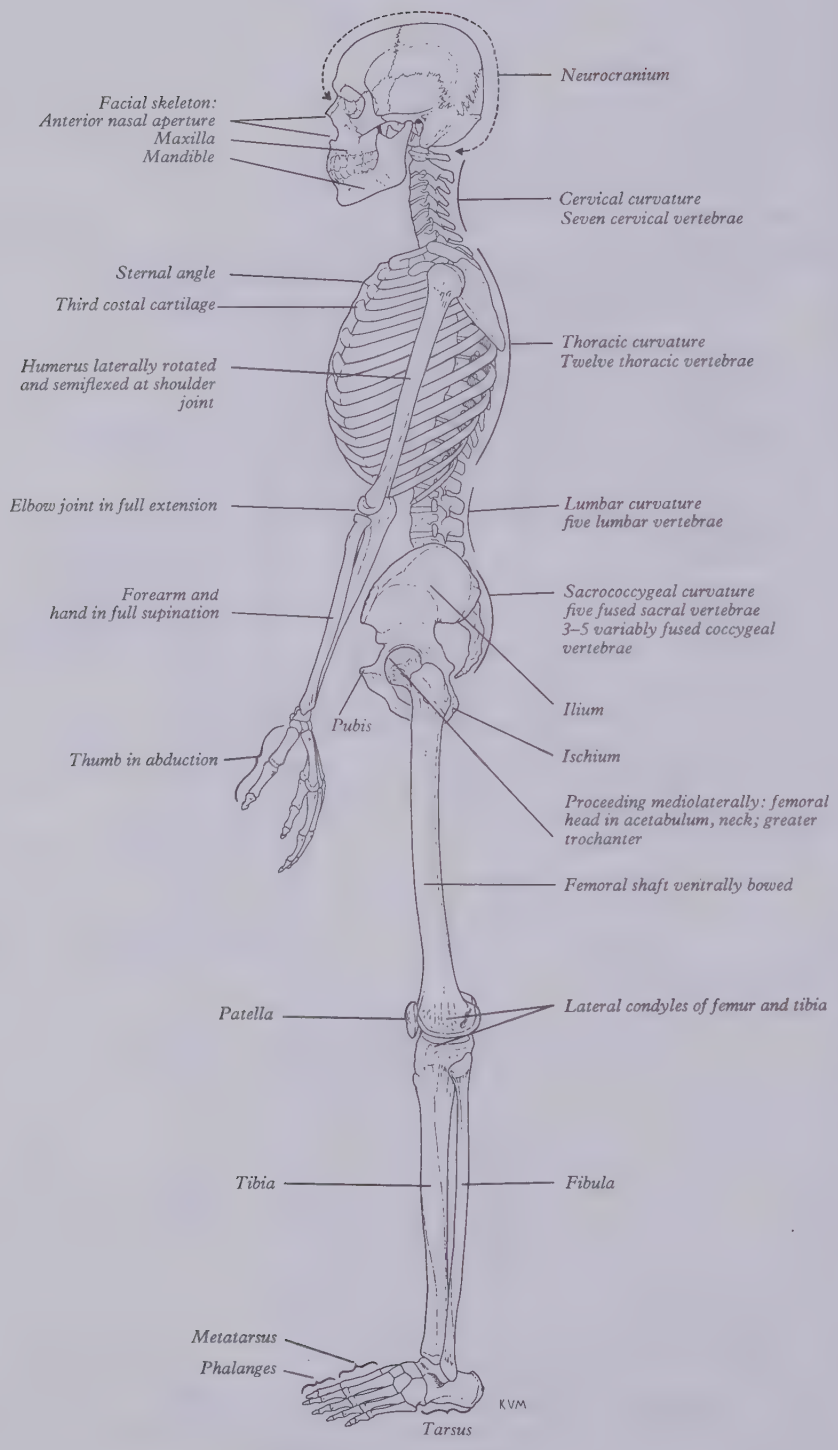
The properties of living bone have been much studied (Bell 1956) at macroscopic, microscopic and ultrastructural levels, especially in relation to mechanical factors. Its intimate blend of hard inorganic and resilient organic components, resistant almost equally to compression and tension, differs from most materials used by man, which are usually better in one respect than the other. In tensile strength bone resembles cast iron, but with only a third of its weight, breaking stresses being respectively 15.5 and 18 metric tons per square inch: about 2400 to 3000 kg per cm^2 (Bell et al 1941, Tables on p. 278). In flexibility bone resembles steel more than iron, but only has half the strength of steel. In compression it has large margins of safety for weight-bearing (Koch 1917) and

for impact. Contracting muscles are much the larger agent of pressure, even at weight-bearing joints, especially in active movement (Bell et al 1941, Williams & Svensson 1968). In hip joints a mere fraction of the pressure is due to body weight (vide infra).



A tubular structure, typical of shafts in many bones, is the strongest, lightest and hence most economical arrangement of material. This adaptation of form to habitual stresses is also seen in the predominant longitudinal orientation of osteons in elongate bones. Thickness of compact cortical bone is greatest at mid-shaft, where torsional and bending stresses are most severe and internal trabecular structure largely absent. At articular regions bones must chiefly withstand compression, often surprisingly large. In symmetrical standing each hip joint takes half the body weight, muscular pull multiplying this by a factor of about six; in walking or running, full body weight (except that of the weight-bearing leg) impinges alternately on each hip joint. Conservatively, in adult males, this yields a total load of 270 kg (600 lb), which may double in powerful exertion. In articular regions bone structure differs from that in shafts, the interior being entirely trabecular, supporting a thin shell of compact bone, an arrangement occurring also in smaller bones, e.g. carpal and tarsal, and vertebral bodies, all of which are mostly stressed by compression. In joints where weight-bearing is slight, pressure may still be large during action, due to the pull of muscles.

The trabeculae of cancellous bone, though individually small, collectively provide powerful support to the thin shells of compact bone, a form of construction widespread in vertebrate skeletons, only modified where bending, twisting and tensile forces demand larger masses of compact bone. Many examples of both arrangements will be noted in individual bones; most larger ones show both forms, and the intermediate arrays adapt to local mechanical needs. Mechanical forces influence growth and form in bones; and during protracted evolutionary time a most apt solution to mechanical demands has been reached, in compliance with nutrition, muscle power, and the best compromise between size and weight (p. 276).



Sections of trabecular bone (**3**.5,8,21,22) show patterns which resemble criss-crossing girderwork. Attempts to equate these patterns in particular bones, such as the femur and calcaneus, with lines of force in habitual stresses were made early (Ward 1838). Such architectural explanations of structure have been criticized (e.g. Murray 1936), but studies of individual bones, or even of the entire skeleton (Hall 1966), show an intimate correlation between stress and structure in trabecular *and* cortical bone. Wherever stresses are locally applied, as in attachments of tendons and ligaments, sections show that external features, e.g. ridges or facets, are not the only local changes. Compact cortical bone may also increase, with subjacent condensation of trabeculae, often pronounced. It is certain that patterns of stress and trabeculation are related, whatever the precise terms of the equation (p. 278). *Surface* features of bones are clear to the naked eye (**3**.5); but much more detail and variation is revealed by a hand lens, macrophotography, incident light microscopy and scanning electron microscopy (**3**.6).

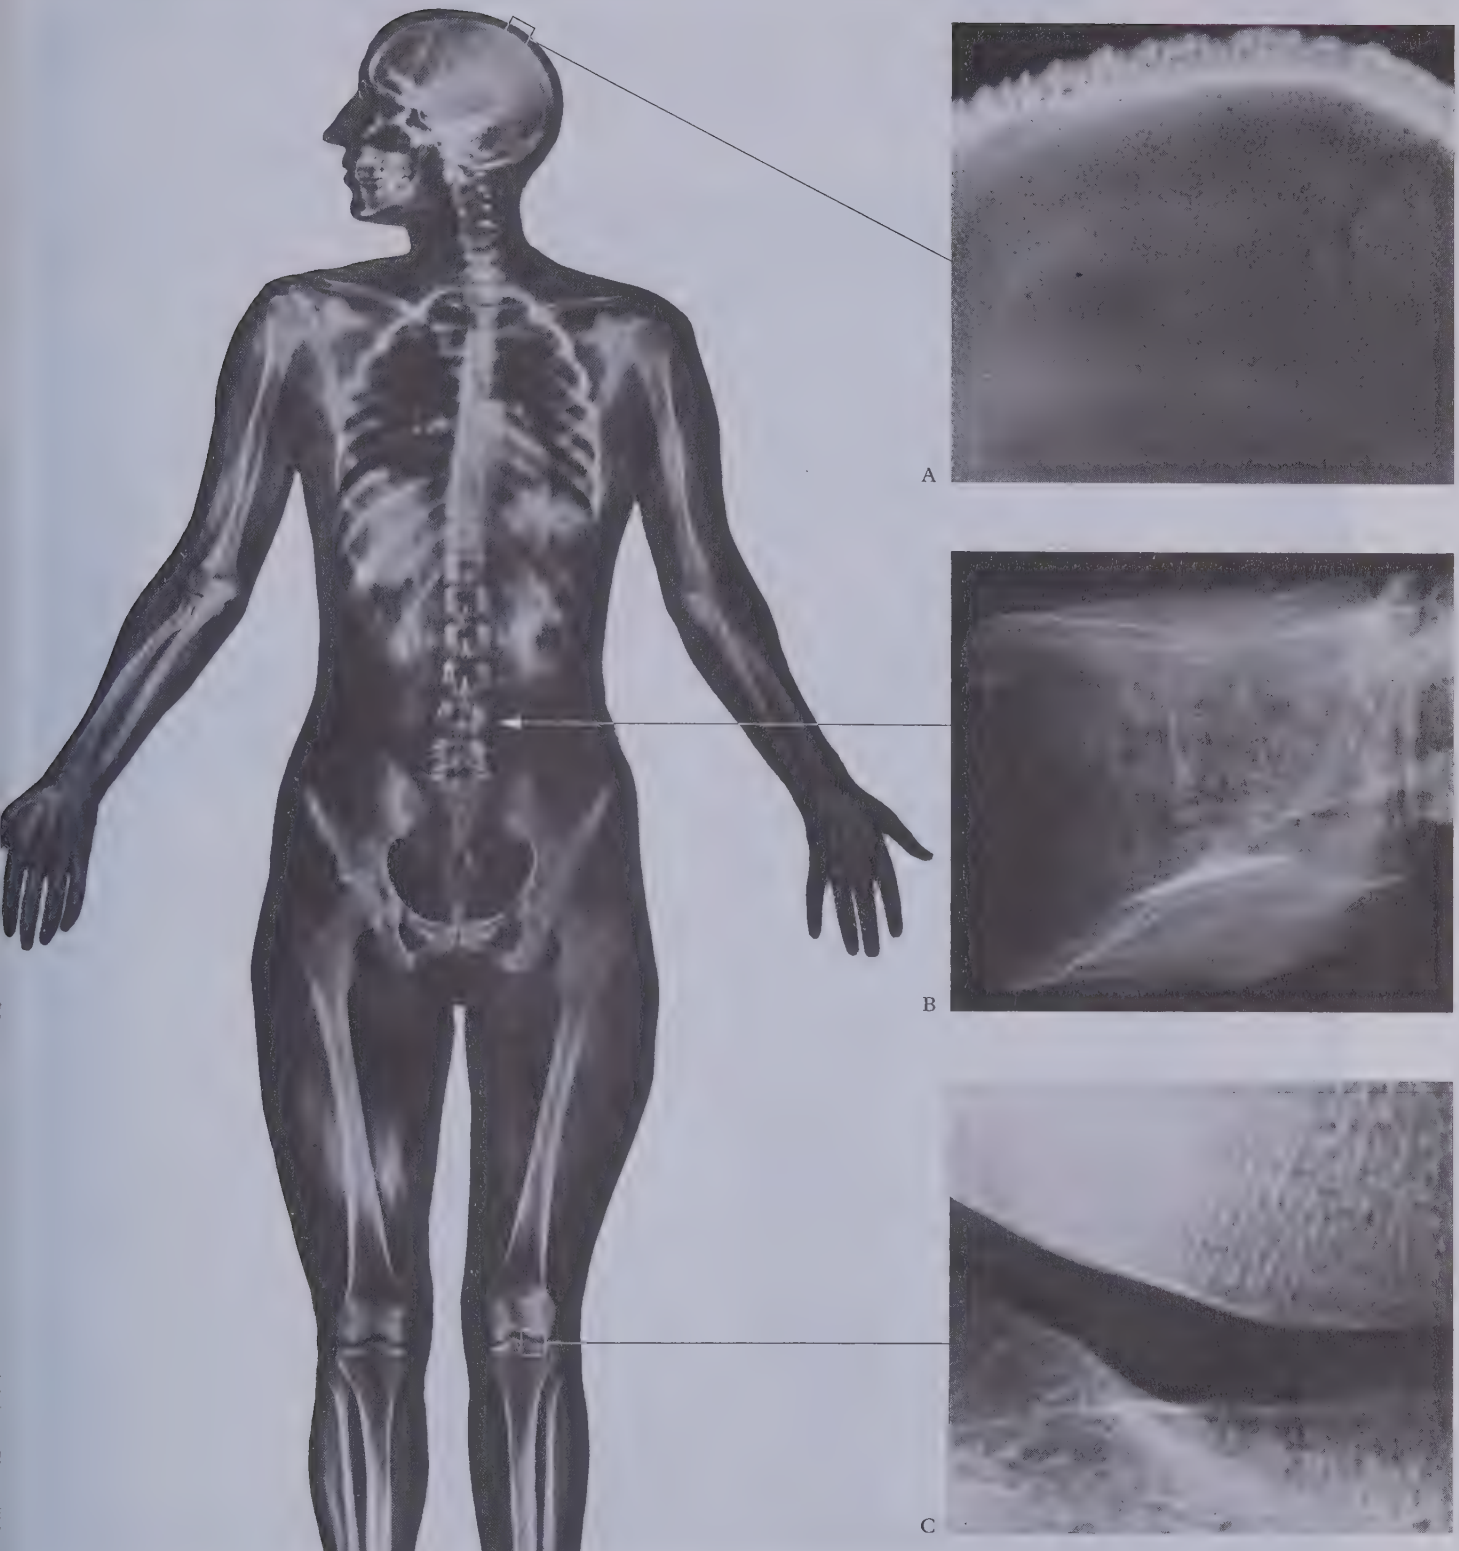
The Shape and Proportions of Bones

Since bones vary in shape their gross appearances have led to a traditional grouping into long, short, flat and irregular bones. *Long* bones are typical of limbs, length reflecting degree of speed and power in movement. Their tubular shafts (diaphyses) have a central medullary cavity and they diverge (metaphyses) towards their expanded articular ends, which are epiphyses with separate centres of ossification, often multiple (e.g. humerus and femur). Metacarpals, metatarsals and phalanges are smaller examples, but they are proportionately greater in diameter of shaft and possess but a single epiphysis. So-called *short* bones occur in the carpus and tarsus, e.g. those appropriately termed cuboid, cuneiform, trapezoid or scaphoid. Being subject to pressure more than other stresses, they have typically a thin cortex of compact bone, supported by an interior which is wholly trabecular. *Flat* bones include curved laminar members of the cranial vault, in which trabecular bone, *diploë*, variable in thickness, is enclosed between

3.2 Adult male skeleton: posterior (dorsal) view.

3.3 Adult male skeleton: lateral view.

laminae, or *tables*, of compact structure (3.5). The scapulae, despite their irregular form, are described as flat. *Irregular bones* include any element not easily assigned to foregoing groups. This time-honoured classification has no great merit. Bones must be studied individually, and in relation to functional demands.



In shape and structure, bones are affected by genetic, metabolic and mechanical factors, and each bone results from a long functional history through countless successive generations. Genetic determination of primary shape has been demonstrated by organ culture and transplantation of embryonic skeletal tissues (Murray & Huxley 1924, Fell & Canti 1934, Willis 1936), and all major characteristics appear to be self-determined, as perhaps is to be expected. Mechanical influences, such as moulding by muscular activity, often regarded as of first importance, are not operative when the primary form is being established. As muscles become active during prenatal life, they may influence bone growth, but to an extent difficult to estimate; after birth, up to adolescence, before all the epiphyses are fused, increased activity augments growth in length and girth. The reduced bone growth in limbs affected by paralyses, e.g. poliomyelitis, implies that activity is necessary to skeletal development. Experimental studies (Appleton 1934, Washburn 1947, Wolffson 1950), involving removal of muscles, point in the same direction. Again, increase in strength and stature show some temporal correlation in adolescents (Jones 1949).

Metabolic influences affect bone growth at all stages of development. The availability of calcium, phosphorus, vitamins A, C, and D, and secretions of the hypophysis, thyroid, parathyroid, adrenal glands and gonads, are all essential to osteogenesis (vide infra) and hence to skeletal form and dimensions. Disturbances in such factors entail recognized pathological states, but it is sometimes impossible to distinguish pathological from normal variation. Body height is an example: between the extremes of dwarfism and gigantism, resulting from hormonal dysfunction, much variation in height occurs. Variations in stature and other dimensions linked with age, sex and race are in part genetically conditioned; but racial variations in nutrition also have profound effects (Greulich 1951, Acheson 1960, Tanner 1962).

Bodily proportions, and absolute dimensions, vary widely in respect of age and sex (3.7) within racial groups, and between them. While partly due to variable muscularity and adiposity, such variations are chiefly skeletal; their study is *anthropometry* (Martin 1928, Hrdlička 1939). The data of anthropometry may be non-metrical, such as presence or absence of a feature (e.g. sagittal crest in Eskimo skulls, preauricular sulcus in female innominate bones), or persistence of an entity (e.g. interfrontal suture), or degree of development (e.g. frontal ridges, projection of chin). However, most anthropometric data are measurements, by internationally agreed techniques, in living subjects or skeletal material. These may involve the whole body, e.g. stature, or sections such as limbs or individual bones. The cranium attracted early attention, but metrical methods are now established for all skeletal elements. Proportions are expressed by indices; e.g. breadth of a skull as a percentage of length, the *cranial index*. Such indices may show ethnic variation. Mongoloid people display higher cranial indices than other races; they are 'broader' in head relatively and, in this instance, absolutely. A Mongolian child, of course, might have a cranial width less than that of a Negro adult, and yet be proportionately broader. Ratios between length of limbs and 'sitting height', or between arm and leg, upper arm and forearm, thigh and foreleg, are all used and show differences related to age, sex and race. Details of some indices are included later in accounts of particular bones.

Observations and measurements suggesting age, sex, size and race of an individual skeleton, or parts of it, are not only useful in anthropology and archaeology (Brothwell 1968, Warwick 1968) but sometimes essential to identification in forensic practice (Glaister & Brash 1937, Boyd & Trevor 1953, Harrison 1957, Stewart 1954).

Estimation of skeletal age involves many criteria, varying in value at different ages. Up to 25 years, including fetal life, dentition and ossification provide numerous data for assessment of age, with accuracy dependent on precision of observations, available statistics for sex and racial affinities of individuals under examination and their nutritional and endocrine history. The

3.4 Compounded series of radiographs of the whole body of a young adult female. Note the general contours of the body (compare with 3.7) and the relationship of the various parts of the skeleton to the disposition of the overlying soft tissues. Note also the relatively gracile proportions of the bones, the overall form of the pelvic skeleton, the obliquity of the femoral shafts and the proportionate lengths of the limbs and their various segments. (Kindly prepared and provided by Messrs Ilford.) Insets are high-resolution projection radiographs of, from above downwards: A part of parietal squama (*c.* × 2); B lumbar vertebral body—lateral view (*c.* × 2); C contiguous femoro-tibial hypochondral articular surfaces adjoining the lateral tubercle of the intercondylar eminence (*c.* × 6). Note contrasting details of osseous architecture. (Projection radiographs kindly supplied by C Buckland-Wright, Department of Anatomy, Guy's Hospital Medical School, London.)

3.5 Some macroscopic features of bone structure. 1. The ventral aspect of the proximal end of an immature humerus. Note the contrasting surface characteristics of the smooth articular surface covered in life by articular cartilage, the smooth periosteal surface of the metaphysis, the vascular foramina at the base of the greater tubercle and the groove across which osseous fusion has not yet occurred, separating the compound epiphysis from the metaphysis. 2. The external aspect of part of the sagittal (horizontal) and coronal (vertical) cranial sutures. Note the variation in the form and degree of interlocking of the bones. 3. The ventral aspect of the proximal end of a mature humerus; complete osseous fusion has occurred between the compound epiphysis and the diaphysis. Note the variations in surface texture and the distribution and size of the vascular foramina. 4. The endocranial aspect of the sagittal margin of a parietal bone. Note the highly complex nature of the disarticulated sutural surface, the presence of vascular grooves and multiple vascular foramina on the endocranial surface. 5. A coronal section through the head, neck, greater trochanter and proximal shaft of an adult femur, showing the variation in thickness of the shell of compact cortical bone, and the geometrical patterning of the deeper intersecting bony trabeculae. 6. The posterior aspect of part of the shaft of a tibia. Note the relatively smooth areas which bear 'fleshy' attachments of muscles, the ridge where dense lamellae of collagen are attached and an oblique vascular foramen which transmits the main nutrient vascular bundle to the shaft. 7. A sectioned bone of the cranial vault showing the internal and external tables of compact bone separated by the trabecular diploë, the diploic spaces of which, in life, are filled with haemopoietic red bone marrow.

The sectioned femur (5) has been reproduced using a specialized photographic technique which produces a 'bas-relief' effect. (Photographs by Kevin Fitzpatrick, Guy's Hospital Medical School.)

latter data are rarely forthcoming; available tables of ossification usually apply to healthy children and adolescents in Caucasian communities of Europe or America. A few studies of other racial groups exist (Todd 1931, Modi 1957). Racial variations in the events of ossification would necessarily be genetic, but there is no clear evidence for this (Krogman 1962). Variations in ossification are affected by wide divergence in nutrition between, and even within, racial groups so far studied, in all of which data for females show earlier ossification and epiphysial fusion, a difference presumably genetic. Nevertheless the age of a complete skeleton up to 25 years can usually be assessed to within a year, or more accurately in earlier years, expecially if dental observations are available. (For details see Teeth and individual bones.)

Above 25 years skeletal age can be estimated within 5 years by the state of cranial sutures and bony surfaces of the symphysis pubis. From mid-twenties onwards, sutures exhibit progressive closure (p. 393, Todd & Lyon 1924–5). Closure begins internally, and without internal inspection observations are misleading (Singer 1953, Genovese & Messmacher 1959); complications due to racial variation have been recorded (Abbie 1950). Progressive changes occur in articular aspects at the pubic symphysis. Features typical of ages from late teens to fifties and beyond are established (Todd 1920–30, McKern & Stewart 1957), and this is now generally considered the best method for estimation of skeletal age in maturity. Sequences of age changes have also been described in other bones (scapula, sternum and costal cartilages), but provide less accurate estimates. Lipping of rims of vertebral bodies and at margins of other articular surfaces, exaggerated secondary markings and ossification into tendons and ligaments all suggest advancing age, but only vaguely indicate *actual* age.

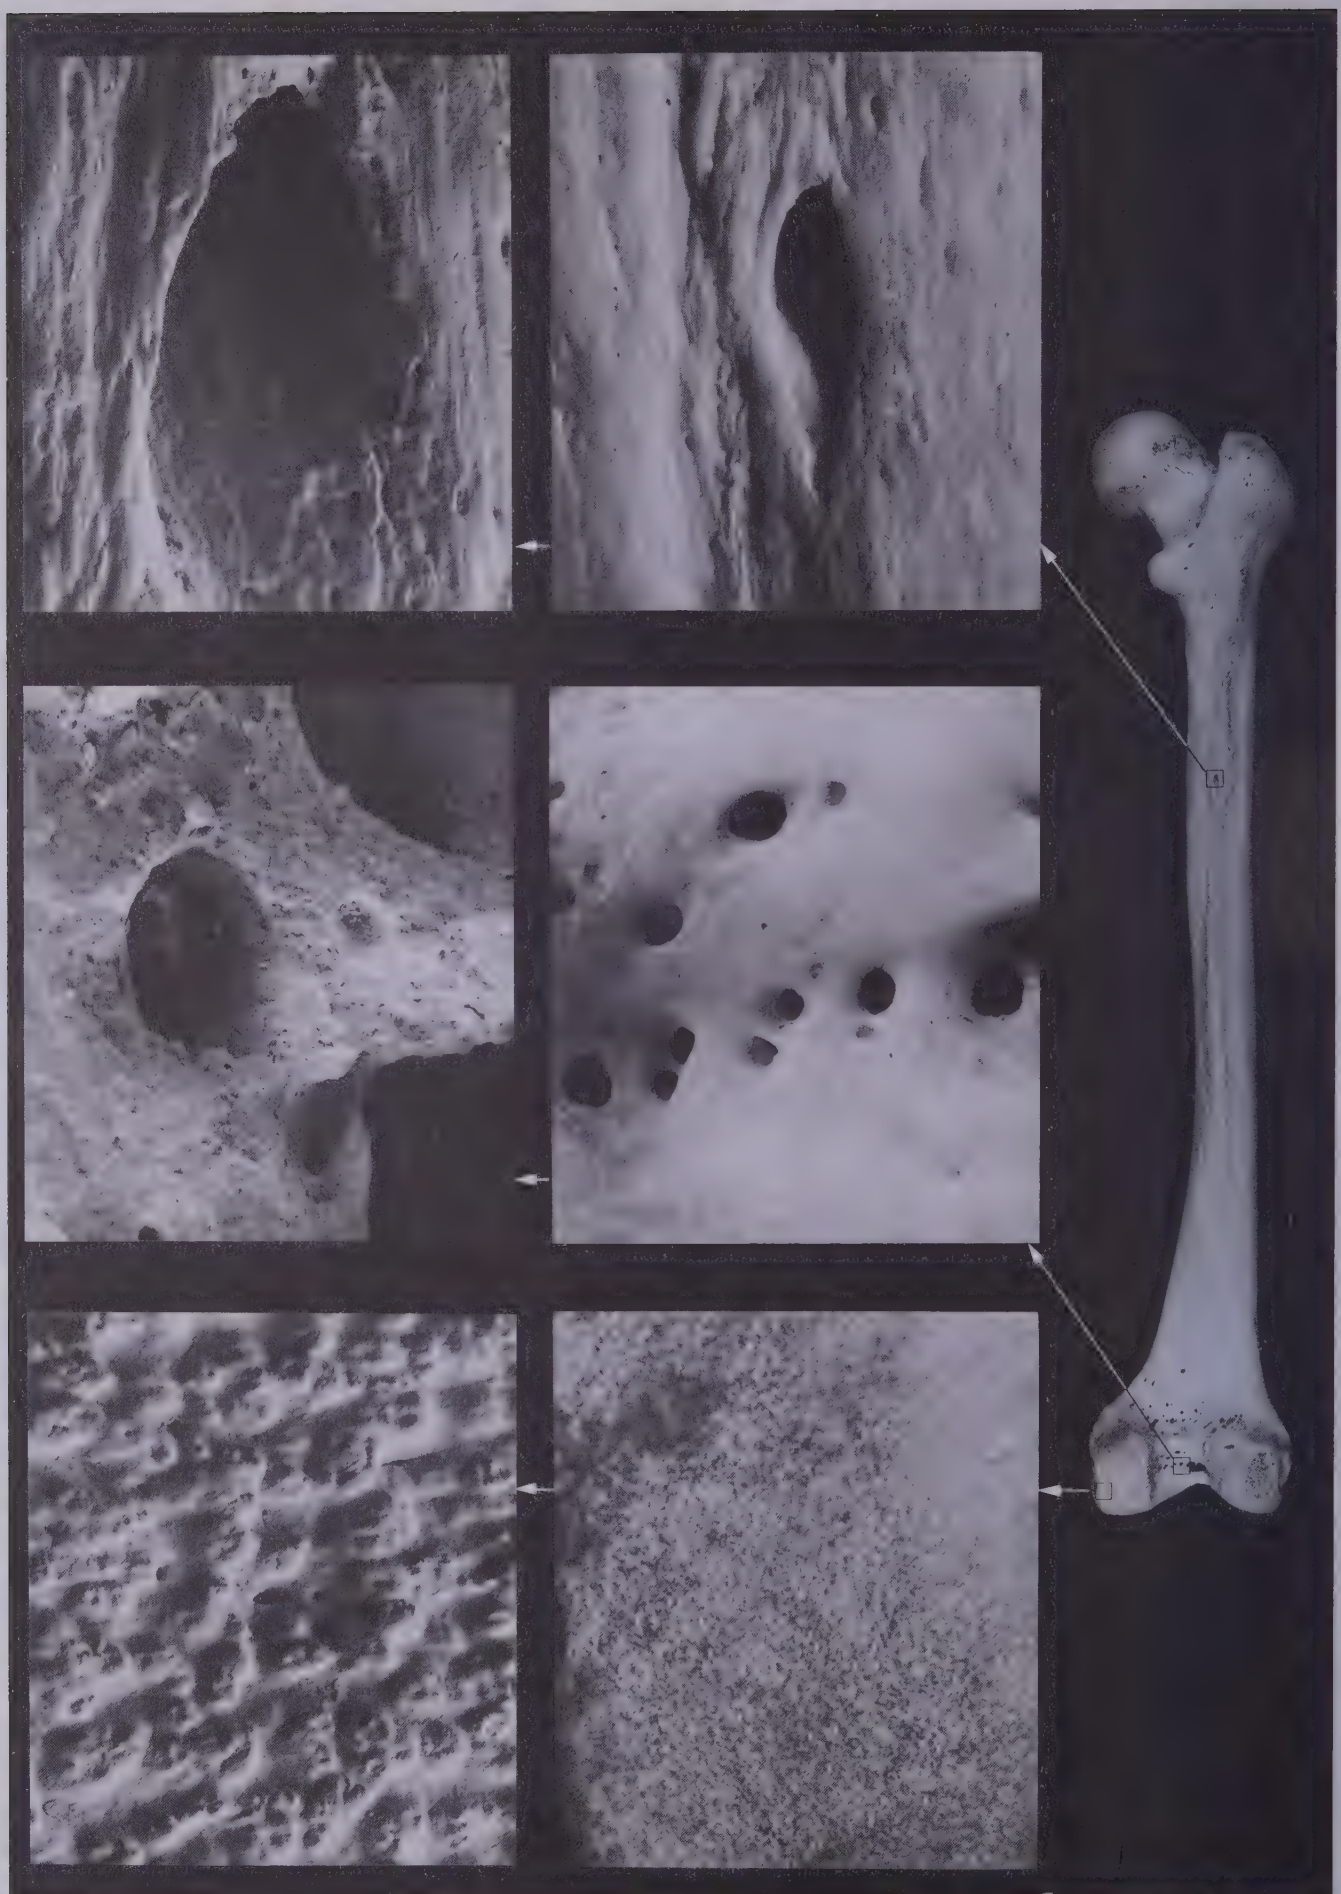
Estimation of sex in complete human skeletons is usually easy, even without measurement, provided they are postpubertal. Sexual differences are marked in pelvis (p. 431) and skull (p. 395), but not equally in all populations. Thus 'sexing' of skeletons from one racial group is almost free from error, whereas assessment of an individual, of unknown extraction, is less certain. Postcranial bones other than the pelvis, especially larger limb bones, may provide clear evidence of sex, if others of like race and both sexes can be compared. Female bones are usually smaller than male equivalents, and also more slender, i.e. of lesser diameter in shaft relative to length. This is reflected in their comparative *weights*. In a study of Hindu femora, mean weights were 385 g in males, 279 g in females (Singh & Singh 1974).

Anatomists, anthropologists, and forensic experts have long judged the sex of skeletal material by non-metrical observations. Latterly, sexual divergence has been based upon measurements in many different bones (Montagu 1960, Krogman 1962). Of discriminant analyses, one example may be quoted: Rother et al (1977) analysed capital dimensions of 70 humeri, concluding that sex was not easy to establish (whereas approximate age *could* be assessed). Such studies emphasize the need for standards of sexual dimorphism in different populations. The pelvis remains, however, the most reliable region for assessing sex, even before puberty, in infancy (Reynolds 1947) and even fetal life (Boucher 1957).

In a recent study of thoracolumbar vertebrae in 1427 Australian subjects (aged 5 to 19 years), Taylor & Twomey (1984) detected sexual dimorphism, female vertebral bodies being more slender in proportions from the eighth year onwards, greater growth in transverse diameter occurring in males.

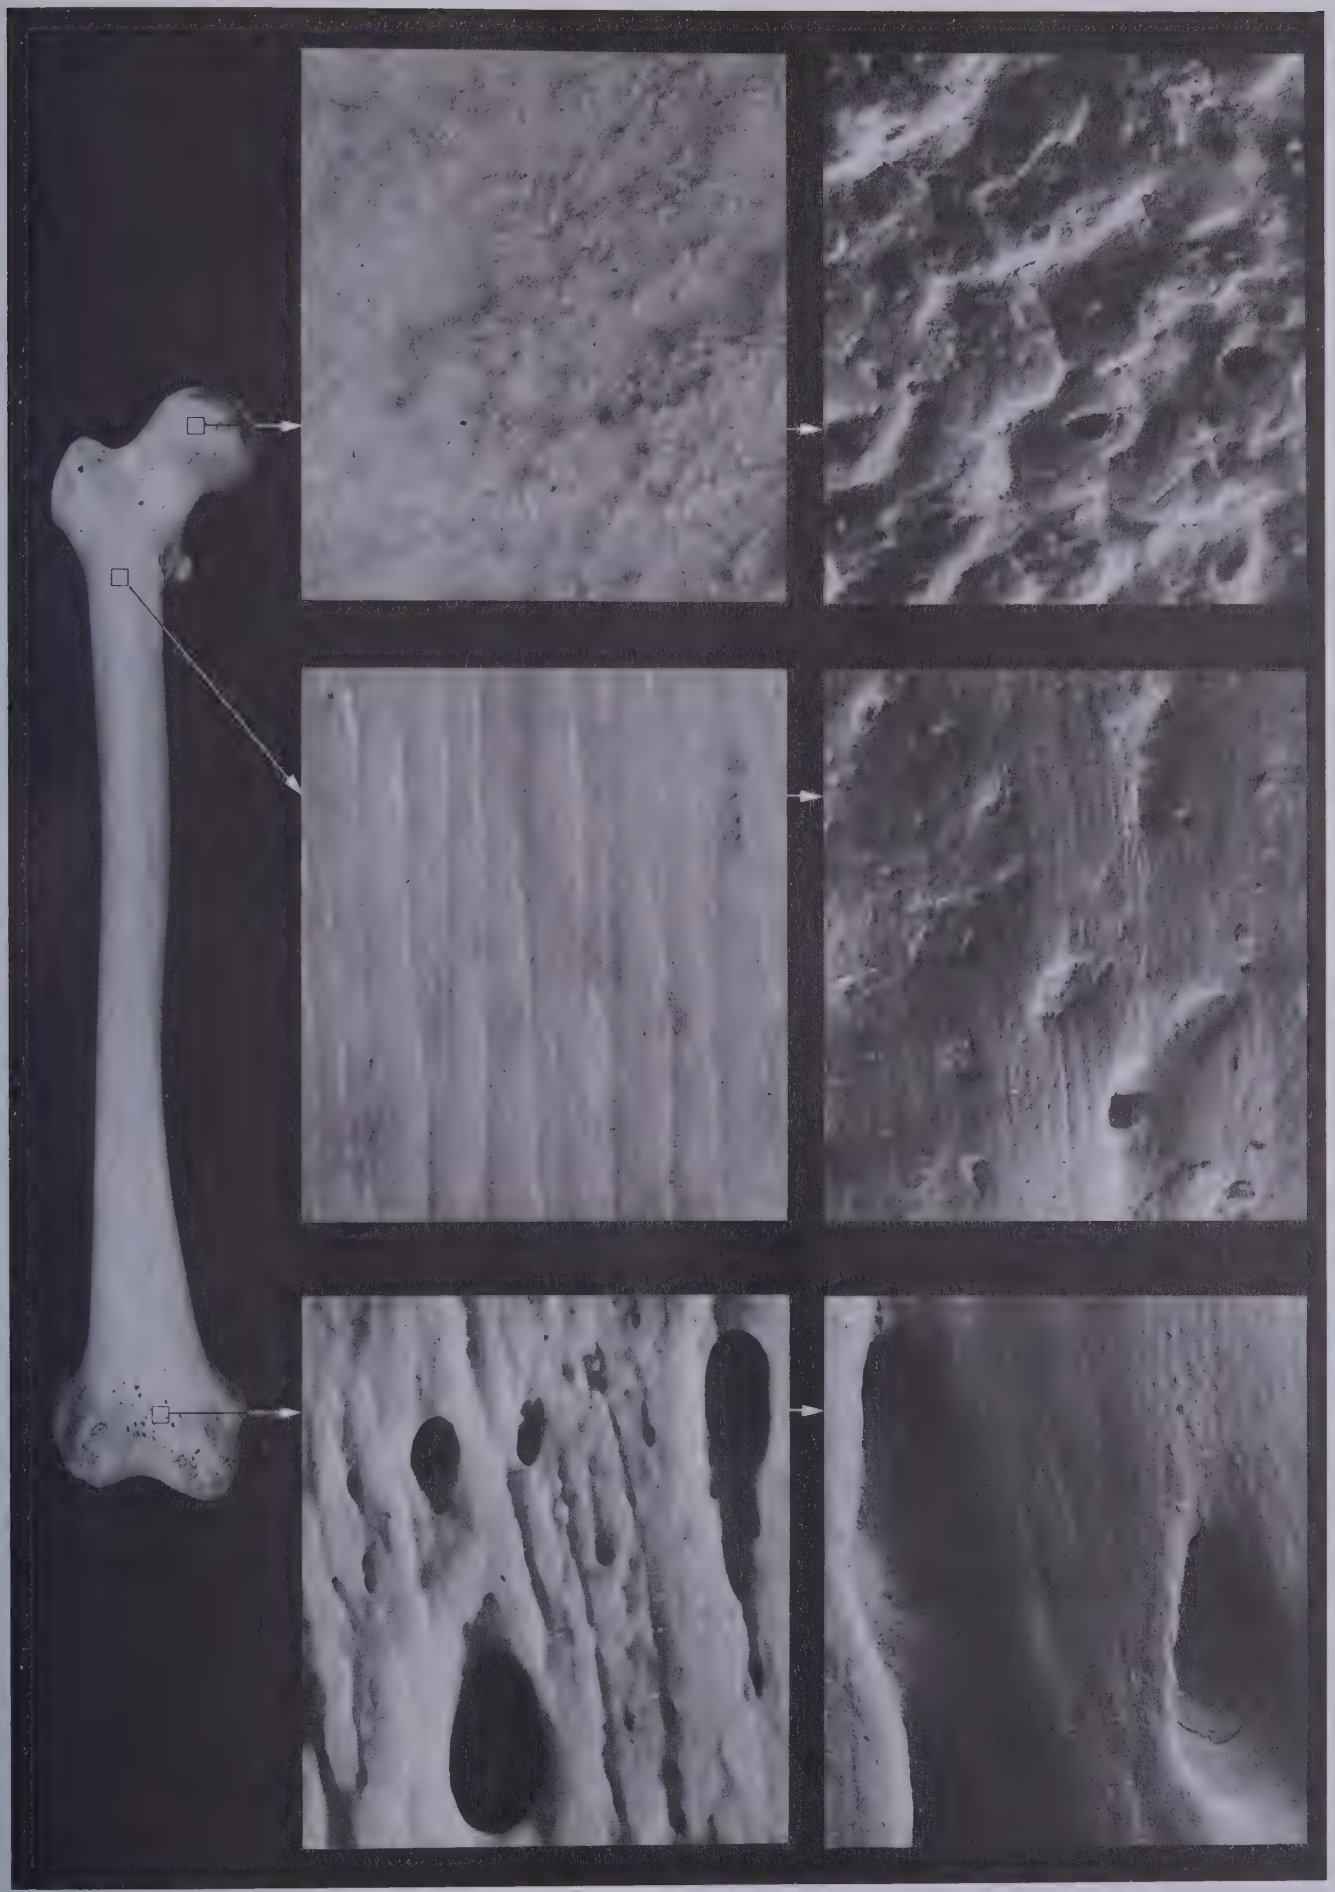
Estimation of size, particularly height, from measurements of limb bones has long been formulated (Rollet 1899), and with increasing accuracy as formulae have been refined (Trotter & Gleser 1958). All such calculation depends on the fact, familiar to artists (cf. Leonardo da Vinci), that major parts, trunk and limbs, exhibit consistent ratios among themselves and relative to total height, these ratios linked to age, sex and race. The relatively huge head, long trunk, short arms and shorter legs present a picture familiar in infants but grotesque even in older children, monstrous in adults. As an infant grows it also changes its proportions gradually towards adult shape, with divergence towards one sex at puberty. Limbs become relatively longer in adult males, shoulders broader and pelvis narrower, and there are other differences (3.7). Between major races, and even smaller ethnic groups, characteristic variations in proportions appear. Negroes are comparatively long in leg and arm; moreover, foreleg and forearm are long relative to upper arm and thigh. Consequently, formulae designed to estimate height from long bones in one population may not apply to another. Alternative formulae for the sexes must also be used, and immature bones must be recognized and subjected to suitable corrections.

Femoral length has commonly been used alone for estimates of stature by using a simple multiplier derived from comparison with known height in many individuals. The humerus, radius, ulna, tibia and fibula have all also been utilized; more complex formulae, based on several long bones, yield more accurate estimates. Whatever the methods used, estimates are no more than mean values with appropriate standard deviations; hence estimated stature of unidentified remains, however careful, may err by several centimetres.



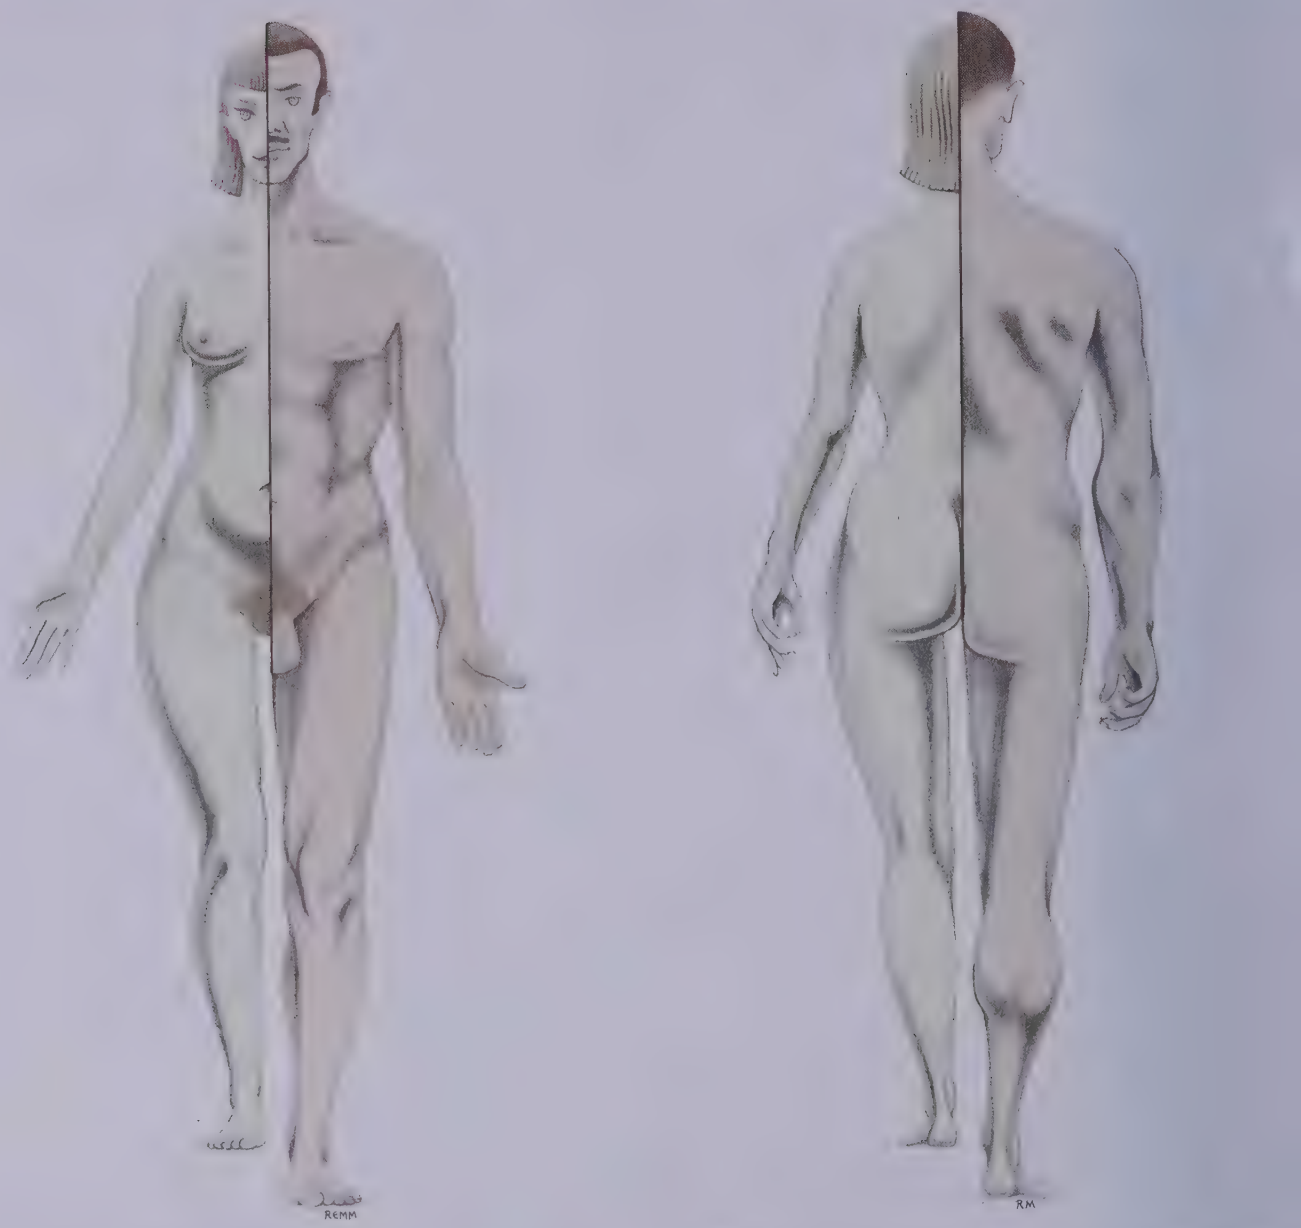
Since estimates of stature (and other assessments) must sometimes be made from *fragments* of bones, attempts to establish reliable formulae have been made (Steele 1970).

Estimation of race from skeletal data has always been a central theme in anthropology. The skull has attracted most attention. An array of *non-metrical* features (Jones 1931) and of cranial, facial and mandibular indices are widely used (Martin & Saller 1958–61, Berry & Berry 1967, Berry 1975), with statistical analysis of *metrical* data (Giles & Elliot 1960). In the three major racial groups, Caucasian, Mongoloid and Negroid, perhaps 85–90% of skulls can be classified without elaborate measurement. However, with further racial division error rises steeply. Worldwide mingling of races renders 'pure' races difficult to indicate. In America, large collections of skeletons, both Caucasian and Negroid, well attested as to origin, have stimulated comparative studies. Critical survey of results (Krogman 1962) suggests that only the skull (but not the mandible) and pelvis (Todd & Lindàla 1928) have any value in estimating race. (For details of *cranial* features of racial significance see p. 395.) However, metrical peculiarities in Japanese limb bones have been claimed by Takahashi (1975, 1976). Racial significance of *postcranial* non-metrical characteristics has been re-examined by Finnegan (1978), with rigorous statistical analysis and summary of many findings. The value of non-metrical features in evaluating populations from skeletal data has been reviewed by Finnegan & Faust (1974).



Functions of Bone and Skeleton

Bone tissue itself, and struts and levers formed of it, are adapted exquisitely to resist all forms of stress, with suitable resilience, in various muscular activities. The skeleton is said to 'give shape and support' to the body; but shape is itself an expression of motor activities, which simply returns to a role in movement. In some lower vertebrates a cartilaginous skeleton, variably calcified, provides the levers of locomotion; but whether cartilage was ancestral to bone in this function remains uncertain (Romer 1942, 1970, Bassett 1962, Krompecher 1967). However, a bony skeleton is not merely a motor advantage; bone differs from cartilage in being intensely vascularized (p. 299) and it is possible that the calcium salts with which it is hardened could be as easily removed as deposited there (p. 303). Part of the osseous calcium can be mobilized into general circulation with little delay. Effects of depressed calcium levels in rickets and osteomalacia indicate that calcium in bone and the body at large are in constant balanced interchange (McLean & Urist 1969). The skeleton, thus integrated with other tissues in general metabolism of calcium, provides the major store (97%).



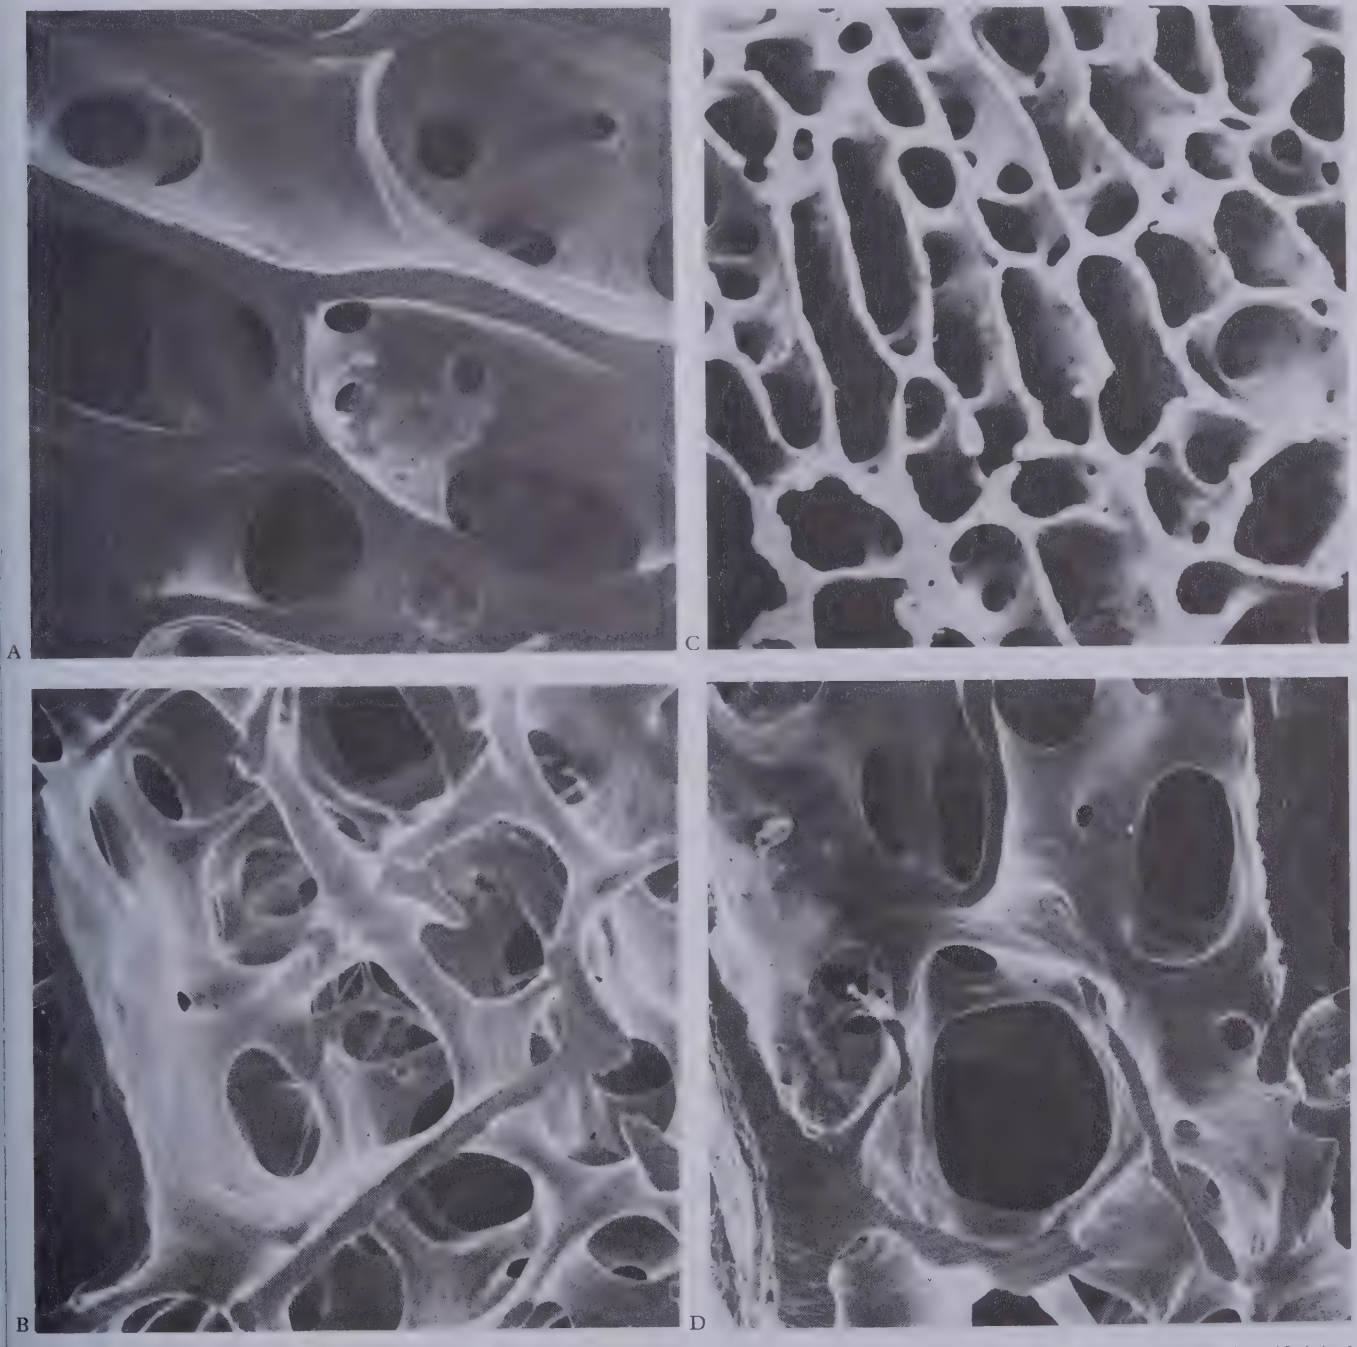
Some skeletal elements protect against extraneous forces; but the exoskeleton, so clearly protective in earlier vertebrates, is much reduced and modified in the human body. Even in the skull, much of whose cavity is enclosed by primitively protective dermal bones, this function is more than a barrier to *external* assault. Powerful muscles, masticatory and postural, have invaded cranial walls, demanding isolation of brain and its circulation from these intrinsic sources of disturbance. Again, ribs are commonly

3.6 Surface details of a normal adult human femur photographed at the sites indicated, by macrophotography and scanning electron microscopy. The macrophotographs which are immediately adjacent to the whole bone photographs are at a magnification of × 5, except for that showing the diaphysial nutrient foramen which is × 4. All the scanning electron micrographs are × 80, with the exception of that showing the diaphysial

nutrient foramen, which is × 15. (Prepared and provided by Kevin Fitzpatrick, Derrick Lovell and Michael Crowder, Department of Anatomy, Guy's Hospital Medical School, London.)

3.7 Comparison profiles of male and female to illustrate common differences in proportions. For details see text. Note, however, the heavier build of the male above the waist, the female below it, differences in limb proportions, carrying angle of forearm, muscularity and apparent length of neck.

dubbed protective. They certainly reduce risks of impact; but such dangers are occasional, whereas respiratory movements *depend* upon ribs.



All bones are, to some extent, internally trabecular, a pattern not only resistant to mechanical stresses but also for siting of bone marrow. Innumerable small spaces between trabeculae, with larger cavities in shafts of longer limb bones, are occupied by marrow, whether haemopoietic or adipose (p. 678). In some cranial bones air-filled cavities develop and they are then termed *pneumatic*. Pneumatization may consist of large hollows, such as the maxillary *sinus*, or multiple, small, communicating *air cells*, as in the temporal mastoid process (**3**.134,135). In human skulls, saving in weight thus effected can scarcely be as significant as it is in the pneumatized cranial vault of elephants; but the trabecular architecture of most bones is conducive to lightness without loss of strength, and with economy in use of materials. Some sinuses, particularly smaller air cells, appear to develop from trabecular tissue (diploë) in certain cranial bones, expressing the above principle. Larger sinuses affect the timbre of voice, but may be due merely to unusual growth patterns.

Mechanical Properties of Bone

The resemblance of bones to man-made levers, supporting columns, arches, struts and girders prompts application of concepts of mechanical engineering to them. Not only are bones like such structures in external shape and internal structure, but also in their uses. The apparently fragile but collectively strong lattices of struts and trusses of trabecular bone and skeletal forms such as tubes, H-girders, and ridges in cortical bone, predate human invention by aeons of time. Once human technology began to overtake natural biomechanics comparisons were inevitable. Galileo (1638) recognized the possible significance of trabeculation and also asserted that hollow cylinders are, weight for weight, *stronger* than solid rods. Havers described his 'systems' and their axial orientation (circa 1691); Ward (1838) likened trabecular patterns, with compressive and tensile elements, to supporting brackets and similar structures. Meyer (1867) and his mathematical collaborator, Culman, first clearly enunciated the *trajectorial theory*; and this, despite much argument, still survives. No more satisfactory hypothesis has replaced it. Basically it states that

trabecular pattern coincides with routes of stress; this has not yet been convincingly demonstrated nor disproved. Trabeculae must support shells of compact bone adjoining them, for these cortical strata are usually thin; but relations between stress and strain and trabecular pattern are often more complex than the simplified mathematical analyses applied to sections or models of bones (Kummer 1972).

In contrast to this largely theoretical approach is direct estimation of strength of bone as a material by engineering methods, to assess response in bone samples or entire skeletal elements. Wertheim (1847), anticipating Meyer, applied physical tests to bone tissue; subsequent workers have expanded such techniques. Developing interest in the mechanics of locomotion has stimulated the study of bone and a bewildering variety of values for various physical parameters of bone have been recorded. The problem is full of difficulties and fallacies. Obviously bone material from various species differs, and sex and age are also factors. The form of specimen tested also varies; whole bones or blocks of cortical or trabecular bone, or mixtures of these behave differently, and source of specimens must be defined if results are to be comparable. Bones from preserved cadavers yield misleading values, especially as regards plastic deformation (Reilly & Burstein 1974), but also in elasticity, hardness, and compressive and tensile properties (Evans 1973). Dead bone, however, if kept wet, does not differ from living bone, tested in vivo, whereas dried bone is harder but less deformable. Sampling from a bone also presents problems, because varying distribution of Haversian systems or trabeculae may vitiate comparisons. Testing of specimens and intact bones, especially to rupture, involves attachment of tension devices, often incurring undesigned collapse at these points, especially in testing axial tension. Hence experimental data, recorded in profusion, present a complex picture, e.g. it is

3.8 Scanning electron micrographs of trabecular bone at different sites in the proximal part of the same human femur. All fields are × 20. A is an area in the subcapital part of the neck, B and C are in the greater trochanter, and D in the rim of the articular surface of the head. Note wide variation in the thickness, orientation and spacing of the trabeculae. (Original photographs from Whitehouse & Dyson 1974, with permission from the authors, the *Journal of Anatomy* and Cambridge University Press.)

impossible to state even useful mean values for the physical properties of bone tissue, because resistance to stress and elasticity vary in different regions of the same bone. In view of the structural complexity in any skeletal element, including variations in thickness, density, cortical modelling and internal trabeculation (3.8A–D), some workers regard the definition of even an approximate picture of mechanical behaviour in any individual bone as improbable. The illustrations (3.8A–D) refer to the proximal end of the human femur (Whitehouse & Dyson 1974); similar regional variability exists in its distal end and in the proximal part of the tibia (Behrens et al 1974); in the tibia strength is not directly related to trabecular pattern or total density, indicating a multifactorial relation. Whitehouse (1975, 1977) has recorded data on the sternum and the iliac squama.

Various techniques, sometimes combined, have been used to assess the isolated physical properties of bone samples and whole bones, and to assess distribution of strains in them due to various forms of stress. Numerous results of tests by engineering techniques have been summarized by Ascenzi & Bell (1972), Kummer (1972) and Evans (1973). Although these values vary, greater disagreement exists in problems of transmission of forces. These have been investigated in bones, commonly the femur, and also plastic models, use of which is based on the false assumption that bone is isotropic and homogeneous. But bone is a viscoelastic, biphasic substance, analogous to fibre-glass, the tropocollagenous content corresponding to its 'fibres', and the crystalline hydroxyapatite to the 'glass'. Hence a plastic model can indicate only the *surface* behaviour of stresses in the bone it is supposed to imitate. In both, its stress pattern can be studied by inspection of cracks produced in a covering of colophonium resin (Kuntscher 1934) or special lacquers (Gurdjian & Lissner 1945); but these superficial cracks may indicate no more than a crude picture of strains in bone. Hallermann (1934) introduced a photoelastic technique, which reveals stress patterns in bones and plastic models by polarized light. Pauwels (1965) and Kummer (1966) exploited this technique, but Brekelmans et al (1972) emphasized its limitations, not only in models but also in oversimplified, two-dimensional mathematical analyses.

Benninghoff (1925) used the *split-line phenomenon* in decalcified bones, claiming that a surface pattern of split-lines or cracks, induced by puncturing with a round-bodied needle, follows distribution of osteons orientated in axes of compression or tension. Accepting the trajectorial theory, he considered it also directly related to behaviour of cortical osteons. Tappen (1954) has made similar claims, but admitted that patterns may follow 'immature' osteons. Isotupa (1972) considered that they represent distribution of points of weakness due to vascular spaces. Subsequently Buckland-Wright (1977) has attributed the cracks to weaker zones of bone (perhaps also concerned in genesis of fractures), and included cement-lines, interlamellar interfaces, osteocytic lacunae, and vascular canals. He considered the split-line technique as unreliable for analysis of structure and force transmission.

Strain gauges have been used to record the results of stresses in whole bones, either as dead, isolated elements, or during in vivo experiments, and also on bone samples. Gauges cannot be bonded to bone in large numbers, and the data obtained are limited; but interesting in vivo results have been obtained by Lanyon (1973) on ovine vertebrae, tibiae, and calcanei, recording deformation cycles during locomotion. Lanyon himself criticized the method, but it confirmed the elasticity of bone and showed that its elastic modulus varied with speed of movement.

Interference holography has been applied to the study of surface strains in human mandibles (Gupta & Knoell 1973); but the technique is difficult, especially in experiments on the living.

Mathematical analysis has been much developed in this field, but since basic data are limited or based on oversimplification inherent in use of models, usefulness is restricted. (Consult Koch 1917, Kummer 1966, Rybicki et al 1972.)

A combination of techniques perhaps offers most help in solving problems of bone mechanics, and this brief review of a complex and difficult field should hence end by reference to a study (Buckland-Wright 1978) of patterns of transmission of strains in the feline skull due to biting; it combined radiology and projection microradiography with use of strain gauges, colophonium resin experiments and histology, the limitations of each technique being complemented by the others. Projection microradiographs

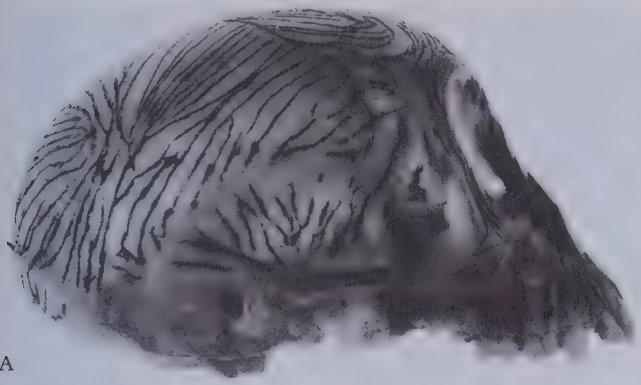


Table of the approximate tensile strengths of bone and a few other materials (From Gordon 1968)

MATERIAL	TONS/INCH	MN/m ^{2}
Traditional cast iron	5–10	75–150

3.9 Photographs illustrating three methods used to investigate possible interrelations between structural organization and patterns of force transmission in bone. A split-line patterns produced in a decalcified skull (*Macaca mulatta*) by repeated puncture with an ink-tipped needle. B pattern of cracks in colophonium resin coating of a femur subjected to a compressive stress of the head, vertically applied. C photo-elastic pattern produced in a flat plastic sheet modelled upon the proximal end of the femur. A compressive force has been applied to the femoral 'head', whilst a tensile force has been applied to its 'greater trochanter'. C is from von Knief 1967, the others contributed by C Buckland-Wright, Department of Anatomy, Guy's Hospital Medical School, London.

were assessed by a stereoscopic technique, permitting three-dimensional correlation between bone structure and the impressed stresses. These observations led to a modified version of the trajectorial theory.

Alexander (1984d) has compared the optimum strengths of bone in terms of their habitual stresses and actual properties and has developed mathematical expressions for the balance between strength and weight of bones. He concludes that mammalian limb bones are often stronger than they need to be, but admits that the equation between stress and structure is difficult to predict with accuracy. Bacon & Griffiths (1985) have investigated texture, stress and ageing in human femora by neutron diffraction patterns in bone samples. They found a vertical orientation of hydroxyapatite crystals able to resist vertical stresses. The alignment was low at birth, maximal by about 13 years, decreasing steadily thereafter.

As stated above a profusion of estimates of physical parameters of bone tissue have been recorded. The following results are cited as representatives of such estimates, including comparison with other materials.

Growth of Individual Bones

As in other mammals human bones are mostly preformed in hyaline cartilage, some in condensed mesenchyme. Thus a model in soft tissue first appears and is gradually changed into bone by onset of osteogenesis, often at a centre from which it spreads, until the whole skeletal element is transformed. Such *centres of ossification* appear over a long period, many in embryonic life (**3**.10), some later in prenatal life and others well into postnatal growing period. The process is complex, and must be studied at different levels of organization. At microscopic, ultrastructural and molecular levels are the basic phenomena of histogenesis, growth and transformation of skeletal tissues, including primitive mesenchyme and its differentiation into other forms of connective tissue, cartilage and bone, all considered later (p. 304).

At first microscopic, the ossific centres soon become macroscopic and their growth then can be followed by plain inspection, dissection or radiological and other scanning techniques. It is the latter scale of events which will be considered here.

Many bones are ossified from a single centre, including carpal, tarsal, lacrimal, nasal, and zygomatic bones, inferior nasal conchae and auditory ossicles. Even in this limited group centres appear from the eighth intrauterine week to the tenth year, a wide sequence in studying growth or estimating age. However, most bones ossify from several foci, one appearing in late embryonic or early fetal life (seventh week to fourth month) centrally in the future bone (**3**.10), from which ossification progresses towards its ends, which are cartilaginous at birth (**3**.11,12), though typical in shape and articular congruities. These terminal regions are ossified from separate centres, sometimes multiple, appearing from birth into late teens; they are thus *secondary* to the earlier *primary* centre from which much of a bone is ossified. This is the mode in long bones, some shorter elements such as metacarpals and metatarsals, and in ribs and clavicles.

At birth a bone such as the tibia is typically ossified throughout its shaft, or *diaphysis*, by a primary centre appearing in the seventh prenatal week, whereas its cartilaginous *epiphyses* are transformed into bone by secondary centres. As these enlarge, replacing cartilage, they transform almost all the articular regions, but a layer of specialized hyaline cartilage persists at joint surfaces (p. 305) and a thicker zone between diaphysis and epiphysis. Persistence of this *epiphysial plate or disc* (*growth plate* or *growth cartilage*) allows increase in length until a bone's usual dimensions are attained, at which stage increase is abolished by discal ossification. The bone has then reached maturity. Coalescence of epiphysis and diaphysis is *fusion*, the amalgamation into one of separate osseous units, developed in the same cartilaginous or mesenchymal model, itself growing throughout the process.

Many bones have epiphyses at both ends, others at only one. Long limb bones illustrate the former, while metacarpals, metatarsals, phalanges, clavicles and ribs have only one epiphysis,

3.10 Alizarin stained and cleared human fetus of about 14 weeks in utero. Note the degree of progression of ossification from primary centres, which is endochondral in the appendicular and axial skeletons, excepting the clavicles, and the intramembranous centres for the majority of the cranial bones which are visible here. The carpus and tarsus are wholly cartilaginous except the primary centre for the calcaneus, as are, of course, the epiphyses of all the long bones. The centra and neural arches of the vertebrae are separate. The sternum is still unossified. The membranous anterolateral and posterolateral fontanelles are particularly obvious. (Photographed by Kevin Fitzpatrick, Department of Anatomy, Guy's Hospital Medical School, London, from a specimen prepared by Roslyn Holthouse, formerly of the same department.)

though costal cartilages may represent epiphyses normally devoid of ossification centres. (For discussion of a *pseudoepiphysis* at the first metacarpal's distal end consult Haines 1974.) Epiphysial ossification is sometimes more complex, e.g. the proximal end of the humerus, wholly cartilaginous at birth, develops three centres during childhood, which coalesce into a single mass before fusing to the diaphysis. Only one centre forms an articular surface, the others forming greater and lesser tubercles for muscular attachments. Similar composite epiphyses occur at the distal humeral ends and in the femora, ribs and vertebrae. Because some centres ossify in regions exposed to articular pressure, and others in regions subject to muscular traction, a classification into *pressure, traction* and *atavistic* epiphyses was proposed by Parsons (1903–5), the atavistic epiphyses being considered to represent skeletal elements separate at earlier evolutionary stages. Comparative morphology suggests that some mammalian bones are composites of separate reptilian or amphibian elements. The skull, clavicle, scapula and innominate bones afford examples; a small centre in the human coracoid process and an epiphysis at the medial end of the clavicle may be vestiges of skeletal elements separate in earlier vertebrates, repeated during development as transient features in subsequent mammalian forms. But the clavicle's medial end could equally be regarded a pressure epiphysis.

3.11 The skeleton of a neonatal infant, with all cartilages preserved. Note particularly proportions of neurocranium, orbital cavities and face, interfrontal (metopic) suture, sternebral ossification, extensive costal cartilages, large cartilaginous epiphyses and metaphysial flaring of long bones, especially the humeri, femora and tibiae. (Photographed by Kevin Fitzpatrick from a preparation by Michael C E Hutchinson, of the Department of Anatomy, Guy's Hospital Medical School, London.)

Many cranial bones ossify from multiple centres, and evidence suggests that some are atavistic. Marked reduction in number of cranial bones in mammals, compared with older vertebrate groups, is clear. The sphenoid, temporal and occipital bones are almost certainly composites of previously multiple elements, some represented by centres which are additional evidence of fusion in dermal (membranous) and cartilaginous derivatives, at first separate but united during growth to form a complex whole (p. 376). These events in cranial development do not precisely parallel atavistic epiphyses in postcranial bones, which are always *secondary*. In human composite cranial bones the result is coalescence of elements, each with a *primary* centre.

Classification of epiphyses, of little significance per se, does, however, direct attention to matters of interest in mammalian skeletal evolution. Epiphysial centres do not occur in other vertebrates, except sporadically in reptiles and birds (Haines 1937), and these are pressure (articular) epiphyses. Traction epiphyses are peculiar to mammals, but genetically established, for their appearance is not arrested by division of structures attached to them (Appleton 1922, Barnett & Lewis 1958); but experimental evidence in connexion with epiphysial development is limited.

The rate of growth in centres of ossification exceeds that of the cartilage in which they occur, though the latter is itself growing in concert with increase in size and change in proportions of the skeletal element for which it is a model. Thus, the epiphysial region, at first cartilaginous, gradually ossifies, with exceptions noted above. The process starts at a time and continues at a rate characteristic for each bone. (Individual, sexual and racial variations must be taken into account, as far as data permit, when assessing individual skeletal age.)

Rate of growth also varies both in bones with epiphysial plates and those without. Were the rate uniform, ossific centres would appear in a strict descending order of size. But primary centres for such different masses as phalangeal and femoral shafts are separated by a week of embryonic life at most. Those for carpal and tarsal bones show some correlation between size and order of ossification, from largest (calcaneus in fifth fetal month) to smallest (pisiform in ninth to twelfth postnatal year). In individual bones, succession of centres is related to the volume of bone which each produces. The largest epiphyses, e.g. the adjacent ends of femur and tibia, do ossify earliest (immediately before or after birth, points of forensic interest); but during comparison between other bones inconsistencies are numerous. Such dissimilar masses as a phalangeal epiphysis and lesser humeral tuberosity begin to ossify about the same time, and both long before the massive greater trochanter of the femur, showing widely disparate rates of ossification.

Experiments in mammals indicate that at epiphysial plates rate of growth is initially equal at both ends of bones possessing two epiphyses, but that after birth one grows faster (Brookes 1963); since this end also usually fuses later with the diaphysis, its contribution to length is greater. Though faster *rate* can only be presumed in human bones, *later* fusion is a radiological fact. Recurrent directions of nutrient arteries as they enter certain bones accords with the above facts (cf. p. 299).

The end of a long limb bone, which is more active in growth in length, is often termed the *growing end*, but this is obviously a misnomer. Variable rate of growth at epiphyses in general also shows in rate of increase of stature (Krogman 1941, Tanner 1962), which is rapid in infancy and again at puberty, but otherwise slower. The spurt at puberty, or slightly before, decreasing as epiphyses fuse in post-adolescent years, has been much studied. For general reviews of fetal and postnatal growth patterns, including the skeleton, consult Sinclair (1969), Tanner (1978).

3.12A Radiograph of neonatal arm. Ossification from primary centres is well advanced in all bones except the carpals, which are still wholly cartilaginous. The gaps by which individual elements appear to be separated are, of course, filled by the radiolucent hyaline cartilage, in which epiphysial or carpal ossification will subsequently occur. In the long bones note the flaring contours, with narrow midshaft and relatively expanded metaphyses. Note also the proportions of the limb segments characteristic of this age and in particular the relatively large hand.

B

C

3.12B (*left*) Photograph of a preparation of a neonatal left arm (from the specimen shown in **3.11**). Compare the radiolucent areas in the radiograph (**3.12A**) with the preserved cartilaginous epiphyses and carpal elements in this specimen. (For acknowledgements see **3.11**.)

3.12C (*above*) Composite bone scan of a male child, aged approximately one year, showing sites of epiphysial growth activity. The tracer used (technetium-99m labelled methylene diphosphonate) also shows the kidneys and bladder. (Provided by Department of Nuclear Medicine, Guy's Hospital; photography by K Fitzpatrick and Sarah Smith.)

Growth cartilages do not grow uniformly at all points; this accounts for changes such as alteration in angle between the humeral shaft and its neck. On their diaphysial faces epiphyses do not have a uniformly flat junction with growth cartilages, nor indeed do the latter at their diaphysial junction. By differential growth osseous surfaces usually become reciprocally curved, the epiphysis forming a shallow cup over the convex end of the shaft (cartilage intervening). This form may resist shearing forces at this relatively weak region. Reciprocity of bone surfaces is augmented by small nodules and ridges, typical of such surfaces when denuded of cartilage. Such adaptations emphasize the formation of many immature bones from several elements held together by

epiphysial cartilages. Most human bones are such complexes, not only through the active years of childhood but also the even more vigorous adolescence; the bonding of bone to bone through cartilage is thus strengthened.

Forces at growth cartilages are largely compressive, but with an element of shear. At traction epiphyses, attached by cartilage prior to fusion, attached structures create tension, perhaps promoting development of abundant collagen fibres aligned along supposed routes of stress (Smith 1962a). Damage to epiphysial growth by violence may occur, but disturbance by constitutional disease, such as fevers, is more frequent, producing visible change in trabecular pattern of bone, visible radiographically as dense transverse *lines of arrested growth* (Harris 1933); several such lines may appear in limb bones of children afflicted by successive illnesses.

Details of fusion are described later (p. 307). The growing part of a diaphysis adjacent to epiphysial cartilage, the *metaphysis*, appears to overtake the cartilage, but epiphysial contribution is shown by the denticulated edges of both bone elements as they bridge the cartilaginous gap. These appearances, extensively described, provide criteria for estimations of times of fusion, by inspection *or* radiography (Stevenson 1924). Knowledge of sites, times of appearance, rates of growth and times of epiphysial fusion is clinically, forensically and anthropometrically valuable. Reliable data depend upon adequate observations and standardized techniques. Variation in published figures is partly due to failure in these respects. Radiography needs to be more frequent than is usual. Angle of view must be carefully controlled; routine positions may be inadequate; e.g. the centre for lesser humeral tubercles is often missed, probably because its image is superimposed upon another centre.

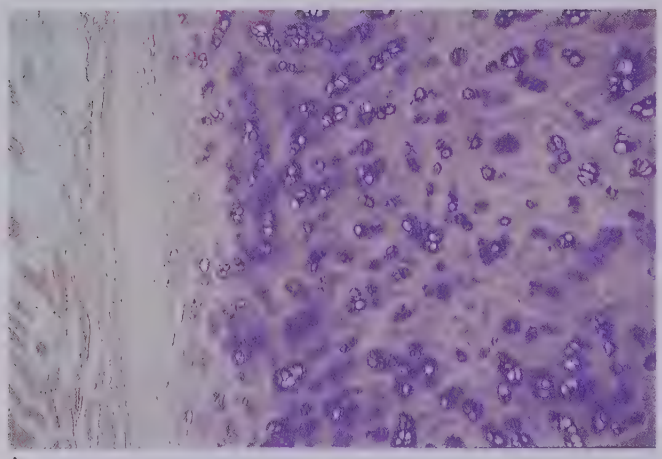
Variation in skeletal development does, of course, occur between individuals, sexes and possibly races. The *sequence* of events, however, shows little variation; it is their timing which varies. *Females antedate males* in all groups studied, and differences, perhaps insignificant before birth, increase thereafter, rising to two years or so in later fusions of adolescence. Data are most reliable for Caucasians, but few of their skeletal parts have been compared in sufficient detail, numbers or over adequate periods. Perhaps the best studies available are for the hand (Todd 1937, Greulich & Pyle 1959, Mathiasen 1973), knee (Pyle & Hoerr 1955) and ankle and foot (Hoerr et al 1962).

Cartilage and bone are specialized connective tissues consisting of the same three elements: *cells* embedded in a *matrix*, permeated by arrays of *fibres*; but sclerous tissues differ from soft, pliant, connective tissues, their matrix being solidified. Cartilage and bone, nevertheless, differ in structure, physical properties, vascularization and modes of growth and regeneration.

THE SKELETAL CONNECTIVE TISSUES

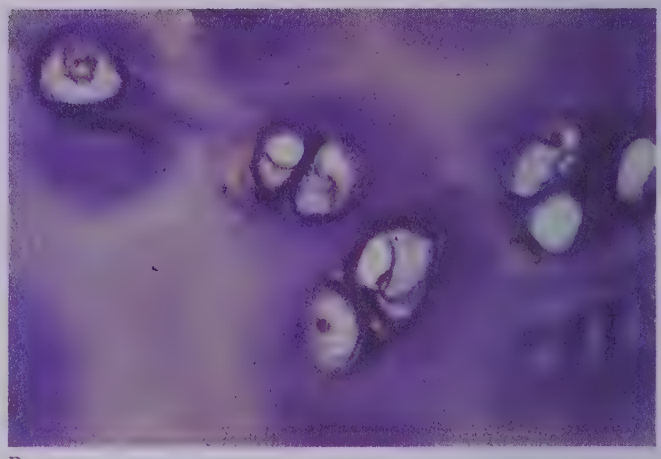
The skeletal tissues, cartilage and bone, are essentially specialized connective tissues and consist of the same components—cells embedded in a matrix permeated by a system of fibres. Physically, however, matrices of skeletal tissues differ from those of general connective tissues in being solidified. Cartilage and bone are, nevertheless, quite distinct in their structure, physical properties, vascularization and in their patterns of growth and regeneration.

Structure of Cartilage



Cartilage is a phylogenetically ancient tissue, widespread in vertebrates as either a permanent or temporary skeletal component. During early fetal life the human skeleton is mostly cartilaginous, but is largely replaced by bone subsequently. In adults cartilage persists at the surfaces of synovial joints, in the walls of the larynx, trachea, bronchi, nose and external ears, in the epiglottis and as isolated small masses in the cranial base. Developmental replacement by bone is a complex process, and cartilaginous *growth plates* between ossifying epiphyses and diaphyses of long bones (and elsewhere) continue to proliferate, increasing the length of the bones concerned until they eventually ossify, when growth ceases. For reviews see Glenister (1976), Reid (1976, visceral cartilage), Stockwell (1978), Hall (1983, structure and biochemistry), for an alternative view of cartilaginous growth plate biology see Lutfi (1974).

Cartilage is essentially a type of stiff, load-bearing connective tissue. Its distinctive properties are a low metabolic rate and a vascular supply confined to its surface or to large, penetrating tunnels, a capacity for continued and often rapid interstitial and appositional growth (vide infra) and a high resistance to tension, compression and shearing, with some resilience and elasticity. Cartilage is covered by a fibrous *perichondrium* except at osseous junctions; at synovial surfaces, the latter are lubricated by secreted, nutrient fluid.



The *matrix*, containing *chondroblasts* and *chondrocytes*, varies in appearance in composition, and in the nature of its fibres. Hence there is *hyaline cartilage* (*hyalos* = glass), *white fibrocartilage* (with much collagen) or *yellow elastic fibrocartilage* (with an elastin network). A densely *cellular cartilage*, with thin septa of matrix between its cells, is a stage in development of early embryonic cartilage and a permanent tissue in many mammalian pinnae. White and yellow elastic fibrocartilage are specific, relatively unvarying tissues, whereas hyaline cartilage embraces a wide range of appearaces varying much in composition and properties according to age and location as well as species.

Cartilage cells (3.13A,B,14) occupy small *lacunae* in the matrix which conform to their shape. Young cells (*chondroblasts*) are smaller, often flat, irregular in contour and bear many surface projections (*filopodia*) fitting complementary recesses in the matrix. Early postmitotic chondroblasts often have intercellular contacts which are necessarily transient, disappearing as matrix synthesis proceeds. As these cells mature, they lose the ability to divide and become metabolically less active. Some authors reserve the name *chondrocytes* for such cells; but this term is, by some, employed to denote cartilage cells of all degrees of activity, a practice which will largely be followed here. When appropriate, however, chondroblasts and chondrocytes are distinguished. Mature *chondrocytes* enlarge with age and, though rounder, still have a few filopodia (p. 31) and an occasional cilium. The internal structure of chondrocytes is typical of cells active in making and secreting proteins (Stockwell 1978, Sheldon 1983, Kühn 1986). Their nucleus is rounded or oval, euchromatic and possesses one or more prominent nucleoli. The cytoplasm is filled with granular endoplasmic reticulum, transport vesicles and Golgi complexes, and contains many mitochondria and frequent lysosomes. Also present are numerous glycogen granules, intermediate filaments (vimentin) and pigment granules. With final maturation of these cells to the relatively inactive chondrocyte stage, the nucleus becomes heterochromatic, the nucleoli smaller, and the apparatus of synthesis and secretion (endoplasmic reticulum, Golgi apparatus, etc.) much reduced; often such cells accumulate lipid vacuoles, quite large in diameter.

The matrix is composed of collagen and, in some cases, elastin fibres, embedded in a water-filled yet stiff ground substance (3.17). These components have various chemical features which are unique to cartilage, and confer upon it unusual mechanical properties. The *ground substance* is a firm gel, rich in carbohydrates and therefore stainable with the periodic acid-Schiff method; the carbohydrates are predominantly acidic, and are hence basophilic, strongly binding such dyes as haematoxylin, alcian blue and toluidine blue, and giving metachromatic coloration with the latter. The chemistry of the ground substance is complex, consisting mainly of water and dissolved salts, held in a meshwork of long interwoven proteoglycan molecules together with various other minor constituents, mainly proteins or glycoproteins and some lipid.

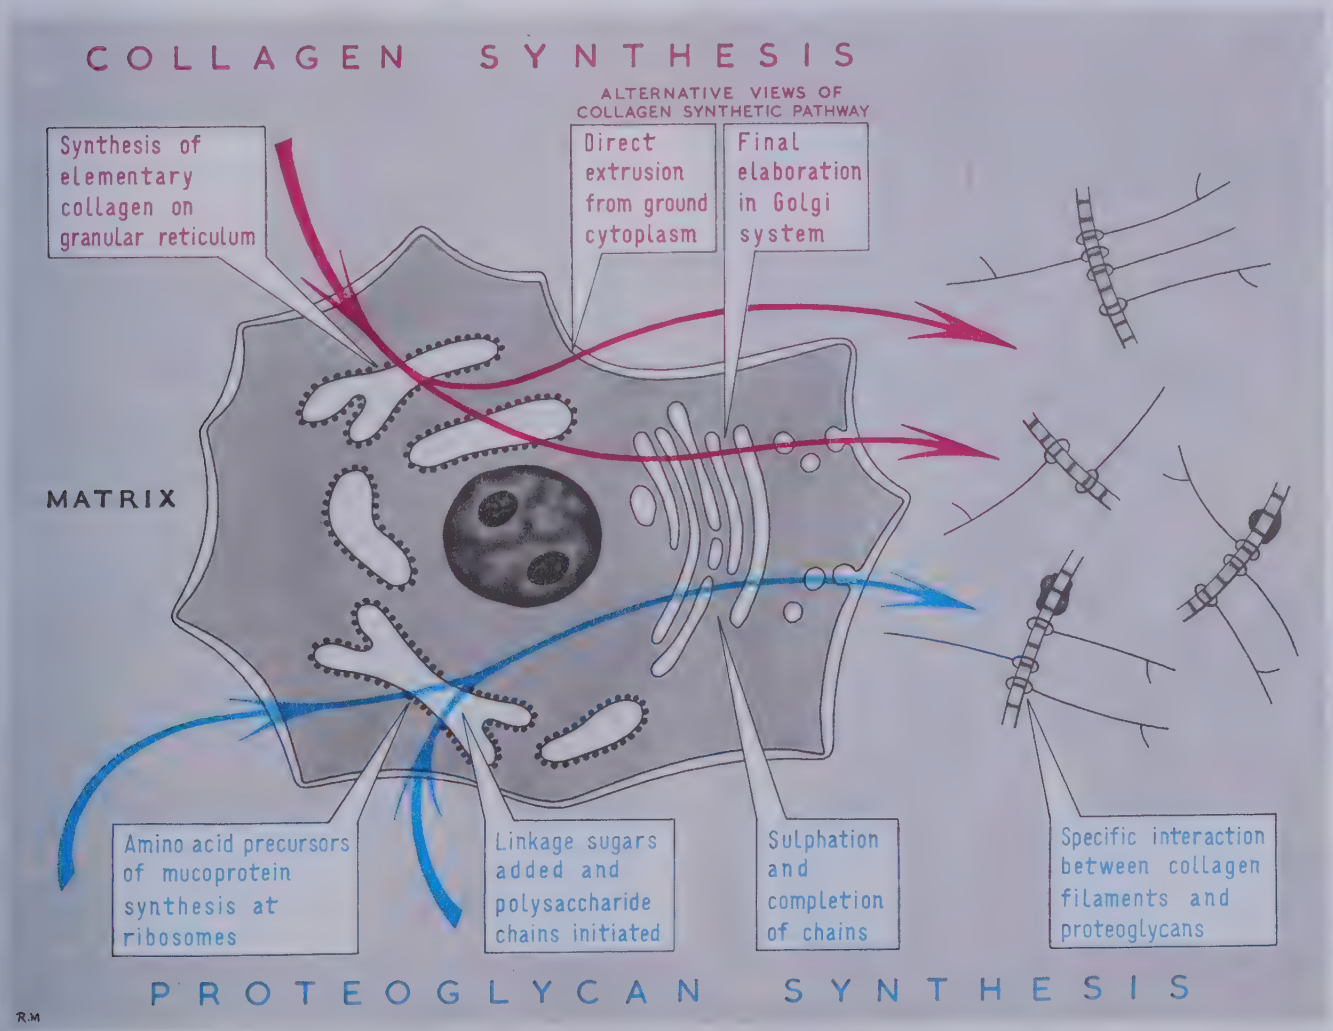
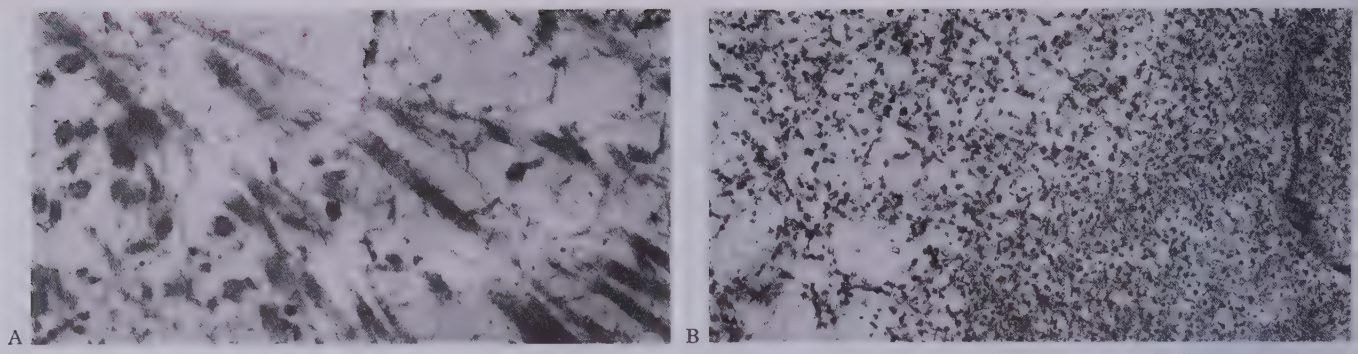
3.13 Sections through hyaline cartilage (human rib), stained with haematoxylin and eosin. A is a low-power view, showing perichondrium, chondroblasts and mature chondrocytes embedded in the basophilic matrix; magnification × 150. B higher magnification showing groups of chondrocytes within lacunae. Note the basophilic zones (rich in proteoglycans) around the cell clusters; magnification × 1000.



3.14 Transmission electron micrograph of an ultra-thin section of a perfusion-fixed specimen of a rabbit's femoral condylar cartilage. The centrally placed chondroblast contains an active euchromatic nucleus with a prominent nucleolus. Its cytoplasm contains a rich concentration of roughly parallel concentric flattened cisternae of rough endoplasmic reticulum, scattered mitochondria, lysosomes and aggregations of glycogen. Its plasma membrane bears numerous short filopodia which project into complementary recesses in the surrounding matrix. The latter shows a delicate fibrillary feltwork with a finely dispersed granular interfibrillary substance. No pericelluar 'lacuna' is present; the matrix separates the central chondroblast from the sectioned cytoplasmic periphery of two adjacent chondroblasts. The left profile, crescentic in outline, is characteristic of chondroblasts with an almost squamous form that are sited near the articular surface; magnification × 14 500. (Preparation by Susan Smith, Department of Anatomy, Guy's Hospital Medical School, London.)

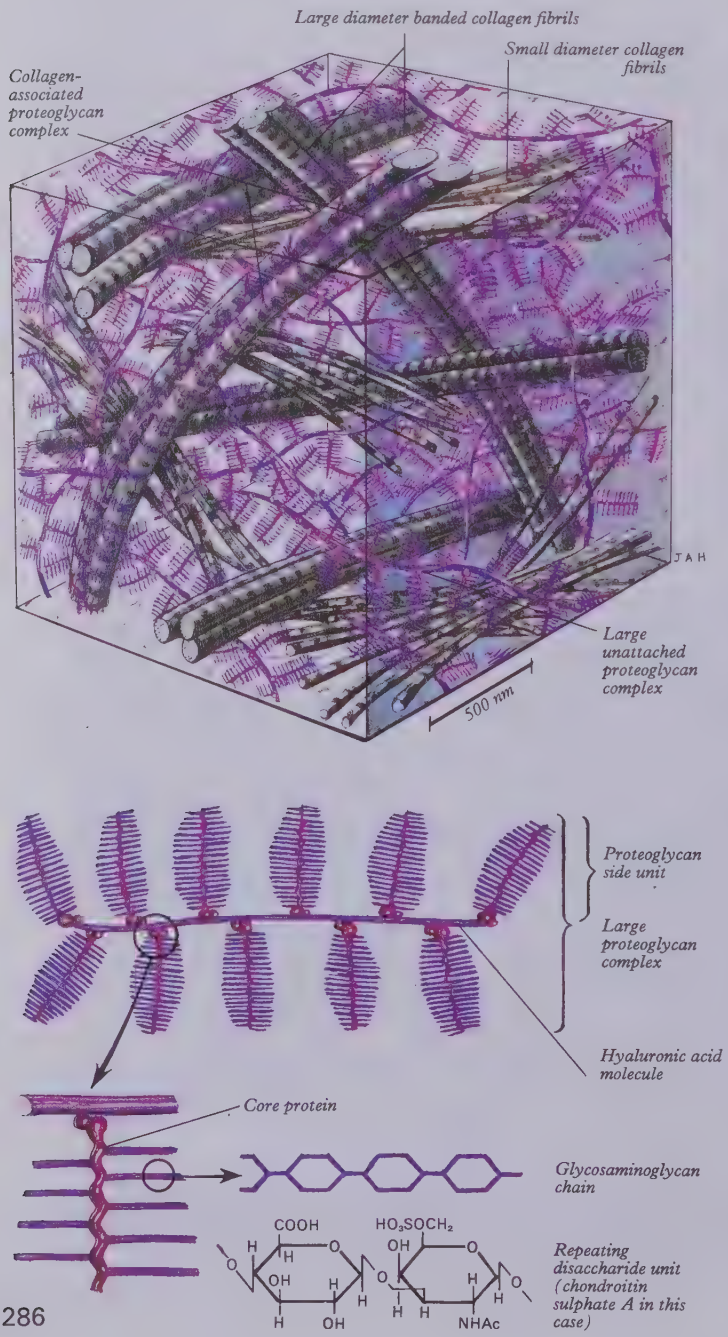
The collagen of the cartilage matrix (3.16), forming up to 50% of its dry weight, is chemically distinct from that of most other tissues, being classed as Type II collagen; elsewhere this variety is only found in the notochord, the nucleus pulposus of the intervertebral disc, the vitreous body of the eye and in the primary corneal stroma. Its tropocollagen subunits are composed of triple helices of identical polypeptides (three α-1 chains; see p. 64), although collagen in the outer layers of the perichondrium and much of the collagen in white fibrocartilage belongs to the general connective tissue type I. The majority of the collagen fibres of cartilage are too small to be individually visible except by electron microscopy; they are relatively short, thin (mainly 10–20 nm diameter) structures with the characteristic cross banding (at 64 nm intervals in sections) and they are interwoven to create a three-dimensional meshwork linked by lateral projections of the proteoglycans associated with their surfaces. Various studies have shown that proteoglycans partially ensheath collagen fibres, and their concentrations often share the periodicity of the fibres. Proteoglycans and other organic molecules thus link collagen fibres with each other, with the interfibrillar material of the ground substance and also with the cells of cartilage (vide infra).



Collagen fibres vary greatly in their amounts, sizes and orientation in different types of cartilage, as also with maturity and position within the cartilage mass. In articular cartilage, collagen fibres close to the surfaces of cells are particularly narrow (4–6 nm across) and resemble fibres of Type II cartilage in non-cartilagenous sites (vide supra).

In addition to Type II collagen, minor quantities of other classes unique to cartilage are present (Mayne & Irwin 1986), including Types IX and X, and isolated collagen polypeptide chains (1α, 2α, 3α). The significance of these is as yet unclear, but they may be involved in stabilizing Type II collagen networks (Type IX) and in hypertrophic changes in some types of cartilage (Type X). As described below, other types of fibre are also present in some classes of cartilage; these include elastin fibres in elastic fibrocartilage and, where ligamentous structures are inserted, as in fibrocartilage, Type I collagen, derived from fibroblasts rather than chondrocytes.

The proteoglycans of cartilage are similar in general outline to those of general connective tissue (see p. 67), although with features peculiar to cartilage. They consist of various long polymers, often branched, of carbohydrates termed glycosaminoglycans (GAGs; see Hascall & Hascall 1981). These are acidic, bearing anionic sulphate and carboxyl groups which give them a net negative charge. Groups of GAGs are covalently bound to a filament of protein (the 'core protein', with an *M*r of 250 000, and a length of 300 nm) which may bear more than on hundred GAGs of different types sticking out sideways like the bristles of a bottle brush (3.17). In turn, several such proteoglycan assemblies can be bound along the length of a relatively huge (a million or more in relative molecular mass) hyaluronate molecule (another type of GAG) to form highly complex, filamentous aggregates. Other, smaller 'link proteins' are involved in this interaction. Because of the predominance of acidic groups there is a tendency for the chains to repel each other, thus standing out stiffly from the central core protein. Weak intermolecular forces hold these aggregates together as a three dimensional network with large water-filled spaces within. This arrangement allows the



3.15 Summary of some of the important biosynthetic pathways of the chondroblast.

3.16 Electron micrography of hyaline cartilage matrix. The matrix in A shows thick, banded collagen fibrils and thinner, unbanded ones. Traces of finely filamentous proteoglycan complexes can also be seen adhering to and connecting collagen fibrils; magnification × 30 000. In B the matrix has been fixed in the presence of ruthenium red to preserve proteoglycan complexes, which are here visible as densely staining beaded structures representing collapsed assemblies of protein and glycosaminoglycans; magnification × 10 000. (Provided by Moya Meredith Smith.)

3.17 Diagram showing the fine structural organization of hyaline cartilage matrix. Depicted are large proteoglycan complexes and type II collagen fibres of the coarser cross-banded and the narrower varieties. Proteoglycan complexes bind to the surface of these fibres and link them together. Detail shows the arrangement of glycosaminoglycans and core filaments. See text for further details.

ready diffusion of water and dissolved materials through the ground substance, although water and other electrolytes are also loosely bound by the electrostatic forces on the surfaces of the charged macromolecules. In the living state the molecular aggregates appear to be compressed into a smaller volume than would be expected from their shape, the length of their chains and electrical repulsions between their subunits. It has been suggested that the proteoglycans may act as minute compressed springs, storing energy when further compacted then releasing it on recoil and so conferring elastic properties on the matrix.

In electron microscope sections, these large molecular arrays generally collapse to small dense granules about 20 nm across as their hydration sheaths are stripped away. However, when separated by centrifugation and negatively stained, their complex feathery nature is clearly visible.

Glycosaminoglycans found in the proteoglycans include chondroitin 4-sulphate, chondroitin 6-sulphate and dermatan sulphate (otherwise termed chondroitin sulphates A,C and B), and also keratan sulphate. These are polysaccharides mainly composed of repeating disaccharides, one invariably a substituted hexosamine and the other an esterified hexuronic acid or substituted hexose. Thus chondroitin 4- and 6-sulphates comprise repeating N-acetylgalactosamine and glucuronyl sulphate disaccharides, differing only in the siting of the sulphate ester linkage. Keratan sulphate is a polymer of disaccharides composed of an N-acetylgalactosamine and a D-galactose with a sulphate ester linkage of variable position. The relatively huge hyaluronate molecules have similar repeating disaccharides of N-acetylglucosamine and glucuronate composition, but are not sulphated and are unbranched.

These different chemical configurations result in different numbers of electrostatic charges, different degrees of interactions between adjacent chains and other variations in bulk properties which determine many of the physical and chemical properties of the matrix.

Cell adhesion proteins. These include various proteins and glycoproteins which have recently been shown to play an important role in the adhesion of chondrocytes to matrix components. The best known is *chondronectin*, a cartilage glycoprotein important in the adhesion of chondroblasts to Type II collagen fibres in the presence of chondroitin sulphates. It has an *M*r of about 150 000 (Hewitt et al 1980); and is synthesized by chondrocytes. Another adhesion molecule is anchorin CII (von der Mark et al 1986), a glycoprotein with an *M*r of 34 000 found at chondrocyte surfaces and binding specifically to Type II collagen. There may also be other similar substances which play a part in stabilizing the structural complex of cells and matrix components.

Lipid is also present as part of the matrix, in the form of small spheroidal masses stainable with lipid-soluble dyes for light microscopy (Meachim & Stockwell 1978). Some of this may be the result of cell disintegration, or shedding of cytoplasm, and some

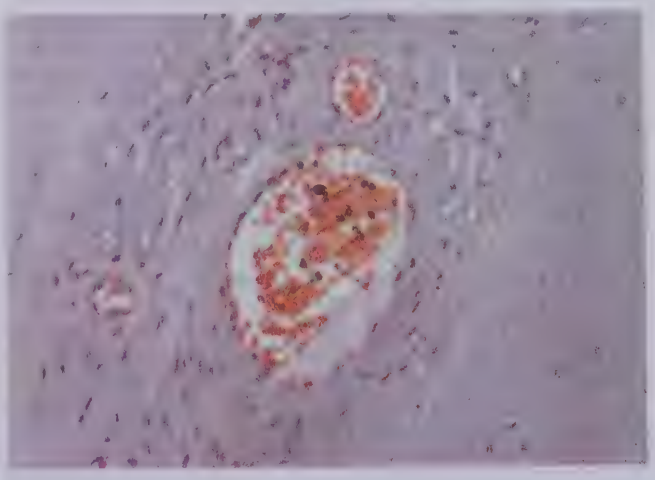
is membranous material or portions of cells, e.g. the matrix vesicles found in epiphyseal plates (p. 302).

In summary, the matrix of cartilage is a labyrinth of protein and proteoglycan filaments, its interstices occupied by bound water, cations and various other small molecules. Reactions to mechanical stresses accordingly reflect interacting contributions from all these structural elements. The properties of the 'walls' and 'contents' of this molecular meshwork also affect the diffusion of nutrient and waste material throughout this remarkable tissue.

Synthesis of matrix by chondrocytes (3.15). It is now well established that all of the major components of the matrix are synthesized and secreted by chondrocytes. These processes have been studied extensively with a battery of biochemical, structural and autoradiographic methods, and more is known about the synthetic activity of these cells than any other cell type of connective tissue (see the reviews by Prockop et al 1979, Dorfman 1981, Mayne & von der Mark 1983). To summarize these findings briefly, collagen is synthesized within the granular endoplasmic reticulum in the same way as in fibroblasts (p. 65), except that Type II rather than Type I procollagen chains are made (Olsen 1981). These assemble into triple helices and some carbohydrate is added at this stage. After transport to the Golgi apparatus, where occurs further glycosylation, they are secreted as procollagen molecules into the extracellular space. Here, terminal registration peptides are cleaved from their ends, so forming tropocollagen molecules, and final assembly into collagen fibres takes place. In other regions of the granular endoplasmic reticulum, core proteins of the proteoglycan complexes are synthesized and addition of GAG chains is begun, completion of the process being carried out by the Golgi complex (Lohmander & Kimura 1986).

The large molecules of glucuronate appear to be synthesized enzymes inserted in the plasma membrane of the chondrocyte and are thought to be extruded directly into the matrix without passing through the endoplasmic reticulum (Prehm 1986).

NUTRITION OF CARTILAGE



Cartilage is often described as totally avascular. This is not wholly true but most cartilage cells are unusually distant from exchange vessels, which are mostly perichondrial. Between this perichondrial capillary network and chondrocytes, nutrient substances and metabolites diffuse along concentration gradients across the intervening matrix. This limitation is reflected in the restriction of most living cartilage masses to a few millimetres in thickness. Cartilage cells further than this from a nutrient vessel do not survive, and their surrounding matrix typically becomes calcified.

Cartilage Canals (Haines 1933–4, Hurrell 1934–5, Levene 1964, Blackwood 1965, Lutfi 1970, Brookes 1971, Stockwell 1978, Kuettner & Pauli 1983).

Nutrition is augmented, at least in cartilaginous epiphyses of large mammals (and their analogues in birds and reptiles) by branching of *cartilage canals* (Brookes 1971), each containing small vessels from centripetal rami of a perichondrial artery and vein. Perfusion (Brookes 1958) and histological examination (Wilsman & Van Sickle 1972) suggest that each canal contains a central small artery or arteriole surrounded by numerous venules and perivascular capillaries (3.18,19). The central vessel, at the blind end of the canal, forms several capillaries from which venules pass back to a parent perichondrial vein. Capillaries lined by fenestrated endothelium also branch off along the canal and, with terminal capillaries, mediate metabolic exchange with the cartilage mass (Wilsman & Van Sickle 1972). The canalicular vessels lie enclosed in loose connective tissue, abundant in fibroblasts and macrophages and continuous with the perichondrium.

Various theories have been proposed for their formation. The possibility that they are derived from perichondral vessels which have been engulfed by the appositional growth of cartilage around them is attractively simple, but does not explain many findings, e.g. that cartilage canals are formed more rapidly than the growing front of cartilage moves forwards. It appears instead that canals actively invade cartilage, probably by the action of macrophages and other erosive cells (Wilsman & Van Sickle 1972); among the latter the endothelium of the central blood vessels may be important, as the ability of these cells to release chondrolytic agents has been demonstrated in tissue culture (Moscatelli et al 1981). However, chondrocytes themselves are also able to degrade cartilage matrix (*chondrocytic chondrolysis*, see Aydelotte et al 1986), and may also play a part in canal formation, either subsequently dying ahead of an advancing blood vessel to present it with a series of preformed cavities or, having freed themselves from the matrix, de-differentiating to form other mesenchymally-derived cells of the cartilage canals.

Cartilage canals are not random, but have a characteristic pattern in each cartilage. Canals in a fetal epiphysis form two groups, the more conspicuous passing from the non-articular surfaces towards its centre, the less prominent from vessels in the ossification groove (of Ranvier, p. 299); capillary tufts at the ends of the latter are complex and glomerular, like those in postnatal

3.18 Section through the proximal cartilaginous end of the tibia of a young child showing a cartilage canal and its contained blood vessels, stained with haematoxylin and eosin.

3.19 Capillary plexuses in the terminal arborization of a cartilage canal in the femoral condylar epiphysis of a seven-month human fetus. Specimen injected with Indian ink. (Provided by Murray Brookes, Department of Anatomy, Guy's Hospital Medical School, London.)

subchondral circulation (Trueta & Morgan 1960). According to Brookes (1971), the pattern of arteries in some adult bony epiphyses closely resembles the canalicular pattern in corresponding fetal epiphyses, concluding that vessels in the canals are forerunners of main epiphysial vessels in mature bone, and that vessels in the minor group of canals originating in Ranvier's groove are precursors of subchondral vascular networks on the epiphysial side of growth cartilages in postnatal life.

Cartilage canals are believed to assist nutrition of large cartilages, which would depend otherwise solely on perichondrial capillaries. This process appears to be faster than formerly considered both in young cartilage and in mature (vide supra); also labelled ions are concentrated by chondrocytes of mature articular cartilage with unexpected rapidity (Hall 1965), despite the absence of canals and perichondrium. Furthermore, the half-life of proteoglycans in rabbit articular cartilage is four days (Mankin & Lipiello 1969). While it might be expected that large cartilages, such as fetal limb epiphyses, possess canals, it is surprising that they also occur in carpal and sesamoid cartilages in early fetal hands, and even in the epiphyses of human fetal phalanges at 11 cm crown-rump length (Gray et al 1957).

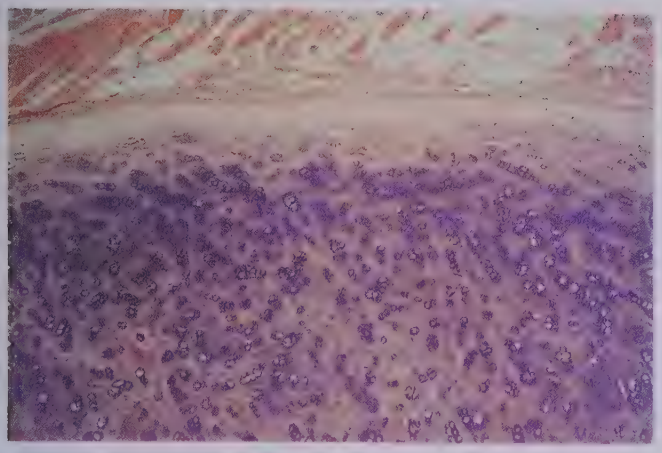
While not denying a nutritional function, most workers consider that cartilage canals are involved in forming secondary centres of ossification (and primary centres in bones without epiphyses). But puzzling anomalies remain. Distal phalangeal and proximal metacarpal epiphyses develop elaborate cartilage canals, though lacking ossification centres. There is also no clear connection between onset of chondrification, the first appearance of canals and onset of ossification; all occur at times peculiar to each skeletal element (Brookes 1971). The contents of canals appear to provide osteogenic cells and capillaries for ossification when an ossification centre appears. The control of the timing of these events remains a complete enigma.

In the mandibular condylar cartilage, canals form until the second year, when they disappear. Canals in laryngeal and nasal cartilages first form in the seventh month in utero, persisting until old age; in costal cartilages they arise in the first year, reaching the centre of the shaft about the tenth year. In long-lived canals, marrow elements may appear after the twentieth year, persisting until the sixties, when atrophy supervenes, canals retaining a mucinous material.

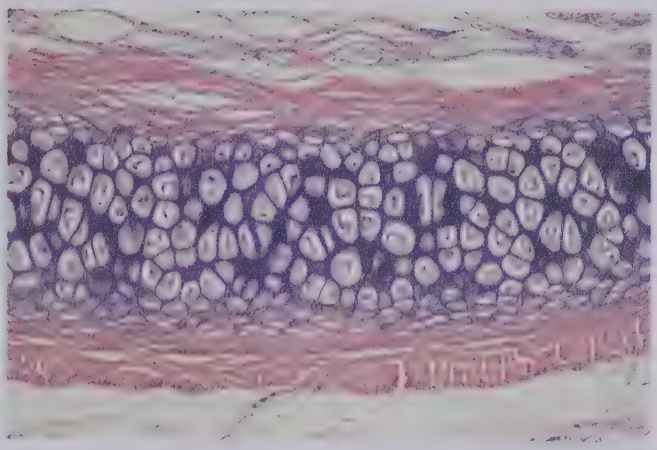
VARIETIES OF CARTILAGE

Cartilage may be *hyaline*, *white* and *yellow fibrocartilage* and *cellular cartilage*. It may also be *calcified*.

Hyaline cartilage (**3**.20A) has a glassy, bluish, opalescent, homogeneous appearance, firm consistency and some elasticity. Costal, nasal, some laryngeal, tracheobronchial, all temporary and most articular cartilages are hyaline but there are marked differences in size, shape and arrangement of cells and fibres and proteoglycan composition at different sites and ages. Its cells vary in shape from quite flat near the perichondrium to rounded or bluntly angular deeper in the tissue. They are often in groups of two or more (*cell nests* or *isogenous cell groups*) which are the offspring of a common parent chondroblast; such cells have a straight outline where apposed to each other, but a rounded contour in general. The matrix is typically basophilic and metachromatic, both more pronounced where recently formed matrix bounds a lacuna. This distinctive zone is the *territorial matrix* or *lacunar capsule*, contrasting with the pale-staining *interterritorial matrix* between cell nests.



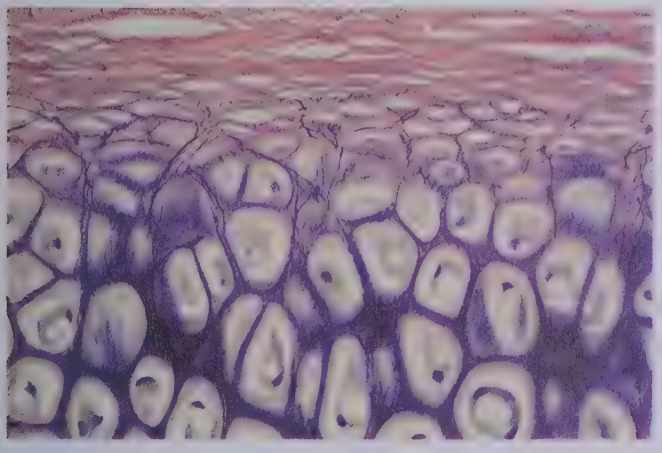
The fresh matrix is transparent and structureless, or dimly granular like ground glass when viewed by standard light microscopy. By polarized light or electron microscopy it appears permeated by fine fibrils and fibres of collagen, 10–20 nm in diameter (see p. 285). Electron microscopy shows that around each chondrocyte there is some zonation of the matrix. In well-fixed tissue where no cell shrinkage has occurred, the irregular surface of the chondrocyte is in direct contact with the matrix. However, there is often an encapsulating layer of proteoglycans containing fine filaments of uncertain composition, but no typical collagen, immediately surrounding the cell, probably corresponding to the limits of the lacuna seen by light microscopy. Outside this there are typical collagen fibres, often arranged in a basket-like network around one or more cells in a group, grading into the parallel fibre domain between cells, the interterritorial zone. Chondroitin sulphates are particularly prevalent in the vicinity of chondrocytes, whereas keratan sulphate predominates in the interterritorial zone.



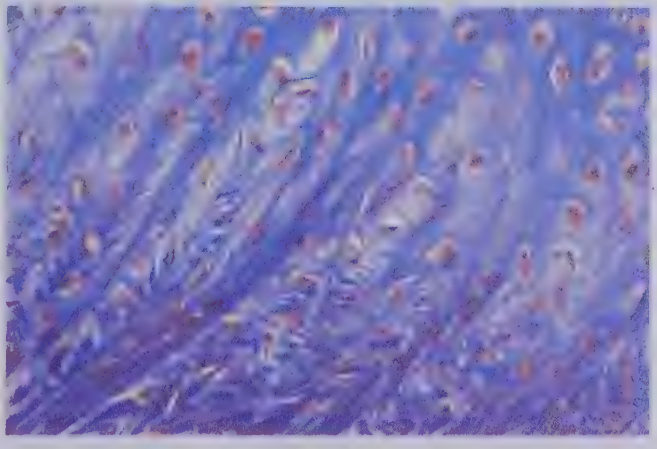
Articular hyaline cartilage (**3**.20E) covers articular surfaces in synovial joints, providing an extremely smooth, resistant surface bathed by synovial fluid, allowing almost frictionless movement (coefficient of friction 0.01–0.02, decreasing as loading increases). Its elasticity, with that of other articular structures, dissipates effects of concussions, giving the whole articulation some flexibility, particularly near extremes of movement. Articular cartilage is admirably constructed to resist the large compressive forces generated by weight transmission, especially during movement (p. 269).

It does not ossify, and varies from 1 to 7 mm in thickness; it is moulded to the shape of the underlying bone but its surface smooths, often accentuates and modifies the surface geometry. On convex osseous surfaces it is thickest centrally, the reverse being true of concave surfaces; its thickness decreases from maturity to old age. The surface of articular cartilage is devoid of perichondrium, but around its edges the synovial membrane overlaps then grades into its structure.

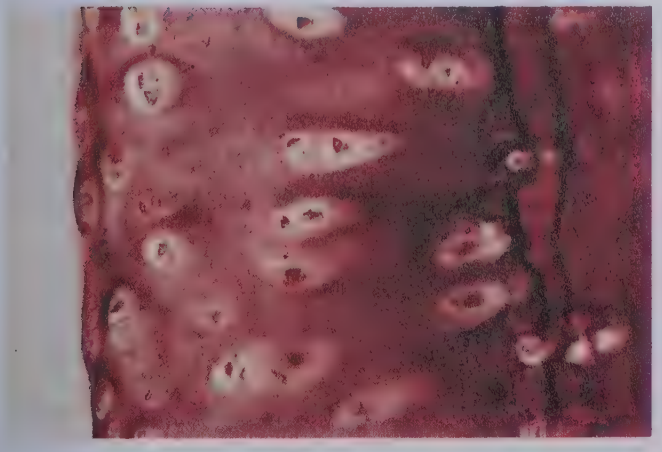
Adult articular cartilage shows a zonation in structure with increasing depth from the surface (Barnett et al 1961, Davies et al 1962, Palfrey & Davies 1966, Ghadially 1983). Except perhaps for a thin surface lamina, the matrix is pervaded by collagen fibres, those near the surface around lacunae being fine, plexiform and, at the most, faintly banded, whereas elsewhere they are coarser with the usual 64 nm banding. Their arrangement is variously described as plexiform, helical, or in the form of serial arcades radiating from the deepest zone to the surface, where they pursue a short tangential course before returning radially, as most workers confirm. It has long been known (Hultkrantz 1898, Amprino 1948) that if the surface of articular cartilage is pierced by a pin a longitudinal 'split-line' shows after withdrawal and that, for any given joint, the patterns of split-lines are constant and distinctive (cf. cleavage lines of skin). Bullough & Goodfellow (1968), using polarized light and electron microscopy, demonstrated that splits follow the *predominant* directions of collagen bundles in *tangential* zones of cartilage (vide infra). Such patterns probably reveal 'tension trajectories' set up in surrounding cartilage by local compression during habitual activities. Subsequent investigations have largely confirmed the views of Bullough & Goodfellow, e.g. split-line analysis by transmission electron microscopy (Meachim et al 1974), polarization microscopy (Ortmann 1975), and scanning microscopy (Minns & Steven 1977). Split-line arrangement, where superficial tangential bundles are not parallel, have been considered by Ortmann (1975); theoretical models for dynamics of articular cartilage have been proposed by Kempson et al (1968) and Mow et al (1974). It is pertinent to recall that some earlier workers considered split-line, and hence predominant collagen, orientation to reflect *direction* of *habitual movements*, the relation of this to tension trajectories being unknown. Others (e.g. McCall 1968) deny any significant collagen orientation in articular cartilage. Serafini-Fracassini & Smith (1974) propose that the basic function of articular cartilage collagen is not resistance to tensile stresses, but provision of *fixation anchors* for viscoelastic *domains* of proteoglycan molecules when subjected to deforming and displacing stresses. Clearly, no model is adequate unless it includes the dynamics of *all interacting* constituents of cartilage. (For an extensive review see Freeman 1979 and **3**.20E.)



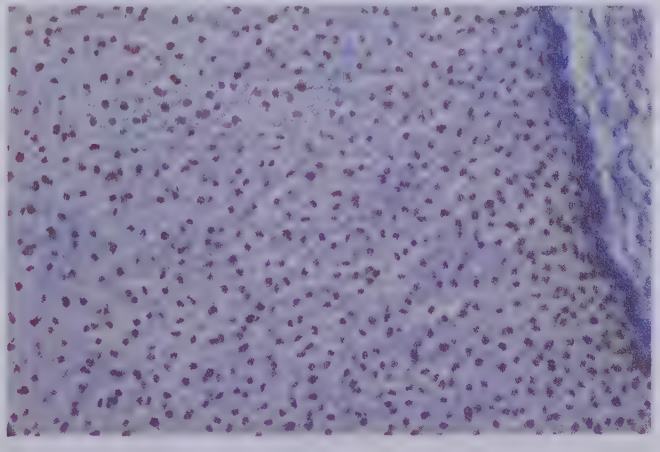
In the *superficial* or *tangential stratum* (*zone* 1) cells are small, oval or elongated, flat and parallel to the surface, and surrounded by fine tangential fibres; they have a few short projections, mainly from their lateral borders and deep surfaces, and display scattered mitochondria and small cisternae of granular endoplasmic reticulum; their Golgi apparatus is not prominent. Cytoplasm is free of filaments, unlike cells in deeper zones. The nature of the *articular surface*, the thin superficial layer of zone 1 (*lamina splendens*), remains uncertain. ('Lamina splendens' was introduced by



3.20 Different types of cartilage: A. Hyaline cartilage (chondral), (see also 3.13 A,B) H & E, magnification × 150.



B. Elastic fibrocartilage, stained with Gomori's elastin stain (blue-black), and van Gieson's collagen stain (pink), which shows the fibrous perichondrium clearly. Pinna (rabbit); magnification × 150.



C. Higher magnification of B, showing fibrous perichondrium, chondroblasts and larger chondrocytes embedded in a matrix rich in elastin fibres, magnification × 400.

D. White fibrocartilage in late fetal intervertebral disc, showing chondroblasts between coarse collagen fibres derived from the annulus fibrosus; H & E, magnification × 150.

E. Articular cartilage stained with silver, showing cellular arrangement of the different layers. Note the absence of a periosteum, the superficial flattended cells of layers I and II, the more rounded chondrocytes of layer III, the lines of calcification in the deeper layer (IV) and the lamellar bone adjacent to the cartilage (see text for details). Interphalangeal joint (Rhesus monkey), magnification × 400.

F. Fetal cartilage, human phalanx, stained with Mallory's triple stain. Note the highly cellular appearance. The cells are small and almost uniform in distribution. Mallory's stain, magnification × 150.

MacConaill 1951, for the brilliantly illuminated surface zone, in contrast to the dark main mass, visible in *oblique* sections by negative phase-contrast. Dimensions thus obtained cannot be compared with the data of other techniques, which limits the term's usefulness.) This surface zone is said to be a cell-free, 3 μm thick layer of compact, non-banded, randomly arranged, fine filaments 4 to 12 nm in diameter (Weiss et al 1968), which appear to branch frequently in a scanty proteoglycan ground substance. Deep to the lamina splendens are typical banded collagen fibres, regularly tangential, their diameters increasing with depth. These observers also noted that flat, oval cells deep in zone 1 closely resemble quiescent mature fibrocytes; they considered that synovial articular surfaces are probably formed by fine modified collagen filaments, their cells of origin more deeply placed. Others (Mow et al 1974) designated the surface layer of zone 1 the *superficial tangential zone*, described as sheets of tightly *woven* collagen fibrils parallel to the surface, from 5 to 20 nm in diameter and forming a layer from 1 to 200 μm in thickness. It is said to be poor in glycosaminoglycans but rich in hyaluronate.

The deeper cells of the *transitional* or *intermediate stratum* (*zone 2*) are larger, rounder, single or in isogenous groups. Most are largely typical active chondrocytes in ultrastructure (vide supra) and around them pass oblique collagen fibres.

Deeper still, in the *radiate stratum* (*zone 3*), cells are large, round, often in vertical columns, with intervening radial collagen fibres.

The deepest layer or *calcified stratum* (*zone 4*) adjoins the *hypochondral osseous lamina* of the epiphysis. These adjacent surfaces show reciprocal fine ridges, grooves and interdigitations, which, with the confluence of their fibrous arrays, resist shearing stresses due to postural changes and muscle action.

Concentrations of glycosaminoglycans vary: that of chondroitin sulphate increases fivefold in the intermediate zone, reducing to threefold in zone 4; but that of keratan sulphate increases linearly with depth; the latter is mainly in the interterritorial matrix, whereas chondroitin sulphates are largely circumlacunar.

This sequence of structural changes from normal hyaline cartilage through columnar arrays of cells, a zone of calcified cartilage and eventually epiphysial bone, is also typical of cartilaginous growth plates (p. 305). It follows radial epiphysial growth by the extension of endochondral ossification into overlying calcified cartilage. This ceases in maturity, but the zones persist throughout life. The same terminal mechanism also occurs in bones lacking epiphyses.

Cells of articular cartilage divide by mitosis, but mitoses are few except in young bones. Progressive loss of superficial cells from normal young joint surfaces, and their replacement by cells from deeper layers, is unconfirmed; but degenerating cells may occur in any of the four zones. This probably accounts for progressive reduction in cellularity of cartilage with advancing age, particularly in superficial layers (Stockwell 1967) and probably contributes to the variable lipid content of the matrix.

Articular cartilage may derive nutriment by diffusion from three sources: vessels of the synovial membrane, synovial fluid and hypochondral vessels of an adjacent medullary cavity, many capillaries from which penetrate and even traverse the calcified cartilage (Holmdahl & Ingelmark 1950, Barnett et al 1961), and have been estimated to contact 1–7% of the osseous aspect of the cartilage. For *relative* contributions from these sources evidence is lacking, but accurate determinations of permeability of articular cartilage are available (Maroudas et al 1975). Small molecules freely traverse articular cartilage, with diffusion coefficients about half those in aqueous solution. Larger molecules have diffusion coefficients inversely related to molecular size, e.g. glucose, inulin and haemoglobin (relative molecular masses: 180, 5000 and 68 000) have molal distribution coefficients in the ratio 85:11:1. Permeability of cartilage to large molecules is much affected by variations in its glycosaminoglycan content; e.g. a threefold increase multiplies the partition coefficient a hundredfold.

In costal cartilage cells and nuclei are large; the matrix is usually homogeneous and transparent, and tends to fibrous striation, especially in old age. In their thickest parts a few large vascular channels and sometimes medullary elements may appear (p. 287). The xiphoid process and the cartilages of nose, larynx and trachea (except the elastic fibrocartilaginous epiglottis and corniculate cartilages) resemble costal cartilage in microstructure. The arytenoid cartilage changes from hyaline at its base to elastic cartilage at apex. Hyaline cartilages, after adolescence, are prone to calcification, especially in costal and laryngeal sites. Quantitative studies demonstrate diminishing cellularity throughout costal cartilages with advancing age (Stockwell 1979).

White fibrocartilage (**3**.20D) is dense, fasciculated, white fibrous tissue, with attendant fibroblasts and small interfascicular groups of chondrocytes; the cells are ovoid and surrounded by concentrically striated matrix. When amassed, as in intervertebral discs, fibrocartilage has great tensile strength with appreciable elasticity. In lesser amounts, as in articular discs (p. 470), glenoid and acetabular labra (pp. 501 and 519), the cartilaginous lining of bony grooves for tendons and some articular cartilages (vide infra), it is a tissue of strength and elasticity able to resist repeated pressure and friction. This tissue is unlike other types of cartilage in having much Type I (general connective tissue) collagen in its matrix; it is perhaps best regarded as a mingling of the two types of tissue, e.g. where a ligament or tendinous tissue inserts into hyaline cartilage, rather than a specific type of cartilage. The fibrocartilage of joints is often altogether lacking in Type II collagen and possibly represents a quite distinctive class of connective tissue, designated cartilage only for the convenience of histologists. The articular surfaces of bones which ossify in mesenchyme are covered by white fibrocartilage (e.g. squamous temporal, mandible and clavicle). Electron microscopy of such articular cartilages (Silva & Hart 1967) shows that *deep layers*, adjacent to hypochondral bone, resemble calcified, degenerative and hypertrophic regions of the radial zone of *hyaline* articular cartilage. The *superficial zone* contains dense parallel bundles of thick collagen fibres, interspersed with typical dense connective tissue fibroblasts and scanty ground substance. Fibre bundles in adjacent layers alternate in direction as in the cornea. A *transitional zone* of irregular bundles of coarse collagen and fibroblasts with prominent Golgi complexes separates the two. The fibroblasts are probably involved in elaboration of proteoglycans, or may be a germinal zone for deeper cartilage. For permeability of white fibrocartilage in intervertebral discs consult Maroudas et al (1975).

Yellow elastic fibrocartilage (**3**.20B,C) occurs in external ears, corniculate cartilages, epiglottis and apices of the arytenoids. It contains typical chondrocytes, but its matrix is pervaded by yellow elastic fibres except around lacunae, where it resembles typical hyaline matrix. As elsewhere its elastic fibres are unaffected by acetic acid, have an affinity for orcein and show no periodic banding (Sheldon & Robinson 1958). Cox & Peacock (1977) have reviewed the ultrastructure, histogenesis and growth of chondroblasts and matrix in the rabbit's pinna. Histogenesis of elastic fibres of cartilage (and probably other tissues) is in two stages; a glycoprotein microfibrillar framework of oxytalan first appears and is then impregnated by elastin (p. 67). Most sites in which elastic fibrocartilage occurs have *vibrational* functions, such as laryngeal sound-wave production and their collection and transmission in the ear.

Histogenesis, Growth and Regeneration

Normally cartilage is formed in embryonic mesenchyme (Glenister 1976, Serafini-Fracassini & Smith 1974, Cox & Peacock 1977). Mesenchymal cells proliferate and become tightly packed, the shape of their condensation foreshadowing that of a subsequent cartilage. The cells become rounded, with prominent rotund or oval nuclei but indistinct intercellular boundaries. Each cell soon begins to secrete a surrounding basophilic halo of matrix, composed of a delicate network of fine Type II collagen filaments and cartilage proteoglycans, indicating differentiation into chondroblasts, (**3**.20F). Continued secretion of matrix further separates the cells and so typical hyaline cartilage is now recognizable. In other sites collagen synthesis predominates, many cells becoming

fibroblasts and chondroblastic activity appearing only in isolated groups or rows of cells. These are soon surrounded by dense bundles of collagen fibres to form white fibrocartilage. Similarly, elsewhere, the matrix of early cellular cartilage is permeated first by anastomosing oxytalan and, later, elastin fibres. In all cases, developing cartilage is surrounded by condensed mesenchyme differentiating into a bilaminar perichondrium in which the cells of the outer layer become fibroblasts secreting a dense collagenous matrix lined externally by vascular mesenchyme; the inner layer of perichondrium contains differentiated but mainly resting chondroblasts or pre-chondroblasts.

The growth of cartilage is both *interstitial* and *appositional*.

Interstitial growth (i.e. from within the cartilage) follows continued mitosis of early chondroblasts throughout the mass. When such a cell divides, its descendants temporarily occupy the same lacuna but are soon separated by thin septa of matrix, which thicken and further separate cells. Continuing division leads to isogenous groups. Interstitial growth is obvious only in young cartilage, where presumably plasticity of matrix permits continued expansion. However, the manner of matrix expansion and reorganization and indeed the factors determining total shape of a cartilage are as yet poorly understood.

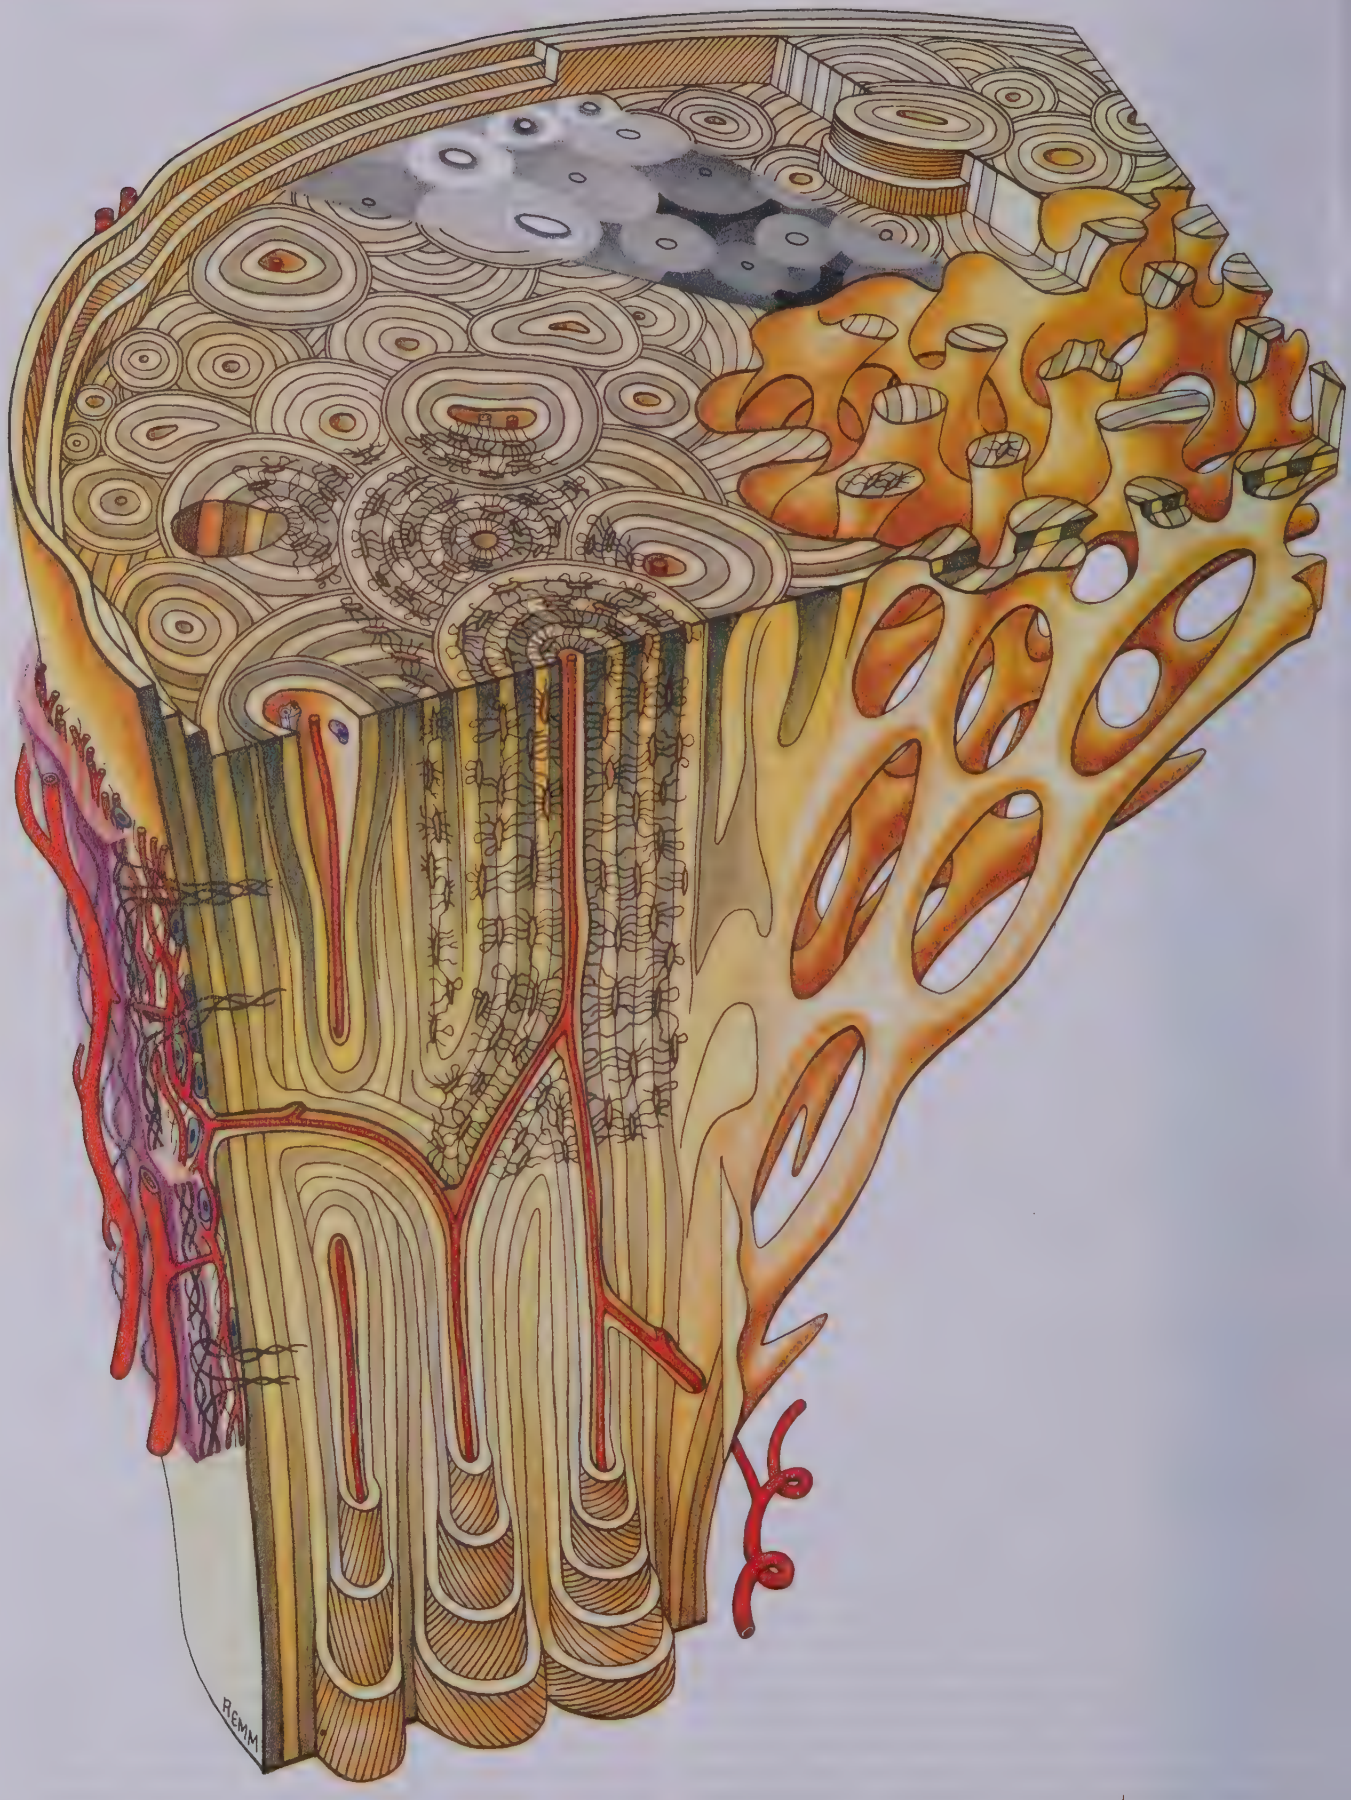
Appositional growth at the cartilage surface results from the proliferation of cells of the internal, chondrogenic layer of perichondrium. Some resultant superficial chondroblasts secrete matrix around themselves, thus creating superficial lacunae. This process, continuing, adds additional surface while the entrapped cells can now participate in interstitial growth. Apposition is often stated to be prevalent in more mature cartilages, but interstitial growth must persist for long periods in epiphysial cartilages (pp. 279, 305).

Regeneration. In mammals regeneration of lost cartilage is poor, defects being slowly filled by vascularized connective (granulation) tissue, which may become less vascular and persist as fibrous tissue. Occasionally, cells in such tissue may become chondroblasts, secreting thin capsules of matrix.

Normal cartilage growth depends on adequate nutrition and hormonal environment; disturbances due to these will be considered with endochondral ossification (p. 304). With advancing years the matrix of many permanent cartilages becomes *calcified*, also an essential step in endochondral ossification during earlier development.

Interesting features of cartilage are the low antigenicity of its matrix, its relatively low vascularity and the isolation of its chondrocytes in lacunae, which permit successful homotransplantation without marked cellular or humoral immune reaction. The paucity of blood vessels is particularly striking; recent evidence suggests that their ingrowth is actively inhibited by factors released by chondrocytes (see Kuettner & Pauli 1983).

Bone as a Tissue



Bone is essentially a highly vascular, living, constantly changing mineralized connective tissue. It is remarkable for its hardness, resilience and regenerative capacity, as well as its characteristic growth mechanisms. Like all other connective tissues (see p. 58), bone consists of cells and an intercellular matrix, the great majority of its cells, osteocytes, lying embedded within it (3.21). The matrix is composed in part (about 40% dry weight in mature bone) of organic materials, mainly collagen fibres, and the rest consists of inorganic salts rich in calcium and phosphate. Together these give bone its unique mechanical properties (see, e.g. Hancox 1972, Currey 1984). Vascular canals ramify within bone, providing its cells with metabolic support and creating avenues of entry for other cells, including osteoclasts, capable of removing bone, and osteoblasts which can deposit it. While these features are found in all bone, their details differ widely with developmental state, site, prevailing mechanical forces and the metabolic state of the body. Bone's collagen framework, permeated with mineral salts, varies from almost randomly orientated coarse bundles (woven-fibred bone) when young, to a system of highly ordered, parallel-fibred sheets or lamellae (lamellar bone) in the mature condition. Collagen fibres and mineralized matrix together usually form minute cylinders (osteons) arranged concentrically around blood vessels both in woven and lamellar bone while, in the mature state, the inner and outer surfaces of bones are lined by a few layers of continuous circumferential (outside) and endosteal (inside) lamellae. Bone may also be penetrated by bundles of collagen fibres derived from surface structures including tendons and ligaments (bundle bone). The outer surface of bone is always lined by a fibrocellular layer, the periosteum, and on the inner surface is a similar, though thinner, endosteum. In these layers lie osteoblasts, osteoclasts and other cells important in the biology of bone. The texture of mature bone also varies between dense (compact) and spongy (cancellous) osseous tissue which have distinctive mechanical and metabolic roles, often related to their positions within bones (diaphyseal, metaphyseal, epiphyseal, etc).

Developmentally, bone may form either by the direct transformation of condensed mesenchyme (intramembranous bone) or be preceded by a cartilage model which bone later replaces (endochondral bone). However, bones of different origins may show any of the features mentioned above, and can only be distinguished by a study of their genesis.

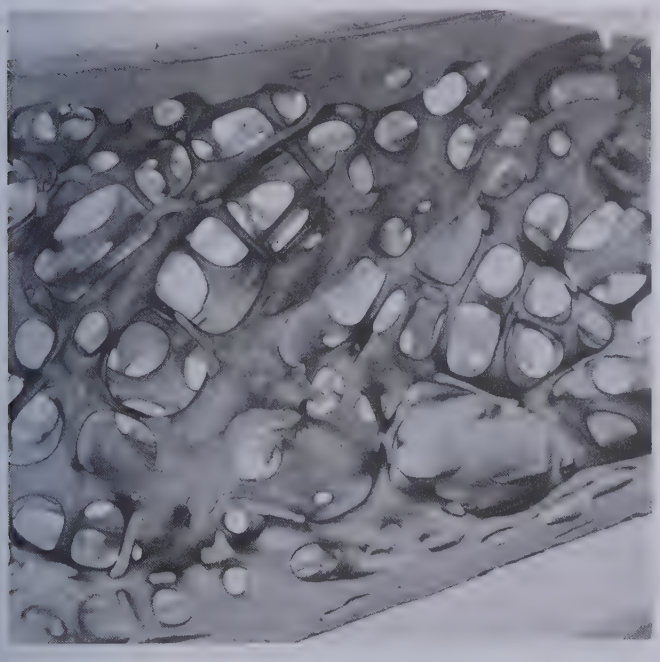
Because of these different types of classification, it may help to refer to the table set out below where the more commonly used terms have been grouped. The concepts which these reflect will be treated more fully in the following pages.

Classification and Terminology

1. **Macroscopic appearance of cut surfaces** (3.5).
   (a) *Compact bone*—the ivory surface layers of mature bone.
   (b) *Trabecular bone*—the interior of mature bones (also termed *cancellous* or *spongy* bone). Early embryonic bone is also spongiose—the *primary spongiosa* (*Os spongiosum primum*).
2. **Developmental origin**
   (a) *Intramembranous* (*mesenchymal* or *dermal* bone)—formed by direct transformation of condensed mesnchyme.
   (b) *Intracartilaginous* (*cartilage* or *endochondral* bone)—replacing a preformed cartilage model.
3. **Regions of long bones**
   (a) *Diaphysis*—intermediate region or shaft.
   (b) *Metaphysis*—developing, juxta-epiphysial regions of shaft.
   (c) *Epiphysis*—extremity with a separate centre of ossification.
4. **Organization of collagen fibres**
   (a) *Woven* bone (*coarse-bundled* bone), with an irregular collagen network—includes embryonic bone, isolated patches in adult bone, and repair tissue in fractures.
   (b) *Parallel-fibred* bone—includes all forms of lamellar bone and non-lamellar primary osteons.
5. **General microstructure**
   (a) *Non-lamellar* bone—includes early woven bone and primary osteons.
   (b) *Lamellar* bone—almost all mature bone.
6. **Disposition of lamellae**
   (a) *Circumferential* lamellae (*primary* lamellae)—parallel to both periosteal and endosteal surfaces.
   (b) *Osteonic* lamellae (*secondary* lamellae)—concentric lamellae around vascular canals of mature bone.
   (c) *Interstitial* lamellae between osteons.
7. **Types of osteon**
   (a) *Primary osteons* (*atypical Haversian systems*)—first formed, non-lamellar osteons.
   (b) *Secondary osteons* (*typical Haversian systems*)—concentric lamellae around vascular canals of mature bone.
8. **General terms**
   (a) *Surface bone*—usually circumferential lamellae but may include woven and bundle bone.
   (b) *Interstitial bone*—between osteons; often lamellar remnants of secondary osteons but may include woven or primary osteon fragments (vide infra).

3.21 Schematic diagram of some of the main features of the microstructure of mature bone seen in both transverse section (top) and longitudinal section. Areas of compact and cancellous bone are included. The central area in transverse section simulates a microradiograph, the densities reflecting variations in mineralization. Note the general construction of the osteons, the distribution of the osteocyte lacunae, the Haversian canals and their contents, resorption spaces and the different views of the structural basis of bone lamellation. See text for more detail.

Structure of Mature Bone



MACROSCOPIC STRUCTURE

Macroscopically, living bone is white, with either a dense texture like ivory (*compact bone*), or honeycombed by large cavities, the bone being reduced to a latticework (*cancellus*) or bars and plates (*trabeculae*), in which case it is called *trabecular, cancellous* or *spongy bone* (3.21). Compact bone is usually limited to the cortices of mature bones (cortical bone) and is of supreme importance in providing their strength. Its thickness and architecture vary for different bones, reflecting their overall shape, position and functional roles. In contrast, cancellous bone lies chiefly in their interior (3.22), and particularly, in the case of long bones, within their expanded ends (metaphyses and epiphyses). Cancellous bone gives additional strength to bones and supports the tissues of their marrow. It also forms a reservoir of metabolic calcium and phosphate which can be readily added to or withdrawn by cellular action under hormonal control; this property is related to its relatively large surface area in comparison with a similar mass of compact bone, making bone resorption and deposition relatively easy.

The proportions of compact to cancellous bone vary greatly. In a long bone the thick cylinder of compact bone forming the shaft presents only a few trabeculae and spicules on its inner surface so that a large central medullary or marrow cavity is enclosed, communicating freely with the intratrabecular spaces of the expanded bone ends. In other bones, especially flat ones such as the ribs, the interior is uniformly cancellous, compact bone forming the surface. These cavities are filled with marrow, either red, haemopoietic or yellow, adipose, its character varying with age and site. In the mastoid bone of the skull, many of the cavities within are filled with air, a situation which is unique in the human body, although common in the wing-bones of most birds.

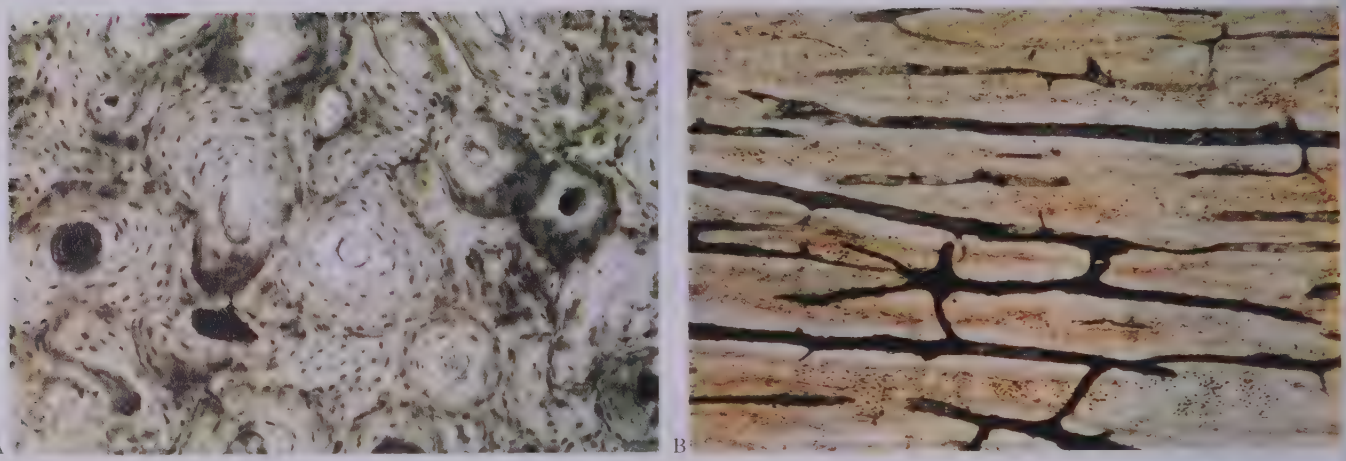
MICROSCOPIC STRUCTURE

As stated earlier, bone is composed of cells embedded in a stiff calcified matrix; these components will now be described in some detail, first individually then in terms of their overall organization.

3.22 Low power scanning electron micrograph of a segment of a human rib. Note the cortical shell of compact bone and the delicate lattice of trabeculae, separated by labyrinthine marrow spaces. (Reproduced by permission of W J Whitehouse, E D Dyson and C K Jackson, Medical Research Council Radiology Unit, Harwell.) Such specimens are used currently for quantitative studies of bone architecture; magnification × 7.

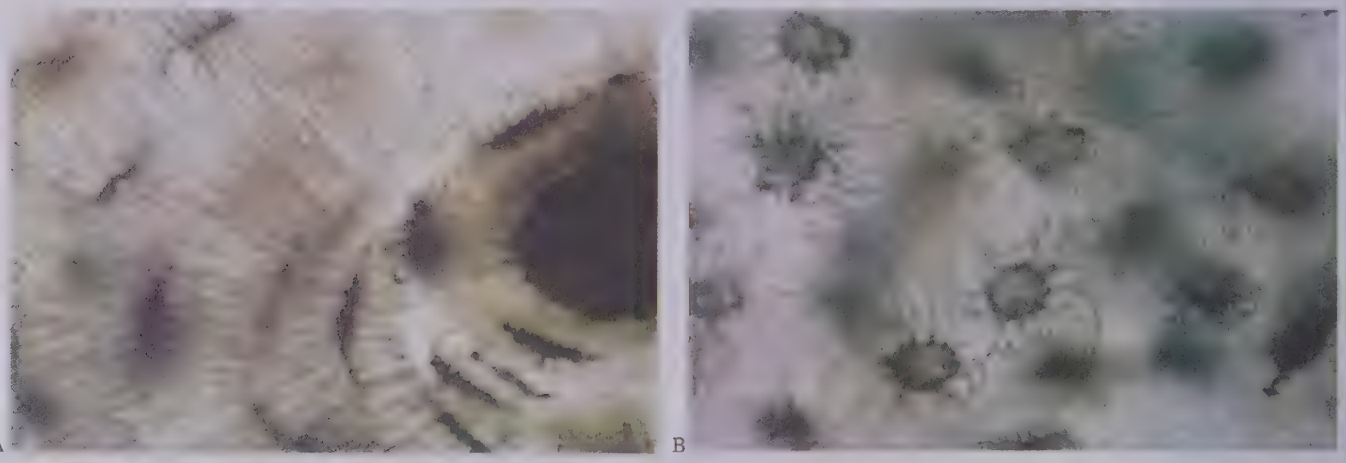
The Cells of Bone

These consist of a number of types, including: (a) osteoprogenitor cells which give rise to various other bone cells; (b) osteoblasts which lay down bone; (c) osteocytes within bone; (d) bone lining cells on its surface; and (e) osteoclasts which erode it. In addition to these are the cells of its vascular and nervous system and other components of the periosteum, endosteum and marrow. Of these different cells, the first four are closely related, while the osteoclasts arise from a quite unrelated source. Vascular and nervous tissue are, of course, of external origins.



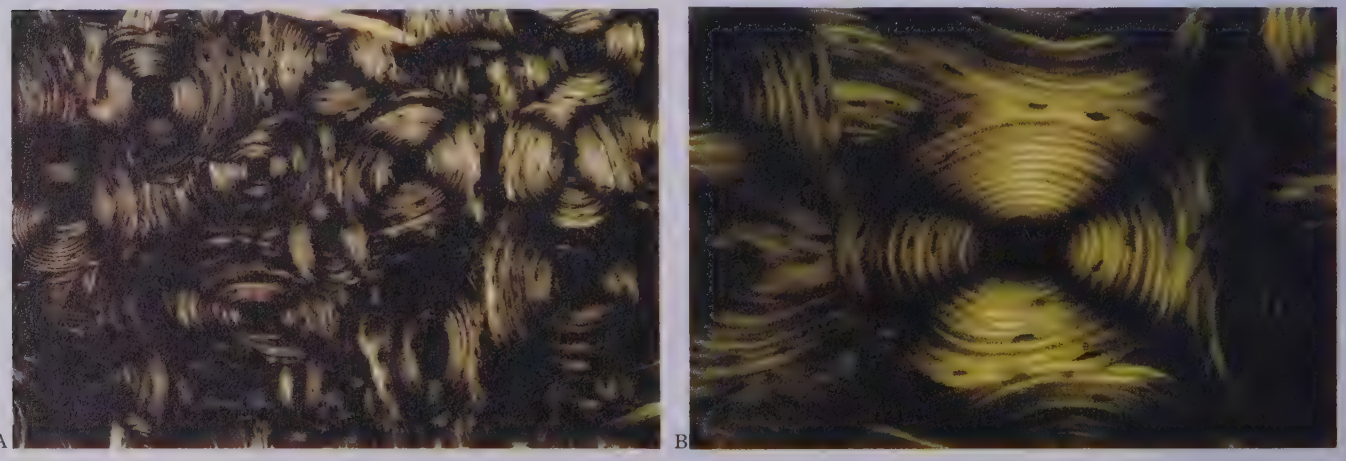
Osteoprogenitor cells. These can be defined as persistent, migratory stem cells which can proliferate and differentiate into osteoblasts prior to bone formation. They resemble young fibroblasts and are, like these, of mesenchymal origin. Such mesenchymally-derived cells are responsible for all bone formation during early development. In intramembranous bone they aggregate and undergo proliferation before transforming into osteoblasts while, during endochondral bone formation, similar cells migrate with the ingrowth of blood vessels from the perichondrium into areas of degenerating cartilage, then likewise differentiate into osteoblasts.

Cells with mesenchymal features, derived from bone, can be grown in culture and these give rise to new osseous tissue when implanted into animals. Ectopic bone formation can also be induced experimentally in various tissues of the body, e.g. skeletal muscle, by implantation of demineralized bone, dentine or urinary bladder epithelium; so it appears that there are two types of osteoprogenitor cell, one totally committed to bone formation (*committed osteoprogenitors*), found associated with bones, and the other (*inducible osteoprogenitors*) widely present in connective tissue and probably able to differentiate into various connective tissue cells (e.g. fibroblasts, adipose cells, chondroblasts, osteoblasts) depending on the nature of the inducer (Friedenstein 1976). It is also noteworthy that osteoblasts and osteoclasts were at one time thought to arise from the same progenitor cell, but it now appears that osteoclasts have a quite separate origin (Kahn et al 1983, see Osteoclasts p. 295; see also 3.40).



Osteoblasts (3.27,35,48). These are basophilic, roughly cuboidal cells about 15–30 μm across, found mainly on the surfaces of maturing or remodelling bone where they form a covering monolayer (see Friedenstein 1976, Kahn et al 1983). In relatively quiescent adult bones they appear to be present chiefly on the endosteal rather than periosteal surfaces, but also occur deep within compact bone where osteons are being remodelled. They are responsible for the synthesis, deposition and mineralization of bone matrix (Rodan & Rodan 1983) and, on becoming embedded in this, they finally transform into osteocytes (see also 3.38).

Ultrastructurally, osteoblasts have features typical of protein-secreting cells, i.e. a pale (euchromatic) oval nucleus placed away from the secreting surface, an extensive granular endoplasmic reticulum, large Golgi complex and numerous secretory vesicles. The cells are orientated so that their secretory surface abuts on to the adjacent bone. They have prominent bundles of actin, myosin and other cytoskeletal proteins associated with the maintenance of cell shape and motility. Their plasma membranes have many extensions, some contacting neighbouring osteoblasts and osteocytes at communicating junctions, by means of which the actions of quite large groups may be coordinated, as seen, e.g. in their concerted action to form large domains of parallel collagen fibres. There are irregular gaps between the cells which allow ready diffusion through the osteoblast monolayers to and from the underlying bone.



The surfaces of osteoblasts are rich in alkaline phosphatase activity, located at the plasma membrane. Some of this enzyme is shed and reaches the circulation where it can be detected in conditions of rapid bone formation or turnover. Osteoblasts of young bones have protrusions which appear to bud off vesicular structures (matrix vesicles) important in mineral deposition (vide infra p. 302). A major activity of osteoblasts is to synthesize and secrete the organic matrix of bone, i.e. Type I collagen (Wright & Leblond 1981) and various other macromolecules including the proteins osteocalcin (of uncertain function), osteonectin, which binds strongly to collagen, catalyzes the nucleation of calcium

3.23 Transverse (A) and longitudinal (B) ground sections of compact bone from human femoral shaft. Note variation in shape and size of osteons and their canals and in distribution of lacunae in A. Haematoxylin staining in B has emphasized the osteons, predominantly longitudinal but showing intercommunications. (Material for 3.23–25 prepared by David Ristow, Guy's Hospital Medical School.)

3.24A,B High-power view of part of an osteon in transverse section seen with transmitted light. Note the relation of the osteocyte lacunae and their canaliculi to each other, and to the central Haversian canal (black). Tangential section of osteocyte lacunae and their associated canaliculi. Contrast with their appearance in A.

3.25A,B Ground transverse section of the compactum of the adult human femur photographed using polarization microscopy. Compare with 3.23A. A single secondary osteon viewed with high-power polarization optics to illustrate its lamellar architecture.

phosphate and may also be a cell adhesion factor, and some minor proteoglycans (see the review of this subject by Rodan & Rodan 1983). Prior to its mineralization this organic matrix is called osteoid or pre-bone (vide infra). An equally important osteoblast function is the mineralization of this matrix, alkaline phosphatase playing a vital role in this process. Collagen synthesis is carried out in much the same manner as in fibroblasts (see p. 65), initially in the granular endoplasmic reticulum then in the Golgi apparatus, before being secreted to the exterior.

There is also much evidence that osteoblasts may play an important though indirect role in the hormonal regulation of bone resorption, since they bear receptors for parathyroid hormone and other stimulants of bone erosion. During bone deposition osteoblasts may inhibit osteoclast activity or may merely fail to

stimulate them, but in the presence of bone resorption stimulators, e.g. parathyroid hormone (PTH), osteoblasts release various intermediaries which activate osteoclasts to remove osseous tissue. This subject, and others related to bone formation and turnover, will be considered more fully in the section on bone remodelling (p. 309).

Osteoblasts are differentiated, non-mitotic cells which arise from osteoprogenitor cells (vide supra) and also possibly by de-differentiation of osteocytes when these are released from bone during its resorption.

Osteoblasts may also themselves de-differentiate into osteoprogenitor cells under certain circumstances. When not active in bone resorption, they may also transform into the bone lining cells of endosteal surfaces, although this relationship is not certain.

Osteocytes (3.24,28). These constitute the major cell type of mature bone, lying scattered within its matrix, but interconnected by numerous cellular extensions to form a complex cellular network. They are derived from osteoblasts which have become enclosed in matrix, but retain contacts with each other and with cells at the surfaces of bone (i.e. osteoblasts and bone-lining cells) throughout their lifespan.

Structurally mature, relatively inactive osteocytes possess a lens-shaped soma, its long axis (about 25 μm) parallel to the surrounding bony lamella and its shortest axis transverse to it. The cytoplasm is faintly basophilic and contains relatively few organelles, including a little granular endoplasmic reticulum, a few free ribosomes and a small Golgi apparatus. The rather narrow rim of cytoplasm surrounds an oval nucleus. Younger, more active osteocytes are more rounded, with a well developed endoplasmic reticulum and larger Golgi complexes, both signs of greater synthetic and secretory activity.

Numerous dendrites emerge from the soma and branch a number of times to form an extensive tree. Such processes contain bundles of microfilaments and some smooth endoplasmic reticulum. At their distal tips they contact the dendrites of adjacent cells (other osteocytes and, at surfaces, osteoblasts and bone-lining cells), with which they form communicating ('gap') junctions and are thus in electrical and metabolic continuity.

The bone matrix surrounds the somata and dendrites but there appears to be a variable space between cell and cell wall containing extracellular fluid. From the cavity (*lacuna*) in which the soma lies extend up to 100 narrow branched tunnels or (*canaliculi*) about 0.25 μm wide containing the dendrites. Thus the bony matrix is riddled with minute branched canals and cavities which, beside housing living cells, provides a route for the diffusion of nutrients, gases and waste products for their maintenance (for a review see Atkinson & Hallsworth 1982). Canaliculi may infrequently extend through and beyond the reversal line surrounding an osteon or communicate with neighbouring systems and, usually at the outer limit of the osteon, loop back to their own lacuna. The walls of lacunae are lined with a variable (0.2–2 μm) layer of unmineralized organic matrix (osteoid).

The average lifespan of an osteocyte has been estimated as about 25 years; old osteocytes may retract their processes from the canaliculi and, when dead, their lacunae and canaliculi may become plugged with cell debris and minerals, so hindering diffusion through the bone. Dead osteocytes occur commonly in interstitial bone, becoming particularly noticeable by the second and third decades.

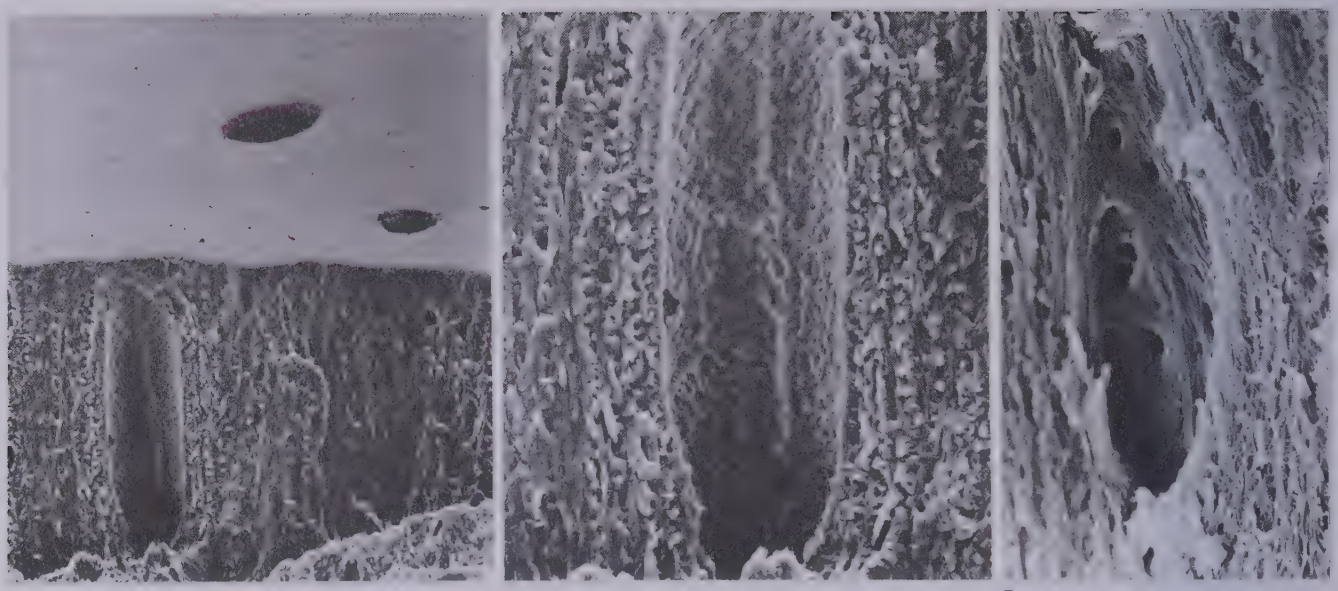
The exact functions of osteocytes are not yet clear but they must have an essential role in the maintenance of bone, as their death leads to the resorption of the matrix by osteoclast activity. They may be responsible for a small amount of matrix turnover, since the sizes of their lacunae can change and labelling of growing bone (e.g. with tetracycline) also indicates continuing matrix deposition. It is also possible that, by means of their communications with cells at the bone surface, they may act as local sensors of the mechanical and chemical state of the bone and initiate erosion or addition of matrix accordingly.

Bone lining cells. These are flattened epithelium-like cells found on the resting surfaces of bone, i.e. those not undergoing deposition or erosion (Menton et al 1982). They form continuous layers and are in contact with each other, and with neighbouring osteocytes, through communicating junctions. On the endosteal surface of narrow cavities they form the outer boundary of the marrow tissue and are present on the periosteal surface and line the system of vascular canals within osteons. Their role is not yet clear, but they may be inactive osteoblasts which can revert to the active state when suitably stimulated. They may also play an active role in regulating the differentiation of osteoprogenitor cells (Menton et al 1982).

Osteoclasts (3.29,30). These are large (20 μm or more) rounded cells with a variable number of oval, closely packed nuclei, often 15–20 (Gothlin & Ericsson 1976, Kahn et al 1983). They are found where there is active erosion of bone and lie in close contact with the bone surface in pits termed *resorption bays* or *lacunae of Howship*.

Osteoclasts contain numerous mitochondria and vacuoles, many being acid phosphatase-positive lysosomes. There is relatively little granular endoplasmic reticulum and only a small Golgi complex, unlike that in osteoblasts. The surface of the cell at the site of bone resorption is highly folded to form a ruffled membrane. Here, many lysosomes are concentrated at the bases of clefts between irregular cell extensions (*lobopodia*) and the plasma membrane has a dense, bristly undercoating similar to that of coated vesicles in other cells active in endocytosis (p. 29). Around the perimeter of the ruffled membrane is a zone of actin filaments, and here the osteoclast is closely attached to the bone surface, so forming a limit to the resorptive activities of the ruffled membrane. In tissue culture the ruffled membrane exhibits constant vigorous movement and active pinocytosis. Collagen fragments and other matrix debris have been found within its clefts and in cytoplasmic vesicles at their bases (Hancox & Boothroyd 1963). The size of the ruffled membrane varies with hormonal treatment, increasing when resorption of bone is stimulated and disappearing in the presence of agents favouring bone deposition, e.g. calcitonin.

Functionally, osteoclasts are responsible for the removal of bone, although exactly how is not known. Clearly, they cause demineralization, and there is also structural evidence of organic matrix destruction. Demineralization of the matrix occurs locally where the osteoclast's ruffled membrane approaches the bone surface; it has been proposed by Chambers et al (1984) that osteoclasts can only attack bone after its organic lining has been removed by osteoblasts or macrophages to expose the mineralized surface. However, there is also much evidence that osteoclasts can readily phagocytose collagen and other organic components of the matrix, so this question is not yet settled.



Agents responsible for stimulating osteoclasts to resorb bone appear to be multiple, including factors released by osteoblasts and probably various other cells such as macrophages and lymphocytes. Various humoral factors such as parathyroid hormone are also involved in bone resorption. This subject will be discussed more fully in a later section (see bone remodelling p. 309).

The cell lineage of osteoclasts has been much studied, and it is now established that they arise by fusion of mononuclear cells which originate in the bone marrow (Ash et al 1980, Ko & Bernard 1981) rather than from osteoblasts or osteoprogenitor cells as was previously believed. This conclusion is based on various types of labelling experiments with grafted cells. Several lines of evidence point to a close similarity between osteoclasts and mononuclear phagocytes (macrophages) which can also fuse to form giant multinuclear cells with phagocytic functions. Both cell types arise from the bone marrow, have an affinity for certain supravital dyes, possess many lysosomes and are motile. However, some monoclonal antibodies specific for macrophages fail to react with osteoclasts, so it is likely that they form a distinct class of cells, although possibly with a common myeloid precursor.

When bone resorption has finished, it is likely that these syncytial cells dissociate into mononuclear cells which may again fuse to form active osteoclasts when suitably stimulated.

The Bone Matrix

This is the extracellular material of bone and consists of a highly mineralized ground substance in which are embedded numerous collagen fibres, usually ordered in parallel arrays (3.26). In

A B C

3.26 Scanning electron micrographs of osteonic bone from human femur. In A a piece of bone has been cut transversely to the osteons within it to show two vascular canals, concentric lamellae and some osteocyte lacunae; it has also been fractured parallel to the long axes of two osteons to expose the lamellar structure; magnification × 400. B shows a higher magnification of one of the osteons in A. The complex appearance of the lamellae reflect changing directions of collagen fibres and bone crystals in alternate layers. The surface of the central vascular canal is seen to be pitted with the minute orifices of canaliculi; magnification × 2000. C shows a more highly magnified osteocyte lacuna, broken open to show the origins of canaliculi on its internal surface; magnification × 8000.

mature bone, the matrix is moderately hydrated, 10–20% of its mass being water; of its dry weight, 60–70% is made up of inorganic, mineral salts (hydroxyapatite-like crystals and amorphous calcium phosphate), 30–40% is collagen and the remainder (about 5%) is protein and carbohydrate, mainly conjugated as glycoproteins (osteonectin, osteocalcin, α 2HS-glycoprotein, etc). The proportions of these various components vary with age, location and metabolic status. In the early stages of bone formation, before mineralization, the matrix is termed *osteoid*. In adult bones the amount of osteoid is very small, reflecting local remodelling of the bone in which mineralization rapidly follows the deposition of the organic matrix. In certain disease states where mineralization is defective, notably rickets, the amounts of osteoid are greatly increased.

Collagen in bone closely resembles that of many other connective tissues belonging to Type I (see p. 64). However, in some details it differs from collagen in loose connective tissue in that in bone its molecular structure is more strongly cross-linked internally, and the gaps within its fibres are somewhat larger. These features make it stronger and chemically more inert, and the internal gaps provide lodging for bone salt crystals—it has been estimated that up to 50% of the hydroxyapatite is located within collagen fibres. The crystals mostly lie in the gaps between the ends of tropocollagen subunits ('hole regions') which, in sectioned material, occur with a 64 nm repeat distance along the collagen (67 nm in hydrated tissue), emphasizing the regular banding pattern in electron microscope preparations. Various glycoproteins are associated with these collagen fibres, including *osteonectin* which acts as an important adhesive between collagen fibres, bone crystals and the cells of bone.

That collagen contributes much to the mechanical strength of this tissue is clearly demonstrated in bones heated to denature their collagen, when the matrix becomes brittle and easily fractured. The precise role of collagen in bone mechanics is still not understood in detail, however, since the direction of fibres, the association of mineral crystals within and outside the fibres and other local features all modify their behaviour under stresses of different kinds, making mathematical analysis a complex matter (see e.g. Frasca et al 1981, Currey 1984). But it is clear that besides contributing to the tensile, compressive and shearing strengths of bone, the small degree of elasticity shown by collagen imparts a measure of resilience to this tissue, helping to resist fracture when mechanically overloaded.

Collagen fibres are also vital to bone development by providing nucleation sites within their substructure for mineral deposition (see p. 302) and otherwise enhancing matrix mineralization.

Collagen fibres are synthesized by osteoblasts (vide supra), polymerizing from tropocollagen extracellularly and becoming progressively more cross-linked as they mature. In primary bone, they form a complex interwoven meshwork (non-lamellar or *woven bone*) which eventually is almost entirely replaced by regular laminar arrays of parallel collagen fibres (lamellar bone). Partially mineralized collagen networks can be seen on the internal surfaces of bone (endosteal faces and linings of vascular canals).

Collagen fibres from the periosteum penetrate cortical bone (*Sharpey's fibres*), anchoring this fibrocellular layer at its surface. The terminal fibres of tendons and ligaments are also inserted deeply into the matrix of cortical bone, traversing many osteons in their path.

Other organic components of the matrix. Various complex macromolecules also exist attached to collagen fibres and surrounding bone crystals in small amounts. *Osteonectin* is a phosphorylated glycoprotein with an *M*r of 32 000, secreted by osteoblasts and unique to bone. It is important in adhesion of collagen to bone crystals and osteocytes (Termine et al 1981).

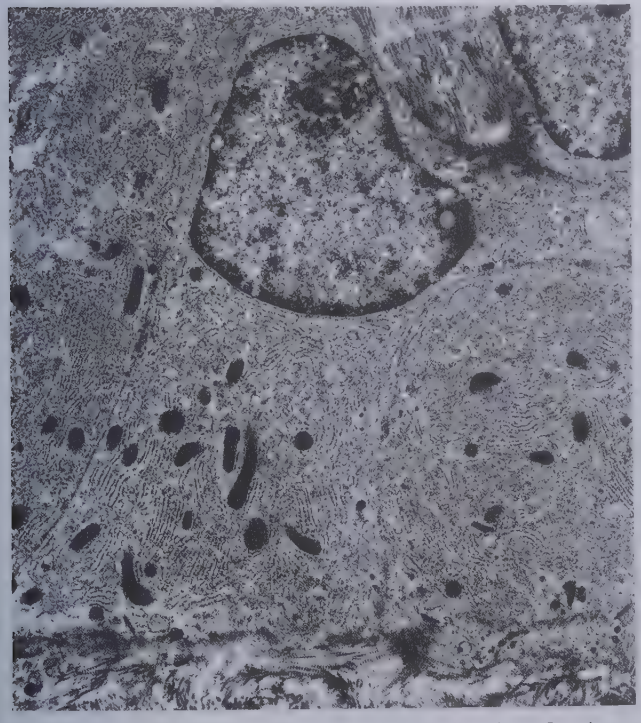
Osteocalcin is another glycoprotein, synthesized by osteoblasts and thought to play a part in calcium deposition, as is also the case with the *α-2HS-glycoprotein*, a substance made in the liver but concentrated by bone from blood plasma. Phospholipids, glycosaminoglycans (including the chondroitin sulphates), phosphoprotein and various other organic substances are also present in small quantities within the matrix; apart from any other role in the ongoing activities of this tissue, these materials may be important in early mineralization and in the maintenance of calcium salts within mature bone.

The bone salts. These form the inorganic constituents of the bone matrix, conferring on bone its hardness and much of its rigidity. Major ions which compose the mineral part of bone include calcium, phosphate, hydroxyl and carbonate; less numerous ions are those of citrate, magnesium, sodium, potassium, fluoride, chloride, iron, zinc, copper, aluminium, lead, strontium, silicon and boron, many of these being present only in trace quantities. The mineral substances of bone are mostly soluble in dilute acids and can be removed by prolonged immersion, e.g. in 2% nitric acid, or in solutions of calcium chelators

such as ethylene diamine tetracetic acid (EDTA). The bone then retains its shape but is highly flexible, so that a long thin bone (such as the fibula) can easily be tied in a knot. In histological sections the microstructure of the bone, including its cells, lamellae, osteons, etc., are well preserved after such gentle demineralization.

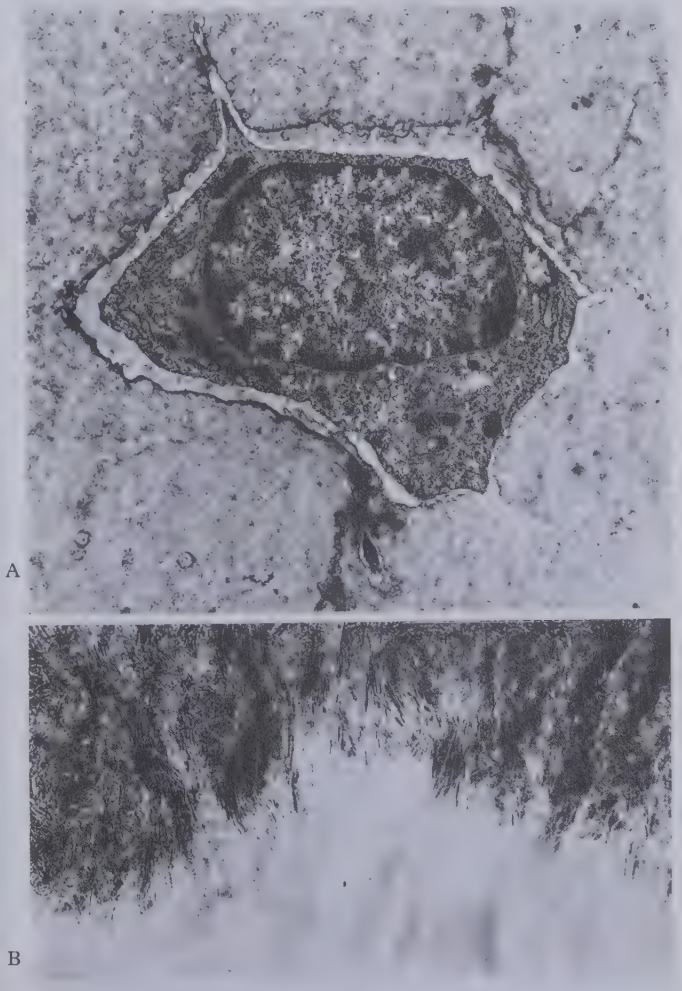
The mineral portion of mature bones is composed largely of *bone crystals* made of a substance generally known as *hydroxyapatite*, together with a small amount of *amorphous calcium phosphate*. Bone crystals take the form of elongated needles, thin plates or leaf-like structures about 10 nm long by 1.5–3 nm thick. They are often packed quite closely together, with long axes parallel to those of neighbouring collagen fibres, or lying within them (vide supra). The narrow gaps between the crystals contain water and organic macromolecules. X-ray crystallography shows that they have a hexagonal prismatic substructure which, although very similar to that of the mineral hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, differs in some respects, e.g. the presence of substantial amounts of other ions such as carbonate. Fluoride ions can substitute for hydroxyl ions, and various other ions can be held within crystal lattices. Likewise, different cations such as those of radium, strontium and lead all readily substitute for calcium and are therefore known as bone-seeking cations; these can be either radioactive or chemically toxic and so constitute a danger to health. When present in bone, they are particularly hazardous since their position in the body close to the haemopoietic tissues of bone marrow may induce various pathologies of that tissue.

Under the electron microscope, bone crystals are electron-dense and, where packed closely together, give the matrix a massive, solid appearance (**3**.28). Amorphous calcium phosphate is composed of more granular, semi-crystalline material and is thought to be the earliest form of mineralization in bone during its development, being largely replaced in mature bone by the crystalline form.



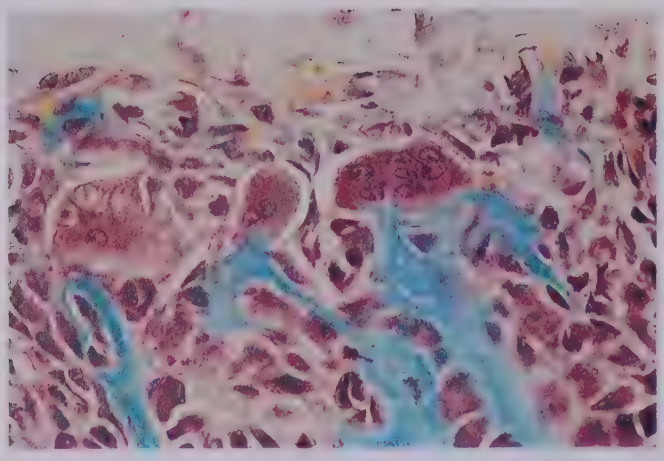
MICROSCOPIC ORGANIZATION OF BONE

While the mechanical properties of bone are dependent on the general composition of its matrix, the manner in which the different components are arranged is also of utmost importance in the strength and resilience of this tissue. Two quite distinct types of organization are found; in primary bone the most immature tissue of developing bones, collagen fibres and bone crystals are irregularly interwoven (*woven bone*). In all other situations, collagen fibres and crystals of bone salts are arranged in highly orientated flattened plates or *lamellae*, giving bone great strength.



Lamellar Bone

This type of bone therefore makes up almost all of the adult osseous skeleton. The precise arrangement of its lamellae varies from site to site, particularly between compact cortical bone and trabecular bone within.

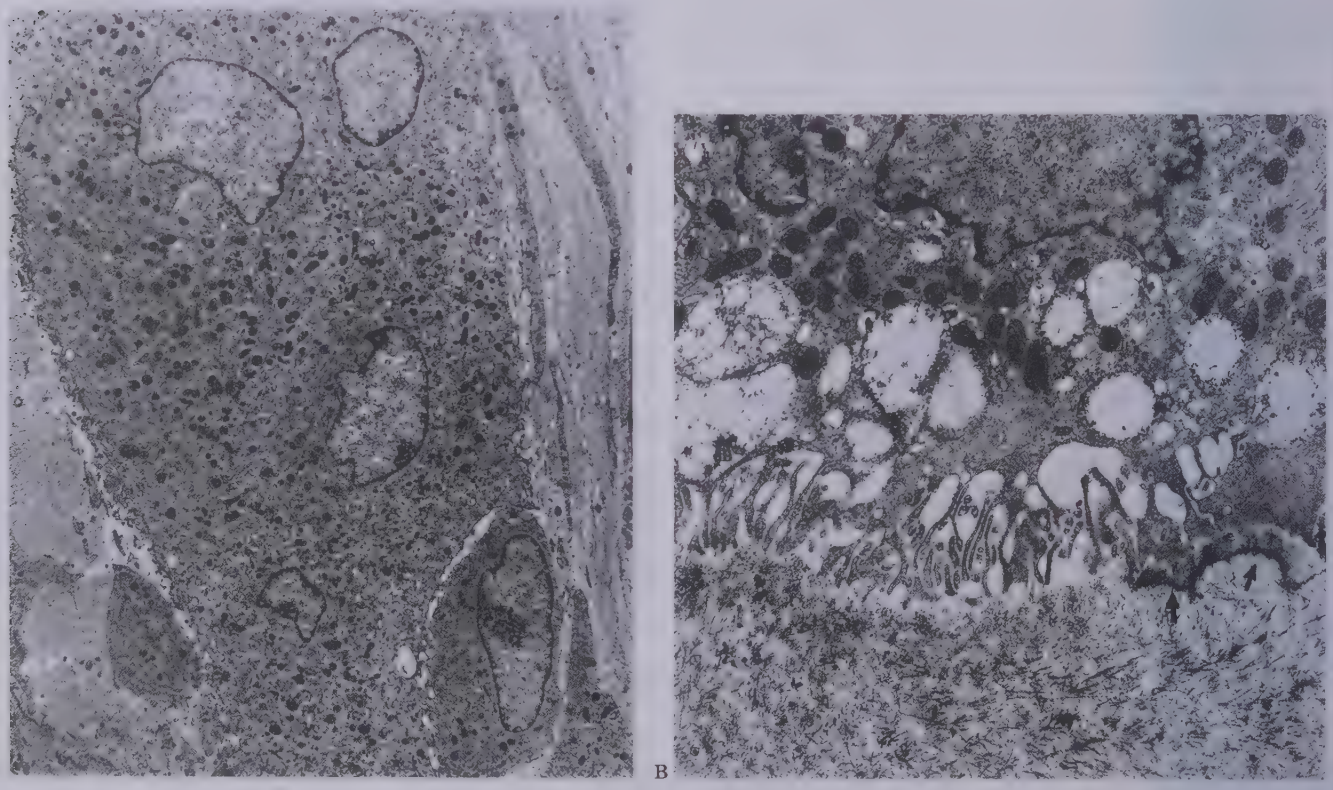


Compact bone (**3**.23–25). As already mentioned, adult bone consists almost entirely of mineralized matrix and collagen fibres arranged in plates or lamellae, embedded in which are the osteocytes. In many bones a few such lamellae form continuous layers at the surface, termed *circumferential lamellae*. By far the greatest proportion, however, are arranged in concentric cylinders around neurovascular channels (*Haversian canals*), so forming the basic units of bone construction, the *Haversian systems* or *osteons* (more correctly called *secondary osteons* to distinguish them from the irregularly organized primary osteons formed during the initial generation of bone, as described below). Secondary osteons

3.27 Electron micrograph of a series of osteoblast on a bone forming surface (below). The cytoplasm is filled with granular endoplasmic reticulum. Some banded collagen fibres are visible at the secretory front at the base of the picture; magnification × 4000. (Provided by A Hayward.)

3.28 Electron micrographs showing (A) a young osteocyte within bone matrix (decalcified during processing for microscopy). Visible are the bases of dendrites extending within the canaliculi, the cell body containing granular endoplasmic reticulum, the lacuna with less dense matrix surrounding the cell body, and many collagen fibres in the matrix, mainly sectioned transversely in this picture; magnification × 3000. (Provided by A Hayward.) B shows bone crystallites (above) and collagen fibres at a mineralizing front on the surface of bone; magnification × 3000. (Provided by Moya Meredith Smith.)

3.29 Section through developing membrane bone showing a group of large, multinucleate osteoclasts eroding spicules of bone (green). Many osteoblasts are also clustered at other surfaces of the spicules where bone is being formed. Masson's trichrome; magnification × 1000. (Provided by Moya Meredith Smith.)



usually lie parallel to each other and, in elongated bones such as those of the appendicular skeleton, with the long axis of the bone, but they frequently spiral, branch or intercommunicate and some end blindly. In transverse section they are round or ellipsoidal, varying from about 100–400 μm in diameter, and the number of lamellae is usually about six, rising to 15 in the largest osteons. Each osteon is permeated with canaliculi of its resident osteocytes which form the pathways for diffusion of nutrients, gases, etc. between the vascular system and the osteons. The rather small maximum diameter ensures that no osteocyte is more than about 200 μm from a blood vessel, a distance which may be a limiting factor in cellular survival. In the intervening spaces between secondary osteons are the fragmentary remains of osteons of older bone which has been partially eroded before the new osteons were formed. This is termed *interstitial bone*.

The central osteonic canals vary in size, with a mean diameter of 50 μm; those near the marrow cavity are somewhat larger (Cohen & Harris 1958). Within each canal are one or two capillaries lined by fenestrated endothelium surrounded by a basal lamina which splits to enclose typical pericytes. Usually there are also some unmyelinated and occasional myelinated nerve fibres, 5–9 μm in diameter (Cooper 1969). The bony surfaces of osteonic canals are perforated by the openings of myriads of canaliculi and are also lined by collagen fibres (**3**.26).

Osteonic canals communicate directly or indirectly with the medullary cavity, channels which run obliquely or transversely in the direction of the osteons being known as Volkmann's canals. These are said not to be surrounded by concentric lamellae of bone. However, the majority of such channels appear to be simple interosteonic, anastomotic canals and the frequency of true vascular connections with the periosteum and endosteum may be rather low (see Cohen & Harris 1958).

All secondary osteons are demarcated from their neighbours by a *cement line* which has little or no collagen and is strongly basophilic due to a high content of glycoproteins and proteoglycans; this marks the limit of bone erosion prior to the formation of an osteon and is therefore also known as a *reversal line*. Similar basophilic lines also occur in the absence of erosion, where bony growth has been interrupted then resumed (*resting lines*). Canaliculi may sometimes pass through such cement lines, so providing a route for exchange between interstitial bone and vascular channels within osteons (Atkinson & Hallsworth 1982).

The lamellation of bone (**3**.20). While each lamella consists of a plate of mineralized matrix containing collagen fibres, the reasons for the lamellar appearance are not yet entirely understood. However, it appears to result from two features, namely the presence of a thin (0.1 μm) layer of matrix with a high mineral and low

A B

3.30 Electron micrograph of osteoclasts. A shows a large multinucleate cell close to the surface of bone, although not, in this case, within an erosion bay; magnification × 2500. B is a higher magnification of an osteoclast ruffled border, where active bone resorption is occurring. The cell has been stained cytochemically for acid phosphatase activity, which is shown by the dense granular precipitate within the large (lysosomal) vacuoles in the cytoplasm. To the right is a dense junctional zone between the cell surface and the matrix arrows; magnification × 6000. (Both micrographs provided by Moya Meredith Smith.)

organic content between adjacent lamellae ('interlamellar bone') and a difference in orientation between the structures (i.e. collagen fibres and bone crystals) of adjacent lamellae, varying between 0° and 90°. Since crystallites are aligned parallel to collagen fibres, when viewed by polarized light microscopy (see 3.25), the plane of polarization is rotated to different degrees by the different lamellae, emphasizing the alternate orientation of these structures.

The earliest descriptions of these fibres suggested that collagen fibres alternate between longitudinal and circumferential in successive lamellae, or that they had spiral paths of different pitches (Gebhardt 1905).

Although a degree of spiralization has been confirmed in investigations into the structure and compressive properties of isolated osteons (Ascenzi & Bonucci 1968, Ascenzi et al 1978), evidence from scanning electron microscopy shows that in each lamella there are small domains or areas of collagen fibres up to 100 μm across. Although fibres within a domain have the same direction, domains are not necessarily parallel with each other so that variation of orientation exists within each lamella (Boyde & Hobdell 1969, Frasca et al 1977). Collagen fibres run in branching fasciculi about 3 μm thick; they often run from one lamella to the next through discontinuities in the interlamellar zones.

Trabecular bone (3.22). The organization of this class of tissue is again basically lamellar, but the bone is in the form of branching and anastomosing bars and plates of various widths and lengths, limiting medullary spaces (see p. 277) and bounded by endosteal tissue. In general, bone lamellae are orientated parallel with the adjacent bone surface and there is the same arrangement of cells and matrix as found in circumferential and osteonic bone. However, except in thick trabeculae which may possess small osteons, blood vessels do not penetrate the bony tissue and osteocytes rely on canalicular diffusion from adjacent medullary vessels. In young bone, calcified cartilage may occur in the cores of trabeculae but this is generally replaced by bone during subsequent remodelling.

Variation in bone composition. Normal variation in composition of bone at different sites and ages is incompletely recorded, though valuable in radiological assessment of rarefaction (osteoporosis) due to disease or disuse. Whether this is actual reduction in total amount of tissue, rather than reduction in mineralization, is difficult to determine because of problems of separation of bone from other tissues. Furthermore, measurement of sizes of vascular, lacunar and medullary spaces is difficult. Minimization of difficulties by limiting estimates to cortical bone has been tried since trabecular is more labile than cortical bone. However, the difference in composition of trabecular and compact bone is considered normally slight. Overall, water content decreases and mineralization increases up to the sixth or seventh decade, but the organic content remains unchanged. Thereafter mineralization declines (Mueller et al 1966).

However, microradiography and interferometry of compact bone show uneven distributions of mineral salt. Inner and outer circumferential and interstitial lamellae are evenly and highly mineralized. Secondary osteons exhibit variable mineralization; in a single osteon concentration varies in different areas. Young osteons have a low but increasing concentration, initially highest centrally and least towards the periphery, a gradient which diminishes with age until in old, highly mineralized osteons mineral distribution is uniform. Bone resorption occurs in areas of high and low concentration (vide infra). In fetal bone mineralization reaches 70–80% in about three weeks, 100% much less rapidly. Events in subsequently formed osteons may have a similar time course.

Blood Vessels and Nerves of Bone

The osseous circulation supplies the living bone tissue, the marrow, perichondrium, epiphysial cartilages in young bones and in part the articular cartilages. Modern researches (Brookes 1964, 1967, 1971, Kelly 1968, Rhinelander 1968) have emphasized a *centrifugal* flow of blood through cortical bone in shafts of long bones, in contrast to an earlier concept of substantial *centripetal* arterial flow into the cortex from periosteal vessels. The vascular supply of a long bone depends on several points of inflow, feeding complex and regionally variable sinusoidal networks within it, which in turn drain to venous channels leaving through all surfaces not covered by articular cartilage. These vascular patterns are summarized in 3.31,32; see also 3.33.

One or two main *diaphysial nutrient arteries* enter the shaft obliquely through *nutrient foramina* leading into *nutrient canals*. Long recognized (Havers 1691, Bernard 1835), their sites of entry and angulation are almost constant and characteristically directed *away* from the dominant growing epiphysis (p. 281). This is the basis of the *growing-end hypothesis* to explain the positions and orientations of nutrient foramina and canals (Clark 1965). But such a simple mechanism does not account for the exceptions to this pattern reported in various species and sites (Hughes 1952). However, in human long bones Mysorekar (1967) observed atypically directed canals only in the fibula, attributing this to its unique pattern of ossification. A subsequent study of 848 metacarpal and 811 metatarsal bones showed that, apart from a few with double or no foramina, over 90% had a single nutrient foramen in the middle third of the shaft. All foramina, single or double, slanted away from the epiphysis, supporting the above hypothesis. For a review of this and alternative hypotheses such as the '*periosteal slip*' theory of Schwalbe (1876), 'vascular theory' of Hughes (1952) and '*asymmetrical muscular development theory*' of Lacroix (1951), consult Patake & Mysorekar (1977). Finally, a comparative study of the contrasting growth patterns of foramen and canal in the rat femur and tibia has been contributed by Henderson (1978). Nutrient arteries do not branch in their canals, but divide into ascending and descending branches in the medullary cavity. These approach the epiphyses, dividing repeatedly into smaller rami which pursue helical courses in the juxta-endosteal medullary zone. Near the epiphyses they are joined by terminals of numerous *metaphysial* and *epiphysial arteries*: the former are direct branches of neighbouring systemic vessels, the latter from periarticular vascular arcades formed on non-articular bone surfaces (p. 3.32). Numerous vascular foramina penetrate bones near their ends, often at fairly specific sites (see 3.6); some are occupied by such arteries, but most contain thin-walled veins. Within bone these arteries are unusual in consisting of endothelium with only a thin layer of supportive connective tissue (Yoffey 1962). Epiphysial and metaphysial arteries quantitatively exceed the diaphysial supply, which they can complement, e.g. when the latter is experimentally destroyed.

Medullary arteries of the shaft (3.31,32) give off (a) centripetal branches to a hexagonal mesh of medullary sinusoids draining into a wide, thin-walled central venous sinus; (b) cortical branches passing through endosteal canals to feed fenestrated capillaries in Haversian systems. The central sinus drains veins retracing the paths of nutrient arteries, sometimes piercing the shaft elsewhere as independent emissary veins.

Cortical capillaries conform in their pattern to the Haversian canals, often described as longitudinal with oblique interosteonic connexions. However, an oblique, radial pattern has been demonstrated, vessels largely radiating from the primary ossification centre (Brookes 1964, 1967, 1971). At bone surfaces cortical capillaries make capillary and venular connections with the periosteal plexuses (3.31,32,34), which are formed by arteries from neighbouring muscles contributing vascular arcades with longitudinal links to the fibrous periosteum. From this external plexus a capillary network permeates the deeper, osteogenetic periosteum. At muscular attachments periosteal and muscular plexuses are confluent and the cortical capillaries then drain into interfascicular venules.

The concept of such an almost exclusively centrifugal supply to the cortex in the shafts of long bones has received increasing support, but some (Marneffe 1951, Morgan 1959) have described an appreciable centripetal arterial flow to outer cortical zones from periosteal vessels.

The large nutrient arteries of epiphyses form many intraosseous anastomoses, branches passing towards the articular surfaces within trabecular spaces of the bone. Near the articular cartilages these form serial anastomotic arcades (e.g. three or four in the femoral head) from which spring end-arterial loops often

3.31 Scheme of the main features of the blood supply of a long bone based upon descriptions by M Brookes (Guy's Hospital Medical School). Note the contrasting supplies of the diaphysis, metaphysis and epiphysis, and their connections with periosteal, endosteal, muscular and periarticular vessels. Consult the text for a more extended description.

piercing the thin hypochondral compact bone (3.6) to enter, and sometimes traverse, the calcified zone of articular cartilage before returning to the epiphysial venous sinusoids.

In immature long bones the supply is similar, but the epiphysis is a discrete vascular zone; epiphysial and metaphysial arteries enter on both sides of the growth cartilage, anastomoses between them being few or absent. Growth cartilages probably receive a supply from both sources and also from an anastomotic collar in the adjoining periosteum, but how much from each is uncertain (Brookes 1964, 1967, 1971, Trueta & Morgan 1960, Rang 1969). Occasionally cartilage canals are incorporated into a growth plate (p. 287). Metaphysial bone is nourished by conjoined terminal branches of metaphysial arteries and primary nutrient arteries of the shaft. They form terminal sinusoidal loops in the zone of advancing ossification, the dilated bend of each separated slightly from adjacent partitions of calcified cartilage (p. 306). Such gaps are often packed with erythrocytes, possibly evidence of 'microrupture' at this point (Trueta & Morgan 1960). However, others have emphasized an intimate contact between sinusoidal endothelium and calcified cartilage, and to such loops have ascribed a nutritive *and* a chrondrolytic role (Cameron 1961, Brookes & Landon 1963). Young periosteum is more vascular; its vessels communicate more freely with those of the shaft than in adults, and have more metaphysial branches.

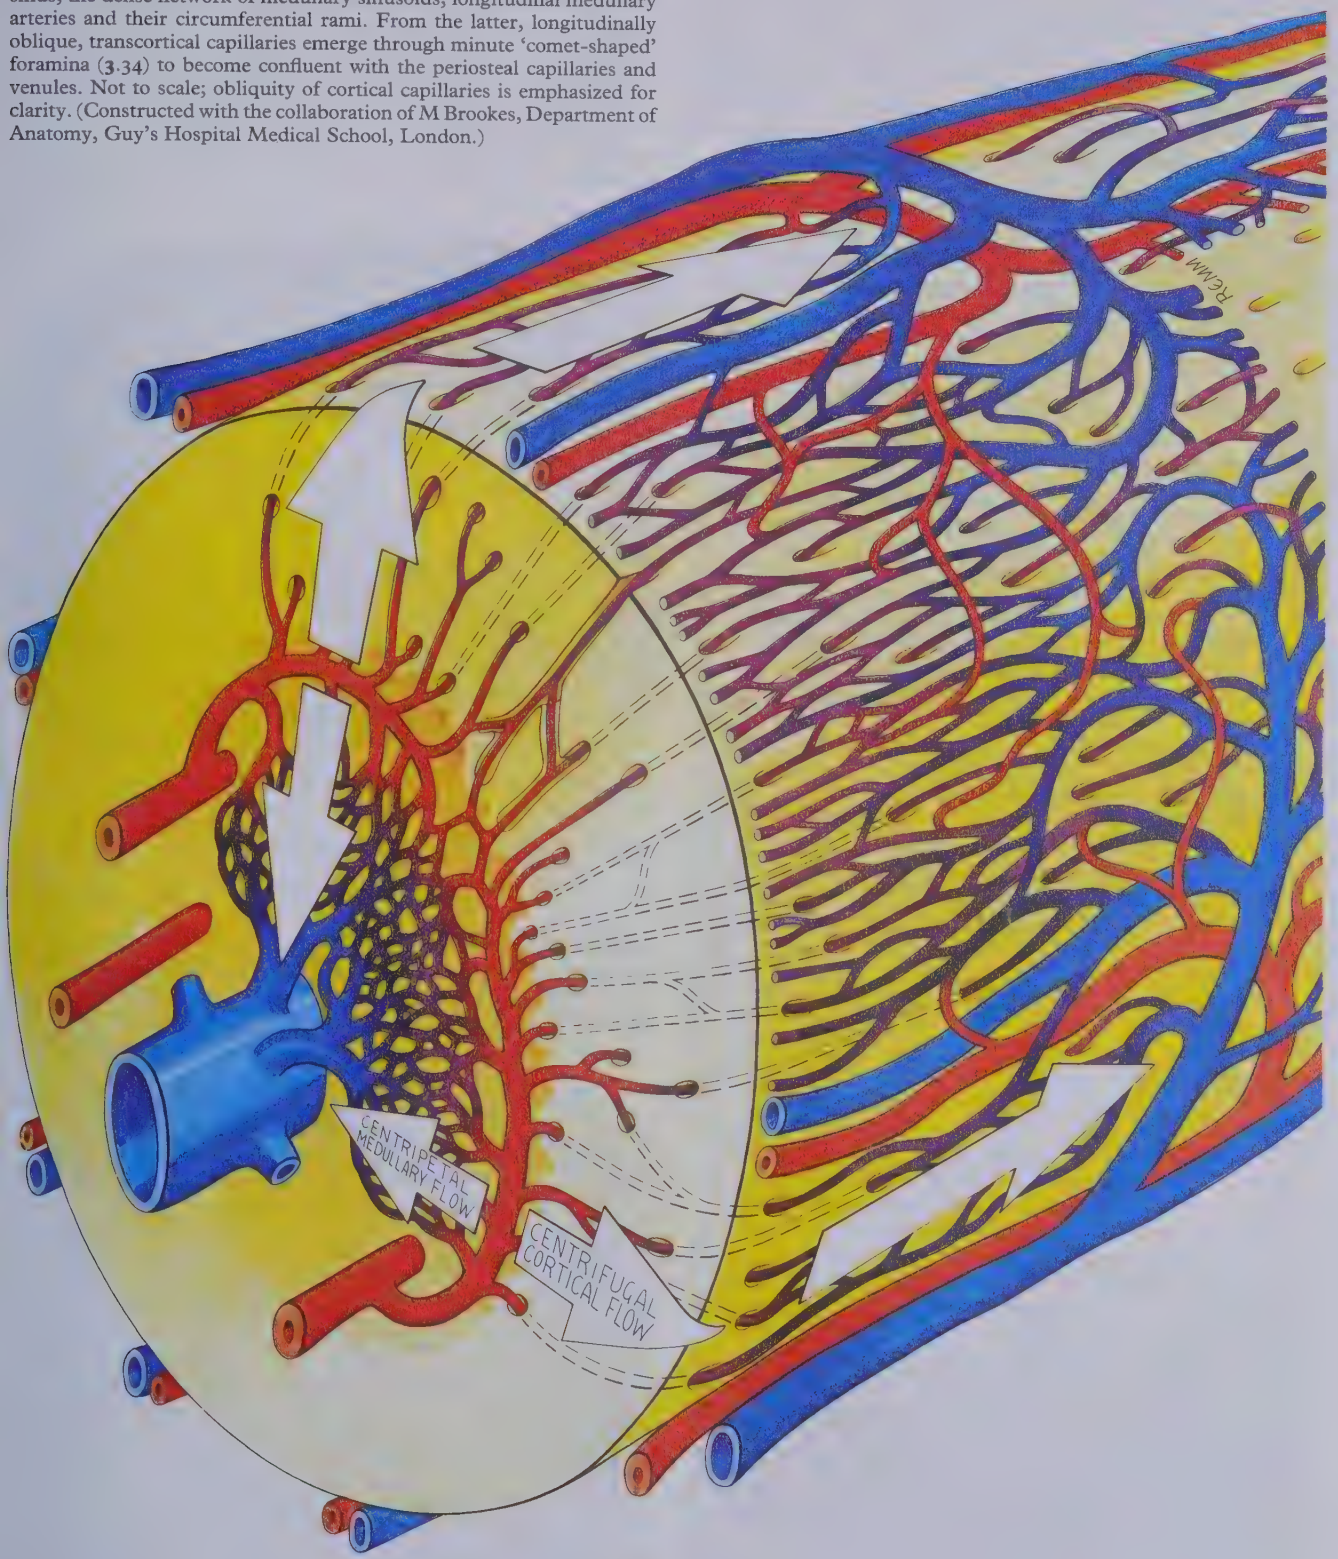
Large irregular bones like the scapula and innominate bone, receive a periosteal supply and often have large nutrient arteries penetrating directly into their cancellous bone. The two systems anastomose freely.

Short bones receive numerous fine vessels from the periosteum at non-articular surfaces, supplying their compact and cancellous bone and medulla. Arteries enter vertebrae close to the bases of transverse processes; their medulla drains to two large basivertebral veins converging to a foramen on the posterior surface of the vertebral body.

Flatter cranial bones are supplied by numerous periosteal or mucoperiosteal vessels. Large veins run tortuously in diploë (cancellous bone). Being thin-walled, they gape when cut.

Lymphatic vessels accompany periosteal vascular plexuses but have never been convincingly demonstrated in bone.

Nerves are most numerous in articular extremities of long bones, vertebrae and larger flat bones. They occur widely in periosteum, and fine myelinated and non-myelinate fibres accompany nutrient vessels into bone and even the perivascular spaces of Haversian canals.



The Histogenesis of Bone

Although there is no basic difference in the deposition of bone at various sites to form the skeleton, the precursors are of two distinct classes; bones such as those in the cranial vault are preceded by a fibrocellular membrane, whereas most bones are formed in rods or masses of cartilage. These two types of ossification are known as intramembranous and endochondral, respectively. They will now be considered in some detail, together with the general topic of the mineralization and subsequent fate of bone.

INTRAMEMBRANOUS (MESENCHYMAL) OSSIFICATION

This process, which is essentially the direct mineralization of a highly vascular connective tissue, spreads from regular *centres of ossification* (3.38A–D), at which differentiating mesenchymal (*osteoprogenitor*) cells (see p. 293) proliferate densely around a capillary network. Between cells and around vessels appears a fine mesh of collagen fibres and amorphous matrix (osteoid). The central cells enlarge and fine strips of eosinophilic matrix (earliest bone) appear between. These rapidly extend and fuse into a delicate labyrinth, enclosing vessels and transforming mesenchyme, whose cells enlarge, become polygonal, cuboidal, or low columnar and form an incomplete layer of osteoblasts (p. 293) in contact with the primitive, eosinophilic bony matrix. The earliest

3.32 Diagram of the circulatory arrangements in part of the diaphysis of a typical long bone. Note, in the marrow cavity, the large central venous sinus, the dense network of medullary sinusoids, longitudinal medullary arteries and their circumferential rami. From the latter, longitudinally oblique, transcortical capillaries emerge through minute 'comet-shaped' foramina (**3**.34) to become confluent with the periosteal capillaries and venules. Not to scale; obliquity of cortical capillaries is emphasized for clarity. (Constructed with the collaboration of M Brookes, Department of Anatomy, Guy's Hospital Medical School, London.)

crystallites appear in minute extracellular *matrix vesicles* produced by these cells (see p. 302 and **3**.35,36).

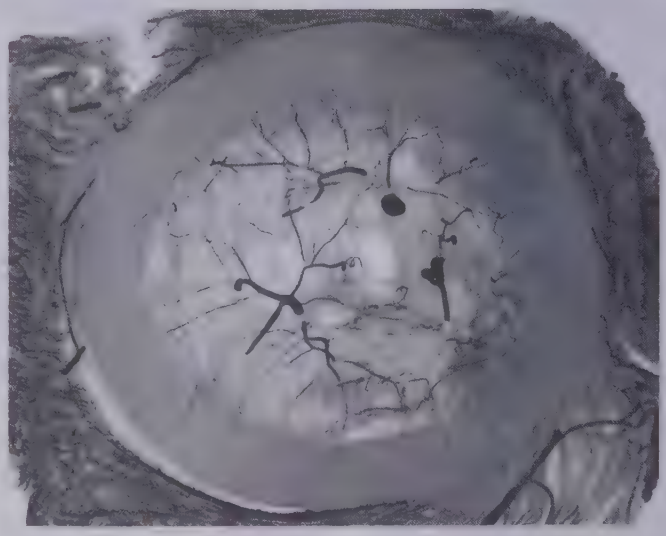
These later change into typical hydroxyapatite crystallites which were, as noted, related first to cores of matrix vesicles and subsequently to collagen fibres which form increasingly wide-meshed reticula in walls of an early labyrinth of *woven bone* (p. 296), the *primary spongiosa*. As layers of calcifying matrix are added to these early trabeculae or *bone spicules*, some osteoblasts are enclosed by matrix in primitive lacunae. However, these retain intercellular contact by means of their surface processes and, as these elongate, matrix condenses around them to form canaliculi. Further osteoblasts are added to trabecular surfaces by transformation of adjacent vascular mesenchyme cells.

As matrix secretion, calcification and enclosure of osteoblasts proceed, the trabeculae thicken and intervening vascular spaces become narrower. Where bone remains trabecular, the process slows and the spaces between them become occupied by haemopoietic tissue. Where compact bone is forming, trabeculae

continue to thicken and vascular spaces to narrow. Meanwhile the collagen fibres of the matrix, secreted on the walls of narrowing spaces between trabeculae, become organized as parallel, longitudinal or spiral bundles and enclosed cells occupy concentric sequential rows. These irregular, interconnected, sometimes cylindroid masses of compact parallel-fibred bone, with a central canal, are *primary osteons* or *atypical Haversian systems*. With intervening woven bone they are later eroded and replaced by generations of lamellar *secondary osteons* (see also pp. 297, 299, 309).

During these changes mesenchyme condenses on the surface to form a fibro-vascular periosteum, and bone is laid down increasingly by osteoblasts differentiating from mitotic stem cells in deeper layers of the periosteum. Thus there is an advancing front of matrix deposition which entraps further periosteal vessels and also osteoblasts which then become osteocytes. Further growth is a continuation of these processes with much remodelling by varying rates of resorption and deposition in different sites. Overall patterns of formation and remodelling vary with the shape and structure of particular bones, and these have been studied by many techniques. Examples are considered elsewhere (p. 309); here we will consider the general processes of calcification and bone resorption in further detail.

Calcification and the Osteoblast



As described above (p. 297) the essential crystallite unit in bone is composed of a complex hydroxyapatite-like substance consisting of calcium, phosphate and hydroxyl ions associated with various other species of ion. Initially the only ions needed for calcification are calcium (Ca^{2+}) and phosphate (PO_4^{3-}) and the mechanism of calcification was traditionally treated as simply a problem of precipitation dynamics. It was assumed that while the product of calcium and phosphate ion concentrations $[Ca^{2+}] \times [PO_4^{3-}]$ in body fluids was generally too low for precipitation to occur, the conditions in osteoid matrix were in some way especially favourable to this process. In support of this view, calcification of bone was known to be reduced when dietary calcium intake was low and, conversely, calcification of blood vessel walls and other non-bony sites could be induced experimentally in animals fed with excessive amounts of calcium or clinically occurred in patients given massive doses of vitamin D or where blood calcium levels were elevated in hyperparathyroidism. It was considered that conditions in the osteoid matrix favouring calcification might be alkaline phosphatase activity in osteoblasts (raising local concentration of phosphate), or some factor raising local *p*H to alkaline levels, with consequent reduction in solubility of the calcium salt. However, this simple model is now considered inadequate; relevant *activity coefficients* must also be considered, which are difficult to extrapolate from in vitro studies to osteoblasts in situ, the precise nature of whose environment is as yet poorly understood. For reviews consult Urist (1966), Anderson 1980).

An interesting development was the theory of *epitactic nucleation* (Neuman & Neuman 1958), based on the concept of *seeding* or *epitaxy*: a nucleus is somehow formed, with crystalline structure like hydroxyapatite, effective in aggregating calcium and phosphate ions. The hydroxyapatite crystal then grows spontaneously by addition of these from the saturated surrounding fluids.

General acceptance of the theory of epitaxy led to many attempts to determine the nature and distribution of nucleation sites, variously claimed to be points in periodic structure of collagen, ground substance links between collagen fibrils or structural aspects of proteoglycans (see the review by Bernard & Pease 1969). The latter authors (foreshadowed by Bonucci 1967) proposed a role for the osteoblast, considering initial nucleation sites to be cellular 'buds' or extrusions with a polysaccharide core and able, possibly with protein, to form an 'image' of crystal salt. Further aggregation of crystals around this initial locus was held to lead to formation of spherulitic bone nodules coalescing to form seams of bone, association with collagen fibres being secondary. Thus 'cellular seeds' initiating calcification would be specific cell products originating solely from osteoblasts and absent in general connective tissues.

Although epitactic nucleation has not been fully confirmed, the essential role of a particular cellular product extruded into the matrix, *the matrix vesicle*, has aroused intense interest and stimulated much investigation.

Matrix vesicles (3.36). These are membrane-bound spheres about 0.1 μm in diameter. They typically have an electron-dense core, often apposed eccentrically to the inner surface of the membrane. They are generally thought to be derived by budding (or fragmentation) of osteoblast processes, (or in other tissues, of the relevant cell). They are the loci of earliest hydroxyapatite

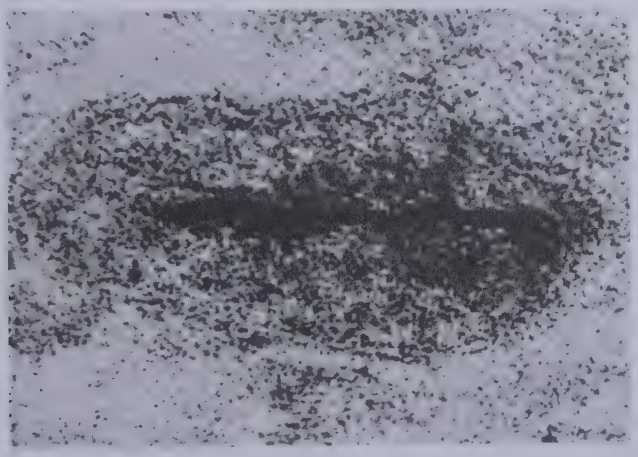
3.33 Microradiograph of long bone in which the arterial supply has been injected with a radio-opaque substance, demonstrating the centrifugal perfusion route of the blood supply. (Provided by M Brookes, Department of Anatomy, UMDS Guy's Campus, London.)

3.34 Scanning electron micrograph of the periosteal surface of the diaphysis of an adolescent tibia. Note the oblique 'comet-shaped' groove and foramen which in life transmitted a minute neurovascular bundle; numerous foramina of this general type are scattered over the surface of the diaphysis, but their pattern, direction and degree of obliquity vary with the overall subperiosteal deposition of bone that characterizes the various growth zones of the diaphysis; magnification × 80. (Preparation by Michael Crowder, Department of Anatomy, Guy's Hospital Medical School.)

crystallite formation in newly forming bone, and indeed in the initial mineralization of all mineralized tissues throughout vertebrates (see the review by Anderson 1985). They occur in calcifying cartilage (Anderson 1967, 1969, Bonucci 1967, 1970), woven bone (Bernard & Pease 1969), dentine (Sisca & Provenza 1972, Katchburian 1973), and subperiosteal bone (Anderson and Reynolds 1973, Reynolds 1976). Matrix vesicles with similar properties can hence be produced by chondroblasts, odontoblasts and osteoblasts. Their role in the initiation of calcification, however, remains speculative since they have not always been found in mineralizing fronts in osteoid of more mature bone. Being membrane-bound, vesicles separate internal and external environments. They carry high concentrations of alkaline phosphatase, ATPase, inorganic pyrophosphatase and, at some sites, high concentration of lipids. It is likely that matrix vesicles provide the enzymes and environment to concentrate calcium and phosphate sufficiently to initiate crystallization, which then spreads outside the vesicle. Other hypotheses include the siting in the vesicular membrane of a centripetal calcium binding by vesicular lipids.

While it is very probable that matrix vesicles are important in beginning the process of calcification, there are also various calcium-binding molecules among the proteins and glycoproteins of osteoid. These include collagen, as already mentioned (p. 296), osteocalcin and α 2HS-glycoprotein (p. 296). These are therefore likely candidates for substances able to increase local concentrations of ions to the point where precipitation occurs, and may be an important mechanism by which calcification continues once the matrix vesicle system has begun it.

Considerable controversy concerns the shape and size of the initial hydroxyapatite crystals which are variously described as plates, rods or needles. Most studies agree a smallest dimension of about 5 nm but estimates of length vary from 20–35 nm to values three times larger, reflecting a variety of techniques: X-ray diffraction and dark-field electron microscopy give low values for length, whereas transmission electron microscopy of ion-beam thinned section yields much larger values (see Boyde 1975, Jackson et al 1976).



3.35 Transmission electron micrograph of part of an osteoblast, its surface bearing long filopodia which project into the surrounding intercellular matrix. Within the latter are clusters of 'matrix vesicles' which provide the initial nucleation sites for the formation of hydroxyapatite crystallites in the early mineralization of bone. The specimen is from the subperiosteal ossifying front of a chick's tibia in tissue culture.

Calcium Balance, Bone Resorption and the Osteoclast

A central theme of physiology is the dependence of many cellular activities on a relatively constant micro-environment (in terms of osmolality, types and concentrations of ions, *p*H, etc.); many finely balanced feedback systems operate to ensure this *homeostasis* (see Reynolds 1974). The level of circulating calcium ions is an example: it is preserved despite wide variation in diet, rates of bone growth and remodelling. Involved in this process but varying quantitatively at different times are both labile and stable areas of bone salts (vide infra), interacting types of cell (osteoblasts, osteocytes and osteoclasts) various hormones including parathyroid hormone and thyrocalcitonin as well as many other factors.

Calcium in blood and tissue fluids is constantly exchanging with calcium in bone to the extent of approximately one-quarter of ionic blood calcium each minute. The blood calcium is in equilibrium with that of tissue fluid, especially in the perivascular space in Haversian canals, lacunae and canaliculi—which present vast exposed areas of bone salt for such physico-chemical exchanges (p. 293). The mineral surface exposed to extracellular fluid in a 70 kilogram person is estimated at between 1500–5000 m^2 (Robinson 1964). The calcium content of newly formed bone is more labile than in older tissue and provides a ready reservoir of calcium ions. The gradual replacement of old osteons by new ones, which continues throughout life, can also be modulated to alter blood calcium levels. Bone salt release may depend on active erosion of matrix by osteocytes (Bélanger et al 1963) but how far such *active cellular osteolysis* contributes to rapid continuous turnover of calcium, or how much is simply a direct physico-chemical exchange, is uncertain.

3.36 High power transmission electron micrograph of a single 'matrix vesicle' from the specimen shown in 3.35. The vesicle is membrane-bound, has a granular content and centrally, along its long axis, is a dense needle-shaped crystallite of hydroxyapatite; magnification × 200 000. (Specimens provided by J J Reynolds, Strangeways Laboratory, Cambridge.)

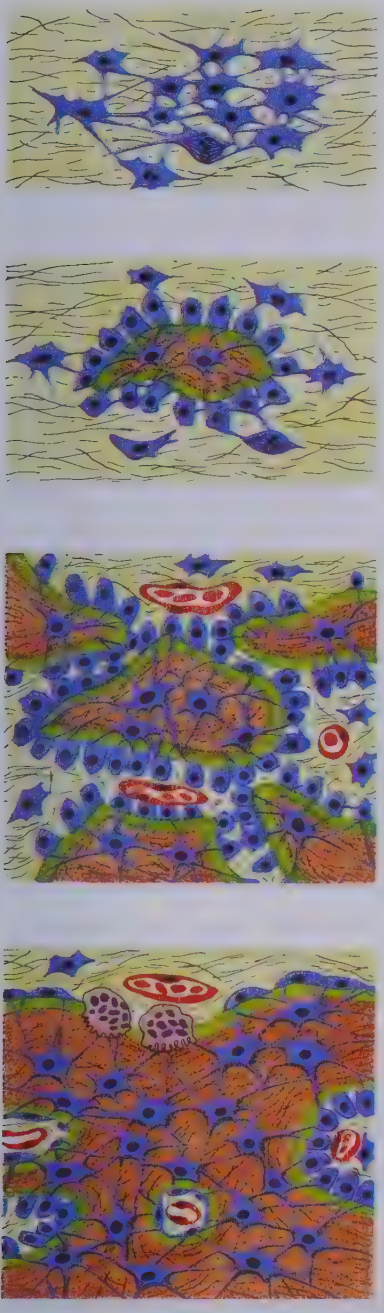
The depression of circulatory ionic calcium levels increases secretion of parathyroid hormone, which raises blood calcium level by several mechanisms: direct action on bone, increased renal tubular reabsorption of calcium and increased intestinal absorption of calcium—a minor effect. The actions of parathyroid hormone on bone are complex and obscure. They may directly modify the surface shells of ions associated with hydroxyapatite crystals, or may change the structure of collagen-associated proteoglycans and glycoproteins or increase osteocyte activity and bone resorption by osteoclast action (vide infra). Conversely, the rise in circulating calcium levels increases secretion of calcitonin (thyrocalcitonin) by thyroid parafollicular cells (p. 1460 and 8.233), depressing circulating calcium by some direct action on bone. Calcium release from bone may be inhibited by the stabilization of collagen and by increased osteoblastic deposition of bone as well as specific inhibitors thought to be released locally by bone cells (including bone-lining cells).

During bone growth, remodelling occurs, involving deposition and removal at different sites. In mature bone also, continued remodelling of osteons is preceded by erosion. Surfaces undergoing massive localized resorption display large, multinuclear *osteoclasts* with foamy, lightly basophilic cytoplasm, often in contact with bone in small erosion cavities (*erosion bays* or *resorption lacunae of Howship*) formation; details of this cell type are given on p. 295.

Such appearances suggest bone removal, but osteoclastic action remains unclear. Lysosomes and high proteolytic enzyme activity may be significant, as may secretion of chelating agents to form soluble, weakly ionized complexes with bone salt constituents. When erosion ends osteoclasts disappear, perhaps degenerating or reverting to parental type.

INTRACARTILAGINOUS (ENDOCHONDRAL) OSSIFICATION (3.39–49)

Most human bones are preformed in cartilage: in early fetal life a 'long' bone is prefigured by a rod of hyaline cartilage (3.37,44), replacing a similar rod of condensed mesenchyme, both foreshadowing in shape the early bone. Smaller (e.g. carpal) bones are also preceded by appropriately shaped cartilaginous 'models' (see 3.37). In such models a sequence of orderly changes signals the appearance of *centres of ossification*. The significance of these, and of growth plates, has been considered elsewhere (p. 279) and only their microscopic changes will be described here.



The cartilaginous model is surrounded by vascular condensed mesenchyme or perichondrium, like that which precedes and surrounds intramembranous ossificatory centres (p. 300). Again, its deeper layers contain osteoprogenitor cells.

The first sign of a centre of primary ossification is seen when chondroblasts deep in the centre of the primitive shaft (3.44) enlarge greatly, their cytoplasm becoming vacuolated and accumulating glycogen. Their intervening matrix is compressed to thin and often perforated septa. As their lacunae enlarge, the cells begin to degenerate and finally die, leaving enlarged and sometimes confluent lacunae as *primary areolae*, whose thin walls have become calcified during these final stages. Simultaneously, cells in the deep layer of the perichondrium surrounding the centre of the model become osteoblasts and form a peripheral layer of fenestrated bone. This '*periosteal collar*', essentially formed by intramembranous ossification (3.44), is at first a thin-walled tube enclosing the central shaft, but as it increases in diameter it also extends towards the ends of the shaft (vide infra). It is noteworthy that both the calcifying cartilage and the matrix of the calcifying perichondral collar contain *matrix vesicles* (see p. 303).

Where the periosteal collar overlies the calcified cartilage walls of primary areolae, it is invaded from the deep periosteal layers by *osteogenic buds*—blind-ending capillaries and accompanying cells which continually divide to form osteoblasts, and osteoclasts. The latter excavate newly formed bone to pass into adjacent calcified cartilage and here continue to erode walls of primary areolae, leading to fusion of these into larger, irregular, communicating *secondary areolae* or *medullary spaces*. These fill with *embryonic* medullary tissue (vascular mesenchyme, osteoblasts and osteoclasts, haemopoietic cells, etc.); osteoblasts attach themselves to the delicate residual walls of calcified cartilage, laying down osteoid which rapidly changes firstly into patches then continuous linings of bone. Further layers of bone are added, enclosing young osteocytes in lacunae, and narrowing the perivascular spaces. As the formation of subperiosteal bone continues, bone deposition on the more central areolar walls ceases. Osteoclastic erosion of the early bone spicules then creates a primitive medullary cavity in which only a few trabeculae composed of bone with central

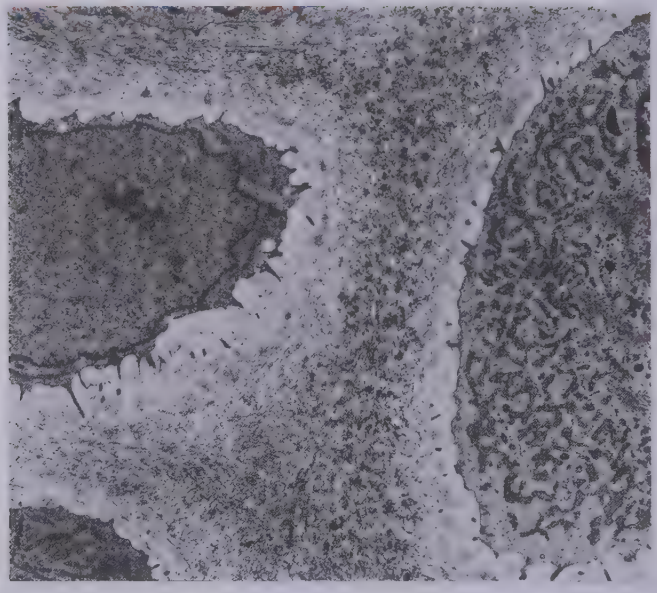
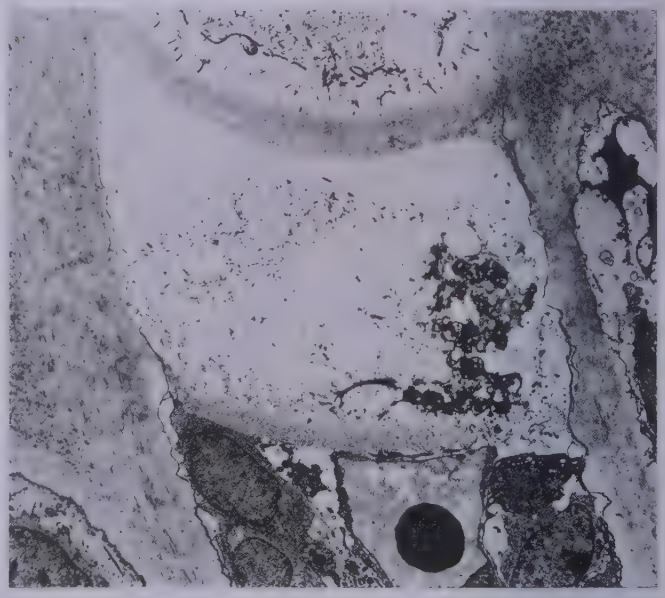
cores of calcified cartilage remain to support the developing marrow tissues. Such trabeculae soon become remodelled and replaced by more mature bone. Meanwhile cartilaginous regions near the shaft go through similar changes (3.37,43,46) and, when covered with bone, may become incorporated in the bone of the periosteal collar. Since these are most advanced centrally and the epiphyses remain cartilaginous, the intervening zones show a sequence of changes in growing bones, when viewed in longitudinal section (3.46A,B,47). This region, which persists until longitudinal growth of the bone ceases, is the *growth plate* or *epiphysial plate*.

The Growth Plate (3.47)



Growth of the cartilaginous extremity (usually an epiphysis) keeps pace with the rest of the bone both by apposition and interstitially (3.51). Where it meets the cartilaginous shaft an organized region of rapid growth appears, as the future growth plate between epiphysis and diaphysis (see e.g. Siffert 1956, Rang 1969), which grows in all dimensions. Transverse or latitudinal growth is due to occasional transverse mitoses and appositional growth due to matrix deposition by cells from the perichondrial collar (or ring) at this level. The future growth plate thus expands in concert with the shaft and adjacent future epiphysis. On the side of the plate closest to the epiphysis is a zone of relatively quiescent chondrocytes, but further towards the centre of the bone is an actively mitotic zone of cells. Here, the more frequent divisions in the long axis soon create numerous longitudinal columns (palisades) of discoidal or cuneiform chondrocytes, each in a flattened lacuna. This proliferation and column formation occupies the *zone of cartilage growth* and continued longitudinal interstitial expansion is the basic mode of elongation of a bone. Traced centrally in the shaft a column of cells shows increasing maturity, passing through the stages already described (vide supra). Thus they increase in size and accumulate glycogen and begin to show positive reactions for oxidative enzymes. Younger chondrocytes display surface projections into reciprocal recesses in lacunar walls, but as they hypertrophy and enter the *zone of cartilage transformation*, projections increase greatly, perhaps due to removal of cartilage matrix and progressive enlargement of lacunae. The largest cells withdraw their projections, then degenerate and die. The empty lacunae are now separated by transverse and longitudinal walls, impregnated with hydroxyapatite crystals (the zone of calcified cartilage). The calcified partitions enter the *zone of bone formation* and are invaded by vascular mesenchyme, with its osteoblasts, osteoclasts, chondroclasts, etc. from adjacent centres of primary ossification (3.48). Partitions, especially the transverse ones, are next partly eroded and on surfaces of the narrowing longitudinal walls occur osteoid deposition, bone formation and osteocyte enclosure as described above. As mentioned above, matrix vesicles occur in all sites undergoing calcification (see, e.g. Reinholt et al 1982). Chondrolysis of calcified partitions has been ascribed to osteoclastic (chondroclastic) action or to chondrolysis by endothelium in terminal loops of vascular sinusoids which occupy and come into close contact with each incomplete, columnar trabecular framework (3.39 and see Irving 1964). Whether these loops have intact endothelium or are temporarily fenestrated and are thus sites of microruptures (Brookes & Landon 1963, Trueta & Morgan 1960, Anderson & Parker 1966) is uncertain. Longitudinal and transverse partitions of matrix have also been considered to differ in structure and chondrolytic mechanisms, the transverse being lightly calcified, with sparse collagen and distinctive proteoglycans susceptible to lysosomes; the more resistant longitudinal ones succumb only to osteoclastic action (Anderson 1962, Dingle 1962).

Continuing cell division in the zone of growth adds to epiphysial ends of cell columns and, with the sequence of changes proceeding away from the diaphysial centre, the bone grows in length. Meanwhile, there is continued internal erosion and remodelling of the newly formed bone tissue and, as further subperiosteal bone deposition continues towards the epiphyses, the bone also grows in diameter, its medullary cavity enlarging transversely and longitudinally.



Growth continues thus for many months or years in different bones (p. 279) but eventually one or more secondary centres usually appears in the cartilaginous extremities. Such epiphysial centres (or ends of bones lacking epiphyses) do not at first display cell columns. Instead, isogenous cell groups hypertrophy and die, with matrix calcification and then invasion by osteogenic vascular mesenchyme (sometimes from cartilage canals, (see p. 287). Many irregular bone spicules, with intervening medullary spaces, are formed on calcified cartilage, as described above for the growth plate. As an epiphysis enlarges, its cartilaginous periphery forms a zone of proliferation and its organization becomes radial, with cell columns and zones of growth, hypertrophy, calcification, erosion and ossification at increasing depths from the surface (3.47). The early osseous epiphysis is thus surrounded by a superficial growth cartilage; but the growth plate next to the metaphysis soon becomes the most active region, and here enlarging cell columns are directed solely towards the metaphysial plate,

3.39A–G Diagram depicting the stages of endochondral ossification in a long bone (e.g. a phalanx). For colour code see **3.38**; additionally, hyaline cartilage is light purple, calcified cartilage deep purple. For further details of postnatal endochondral ossification, see **3.47**.

3.41 Micrographs of immature woven bone (fetal human). A is a section of part of the maxilla, stained with haematoxylin and eosin. The mineralized bone is eosinophilic, but shows a paler front of osteoid formation where many osteoblasts are clustered; magnification × 150. Osteocytes are also visible within the bone. B is a higher magnification of woven bone stained with picrothionin to show the typically large osteocytes and their branched processes; magnification × 800. (Both micrographs provided by Moya Meredith Smith, UMDS, Guy's Campus, London.)

whereas elsewhere they are directed to the underlying epiphysial ossification (Payton 1934, Rang 1969).

As the bone reaches maturity, epiphysial and metaphysial ossification processes gradually encroach upon this growth plate from either side, eventually meeting, when bony fusion of the epiphysis occurs and longitudinal growth of the bone ceases. Unlike changes in growth plates, events of fusion have attracted little interest (Rang 1969), but in the rat (Becks et al 1948) they are as follows. When growth ceases, the cartilaginous plate becomes quiescent and gradually thins. Proliferation, palisading and hypertrophy of chondrocytes ceases; they become short, irregular conical masses. Patchy calcification is then accompanied by absorption of patches and some adjacent metaphysial bone. These erosion channels are invaded by vascular mesenchyme, some endothelial sprouts piercing the thin plate of cartilage, and here metaphysial and epiphysial vessels unite. Final bony fusion is by ossification around these vessels, spreading into the intervening zones. Such bone is very dense and visible in radiographs as an *epiphysial line* (a term also used for the level of the perichondrial ring around the growth cartilage of immature bones, or the surface junction

3.42A Section through the surface of a mature bone showing the periosteum into which are inserted skeletal muscle fibres. Notice both fibrous and deeper cellular components of the periosteum. 3.44 Longitudinal section of a phalanx (from the hand in 3.37) showing an early primary ossification centre. The cartilage cells in the shaft centre have hypertrophied and this region is surrounded by a delicate tube or collar of subperiosteal bone (red); magnification × 50. (Photography by Kevin Fitzpatrick, Guy's Hospital Medical School.)

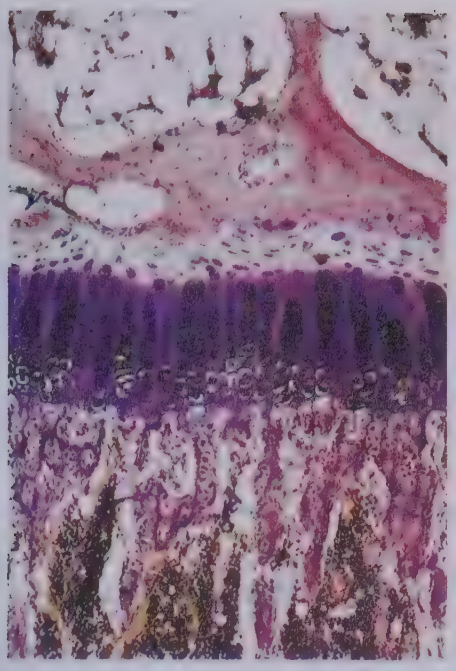
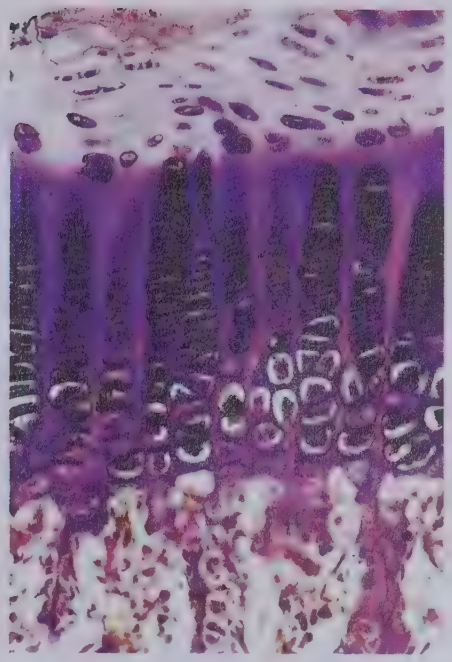
3.42B Microradiograph of a section through compact, osteonic bone, showing different degrees of mineralization of osteons which reflect progressive remodelling around large vascular canals. The most recent bone tissue appears denser; magnification × 150. (Provided by Moya Meredith Smith.)



3.45 Longitudinal section of the proximal half of a fetal metacarpal bone (from 3.37) at a more advanced stage than the phalanx in 3.44. The periosteal collar of woven bone is thicker, contains radially-disposed vascular spaces; vascular invasion of the shaft centre has occurred and is proceeding towards its extremities; magnification × 40. (Photography by Kevin Fitzpatrick, Guy's Hospital Medical School.)



3.43 Section showing the transformation of cartilage cells and their lacunae as the ossifying front of an early primary centre of ossification is approached (below). Note the cell hypertrophy, lacunar enlargement with matrix partition reduction and increased density of the partitions following calcification; magnification × 600.

between epiphysis and metaphysis in a mature bone). For analyses of epiphysio-diaphysial union, studied in dog and man consult Haines (1975), who found an essentially similar sequence of events as seen in the rat. In smaller epiphyses, uniting earlier, there is usually one eccentric, initial area of fusion, with thinning of the residual cartilaginous plate. Subsequently the original sites of fusion, now mineralized cartilage ('metaplastic bone') with superficial lamellar bone and medulla inside, are eroded and replaced by new bone and medullary tissue extending into the whole cartilaginous plate until union is complete, so that no *epiphysial 'scars'* persist. In larger epiphyses, uniting later, similar processes also involve multiple perforations in growth plates, *islands* of epiphysial bone often persisting as epiphysial scars. (Special features of *metaplastic bone* subjacent to articular cartilage and attachments of tendons, ligaments, and other dense connective tissues, have been surveyed by Haines & Mohuiddin 1968).

The cartilaginous surfaces of epiphyses involved in synovial articulations remain unossified, but the typical sequence of cartilaginous zones in them persists throughout life.

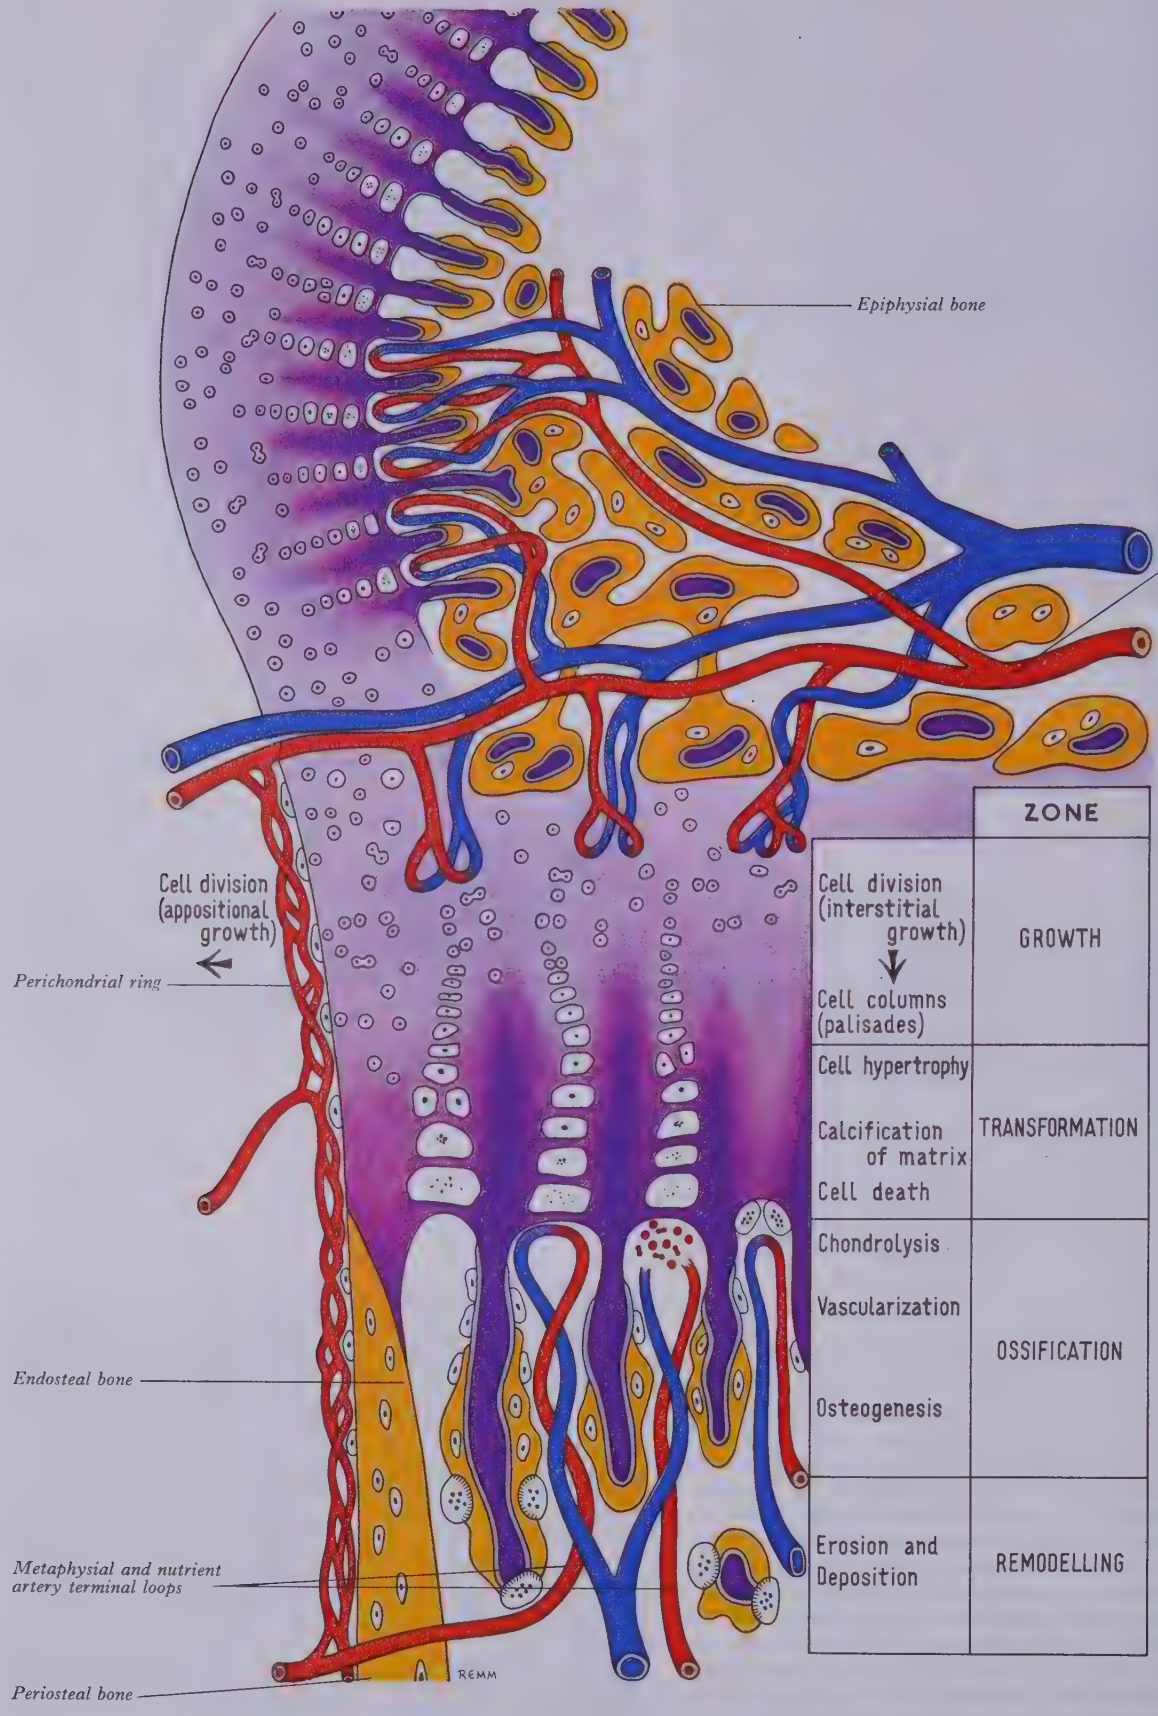
Note the transition from hyaline cartilage, through zones of cell multiplication, hypertrophy, column formation, matrix calcification and partial chondrolysis to the ossifying front. Compare with 3.47 and consult text for further details.

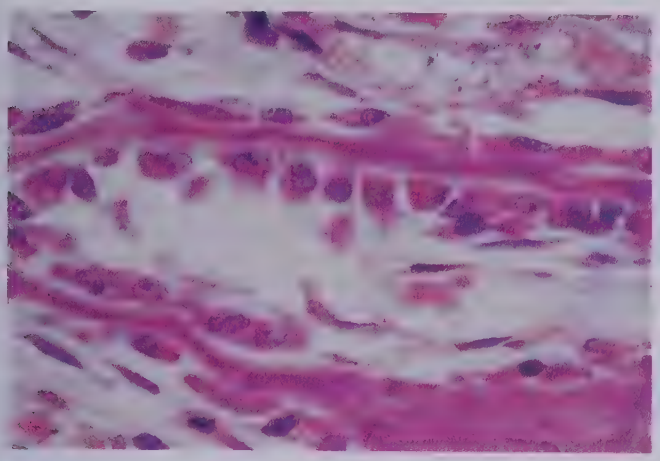
Further Development and Remodelling of Bone

In all situations so far described bone is initially trabecular, with a continuous labyrinth of large vascular spaces; osteocytes are irregularly scattered, there is no lamellation and collagen fascicles in the matrix form a random network. This *woven-fibred* tissue is typical of young fetal bones, but occurs also in adults (e.g. lining tooth sockets) and during repair of fractures. Later concentric tracts of non-lamellar, parallel-fibred bone, primary osteons or *atypical Haversian systems*, are deposited within the vascular spaces, narrowing or dividing them by osseous bridges. Collagen bundles in the matrix form parallel longitudinal spirals. No erosion precedes formation of such osteons; hence no cement lines separate them from surrounding woven bone. Bone deposited circumferentially on periosteal and endosteal surfaces is mostly lamellar with longitudinal or circumferential parallel fibres in successive lamellae; where these are thin, lamellation is indistinct. Circumferential bone may also be non-lamellar or woven, in some species, and the term *surface bone* is then preferable.



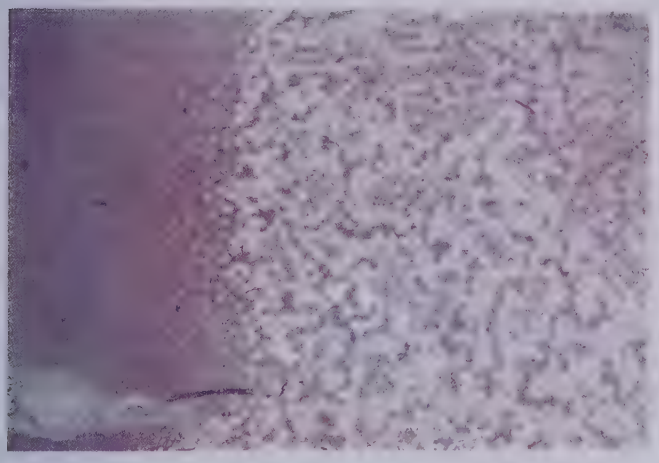
As bone matures, *typical Haversian systems (secondary osteons)* gradually replace primary osteons and woven bone. They are always preceded by erosion, usually eccentric, of the vascular channels within primary osteons or woven bone. Remodelling of the interiors of bone is marked by the balanced activities of osteoclasts and osteoblasts; osteoclasts first excavate a cylindrical tunnel by concerted action (a 'cutting cone'), and then they are followed by osteoblasts which fill in the space created by concentric deposition around a centrally ingrowing blood vessel (forming a 'closing cone'). Concentric deposition of lamellae of parallel-fibred bone follows on walls of *resorption cavities* and around vascular channels, which are thereby narrowed. A cement line always marks a site of reversal from erosion to deposition. Formation of secondary osteons does not end with growth but endures variably throughout life; some of the earliest secondary osteons are eventually eroded. Remnants of woven bone, primary osteons, circumferential lamellae and finally secondary osteons form *interstitial bone* occupying crevices between later osteons. The degree of remodelling is in general an indication of age, so that the number of osteons and osteon fragments can be used to estimate the age of skeletal material at death. (For quantitative data on the ageing of human bone see Courpron et al 1973, and for ageing effects of osteon remodelling in human tibia see Ortner 1975.)

Bone growth is solely *appositional*, i.e., new layers are added to pre-existing surfaces, osteocytes being enclosed in lacunae and ceasing to divide. The rigidity of mineralized bone matrix of course prevents internal expansion, so that interstitial growth, characteristic of most tissues, including cartilage, is absent in bone, though essential in growth cartilages, as discussed above.



Hence remodelling of bone, which involves either major readjustment after fracture or remodelling throughout life, depends upon delicate geometric balances between deposition and removal. Demonstrations of these main features have, with increasing refinement, spanned the last two centuries. Earlier experimenters used metal markers, such as wires encircling shafts of bones, or pellets embedded in them. An early observation that, in growing pigs fed with the plant *madder*, newly formed bone is identifiably pink initiated numerous studies of bone growth by alternating periods of feeding with madder and without it (Brash 1934). Intraperitoneal injection of alizarin red has been used with greater precision for the same purpose (Hoyte 1960). Such studies confirm that bone grows by accretion; later techniques have merely increased accuracy, making quantitative histological studies possible. These include administration of osseotropic isotopes followed by autoradiography (Leblond 1950), exposure to tetracycline at intervals followed by fluorescence microscopy, and historadiography (Amprino & Engström 1952, Amprino 1968).

Major remodelling, i.e. change in general shape, occurs in all growing bones; much studied examples are cranial and long bones with expanded extremities. A bone such as the parietal thickens and expands during growth, but decreases in curvature (3.50). Accretion continues at its edges by interstitial multiplication of osteoblasts at sutures. Periosteal bone is added externally and eroded internally, but not at uniform rates; the rate increases with radial distance from the centre of ossification (the future parietal eminence).



Long bones elongate mainly by extension of endochondral ossification into calcified zones of adjacent growth cartilages continually replaced by longitudinal interstitial growth of their proliferative zones, with minor additions by radial epiphysial growth (p. 304). Simultaneously diametric increases of growth cartilages and shafts occur by continuing subperiosteal deposition and endosteal erosion. In many bones, however, growth is at different rates, or even reversed, at different places. A bone

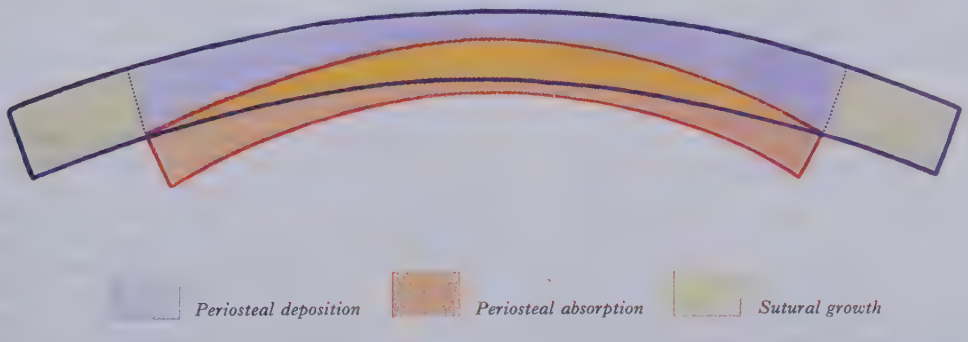
3.47 Scheme of the main features of an active growth cartilage and the adjacent metaphysis and epiphysis. The different views concerning the mechanism of chondrolysis described in the text are indicated.

3.48 Section through the metaphysis of a fetal bone stained with haematoxylin and eosin showing developing spicules of early bone. Each spicule contains a deeply stained basophilic core of calcified cartilage, which is covered on both aspects by a lightly stained eosinophilic layer of young bone along which are ranged rows of active osteoblasts.

3.49 Transverse section through an epiphysis of a long bone at a more advanced stage of ossification. Note the gradation of cartilage cell lacunae (left) as the ossifying front is approached. The bony trabeculae (light pink) contain dark patches of basophilic calcified cartilage and the intertrabecular spaces are filled with red bone marrow.

initially tubular may thus become triangular in section, e.g. the tibia. Similarly, the waisted contours of metaphyses are preserved by differential rates of periosteal erosion and endosteal deposition (see 3.51).

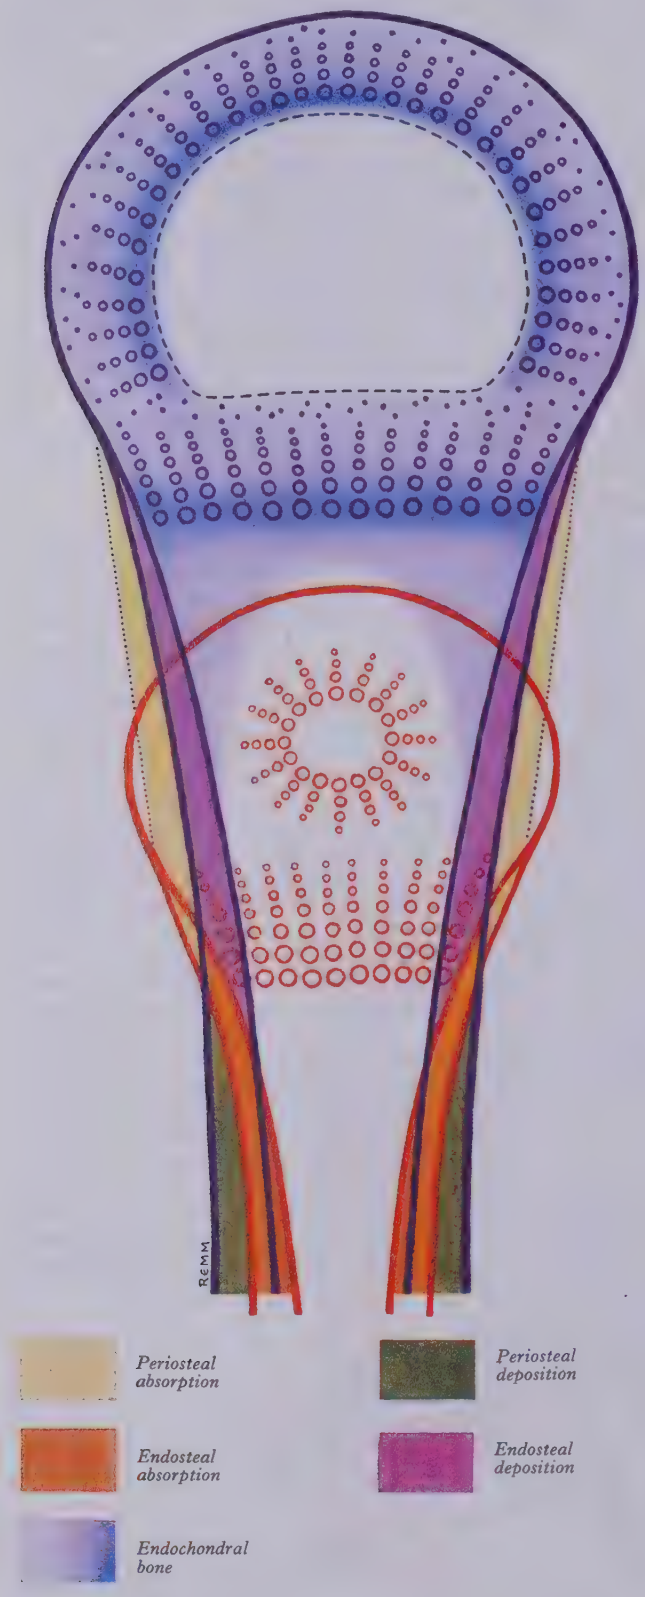
Tetracycline marking techniques have emphasized the mutability of even mature compact bone, where a single section may include mature quiescent osteons, and recently formed, forming or resorbing osteons. Lamellar bone forms at a variable rate; a resorption canal forms in 1–3 months and a new osteon in a similar period (Lee 1964). Internal remodelling continuously supplies young osteons with labile calcium reserves (p. 303), and a malleable osseous architecture responsive to altering patterns of stress (p. 276). Total morphogenetic control of shape is not clear, but suggestions largely involve responses to stress. Certainly bone resorption typically occurs when the gravitational or other mechanical stresses are reduced, as in bed rest, or in zero gravity conditions in space. Likewise bone subjected to constant pressure tends to resorb and, with constant tension, is deposited; this forms the basis of much orthodontic treatment, as teeth can be made to migrate slowly through alveolar bone by the application of steady lateral or medial pressure.



Like other crystalline substances, bone is piezo-electric, i.e. it generates electric currents when deformed, and distribution of potential differences reflects form of distortion. Such currents may affect cells responsible for osteolysis and bone deposition, promoting structural remodelling to resist predominating stresses (see Currey 1984 for a review of this subject). Data concerning sources, intensities and distributions of bioelectric phenomena in stressed connective tissues in general are not yet sufficient to show causal relationships between such events and to relate them to morphogenesis.

Metabolic and Endocrine Effects on Bone

The roles of bone salts, parathyroid hormone and calcitonin in regulating circulating calcium levels are considered elsewhere (p. 302). However, the normal development and maintenance of bone also require adequate intake and absorption of calcium, phosphorus, vitamins A, C and D and a balance between somatotrophic hormone, thyroid hormones, oestrogens and androgens. Various other factors, including different prostaglandins and glucocorticoids may also play important roles in the maintenance and turnover of osseous tissue (see Rodan & Rodan 1983).



Prolonged deficiency of calcium causes loss of bone mineral or *osteoporosis*, and consequent fragility of bones. Vitamin D influences intestinal absorption of calcium (and indirectly of phosphorus) and therefore affects circulatory calcium levels; prolonged deficiency (with or without low intake) leads, in adults, to *osteomalacia*, in which bones are poorly mineralized and often contain regions of deformable, uncalcified osteoid. Similar deficiencies, during growth, lead to classic rachitis (*rickets*), with severe disturbance of growth cartilages and ossification, including reductions of regular columnar organization in growth plates and failure of cartilage calcification (although chondrocytes proliferate); growth plates also become thicker and less regular than normal. In metaphysial regions cartilage is partially eroded, and osteoblasts secrete layers of osteoid, which fail to ossify on uncalcified or poorly calcified cartilage trabeculae. Ultimately gravity deforms such softened bones. (For reviews of the role of vitamin D, see Reynolds 1974, Rodan & Rodan 1983).

Deficiency of vitamin C causes *scurvy*, with widespread changes in all connective tissues, particularly growth cartilages and metaphyses of long bones. It appears essential for adequate

3.50 Scheme illustrating the gross patterns of growth and remodelling of a bone of the cranial vault, in section. Note the changes in surface area, thickness and curvature. See text for further details.

synthesis of collagen *and* matrix proteoglycans in connective tissues and, when deficient growth plates become thin, ossification almost ceases and metaphysial trabeculae and cortical bone are reduced in thickness, causing fragility and delayed healing of fractures.

3.51 Scheme of the patterns of remodelling which occur during the growth of a long bone. Note the changing shape of the epiphysial ossification centre, the altered organization of the cartilaginous growth plates and the varying zones of bone deposition and absorption. See text for further details.

Vitamin A is also necessary for normal growth and for a correct balance of deposition and removal of bone. Deficiency retards growth due to the failure of internal erosion and remodelling, particularly in the cranial base. Foramina are narrowed, sometimes causing pressure atrophy of contained nerves; the cranial cavity and spinal canal may fail to expand with the central nervous system, impairing nervous function. Conversely, *excessive* vitamin A stimulates vascular erosion of growth cartilages, which become thin or totally lost; as a result, longitudinal growth ceases.

Balanced endocrine activities are essential to normal bone maturation, and disturbances may have profound effects.In addition to its role in calcium metabolism, parathyroid hormone in excess stimulates osteoclasts and perhaps osteocytes to widespread osteolysis and erosion, leaving a demineralized framework—a condition termed *osteitis fibrosa*.

Acidophil cells of the adenohypophysis cerebri secrete *growth hormone* (somatotropin) necessary for normal interstitial proliferation in growth cartilages and hence increase in stature. Termination of normal growth is imperfectly understood, but may involve a fall in hormone production or in the sensitivity of chondroblasts to hormones. Experimental hypophysectomy, or clinical reduction of growth hormone in the young, leads to quiescence and thinning of growth plates and hence *pituitary dwarfism*. Conversely, continued hypersecretion in the immature leads to *giantism*, but in maturity it results in thickening of bones by subperiosteal deposition, the mandible, hands and feet being most affected, an affliction known as *acromegaly*.

While continued longitudinal growth of bones depends on adequate levels of growth hormone, the effective remodelling to a mature shape also requires the action of the thyroid hormones, tri-iodothyronin and tetraiodothyronin (T_3 and T_4); growth and skeletal maturity are also closely related to endocrine activities of the ovaries, testes and adrenal cortices. High oestrogen levels increase deposition of endosteal and trabecular bone; conversely, osteoporosis in aged women may reflect reduced ovarian function. Fluctuations in the rate of growth and the timing of skeletal maturation reflect circulating levels of adrenal and testicular androgens (p. 1429). In hypogonadism, maturation (marked by growth plate obliteration) is late and the limbs therefore elongate excessively; conversely, in hypergonadism, premature fusion of the epiphyses results in diminished stature.

The normal growth and pathology of growth cartilages has a large literature, beyond the present scope, but several excellent accounts have appeared (Rang 1969, Serafini-Fracassini & Smith 1974, Kahn et al 1983).

General Features of Bones

Bones vary not only in their *primary* shape but also in lesser surface details, or *secondary* markings which appear mainly in postnatal life. Certain features—elevations and depressions, smooth areas and rough ridges—are found in many bones. For such, a repertoire of general terms is used, since the same form of marking or surface texture usually has the same functional significance wherever it occurs. For example, bones display *articular surfaces* at synovial joints with their neighbours; if small, these are *facets* or *foveae*. Knuckle-shaped surfaces are *condyles*, and a *trochlea* is grooved like a pulley. Adapted in shape to the movements of particular joints, such surfaces are smooth, though in life they are, of course, covered by articular cartilages forming the actual surfaces of synovial joints. The texture of such osseous surfaces is due to another feature, frequently overlooked; they are devoid of the vascular foramina typical of most other bone surfaces, articular cartilage being poorly vascularized. However, osseous articular surfaces are not completely impermeable, though the cartilage contiguous with subjacent bone is usually calcified; hence substantial interchange is improbable (the nutritive avenue to articular cartilage may be largely from synovial fluid). Scanning electron microscopy shows that *all* bony surfaces, including those appearing smooth to the naked eye or hand lens, display large numbers of minute foramina. The proportion of these occupied by vascular, nervous or collagenous elements is unknown. (For surface architecture consult **3**.5,6.)

Large tendons (e.g. adductor magnus, subscapularis) are attached to facets which lack the regular contours of articular surfaces but resemble them in texture, being poorly vascularized. Such tendon facets are sometimes depressed (the adductor 'tubercle' is often a small pit); alternatively they may surmount large elevations, e.g. the humeral tuberosities.

Depressions and elevations, varying in size and shape, interrupt otherwise featureless osseous surfaces. A depression is a *fossa*, and some articular surfaces are fossae (cf. temporomandibular joint). Lengthy depressions are *grooves* or *sulci* (e.g. humeral bicipital sulcus); a notch is an *incisura*, and an actual gap is a *hiatus*. A large projection is termed a *process* or, if elongated, slender or pointed, a *spine*. A curved process is a *hamulus* or *cornu* (cf. sphenoidal pterygoid hamuli and hyoid cornua). A rounded projection is a *tuberosity* or *tubercle*, occasionally a *trochanter*. Long elevations are *crests*, or *lines* if less developed; crests are wider and present boundary edges or *lips*; however, these terms are ill-defined, and one most substantial crest is the *linea aspera* (cf. femur). An *epicondyle* is a projection close to a condyle and usually an attachment for the collateral ligaments of the adjacent joint or common myotendinal attachments for superficial muscle groups (cf. humerus). The terms protuberance, prominence, eminence and torus are also less often applied to certain bony projections. The expanded proximal ends of many long bones are often termed the '*head*' or *caput* (cf. humerus, femur, radius, etc.).

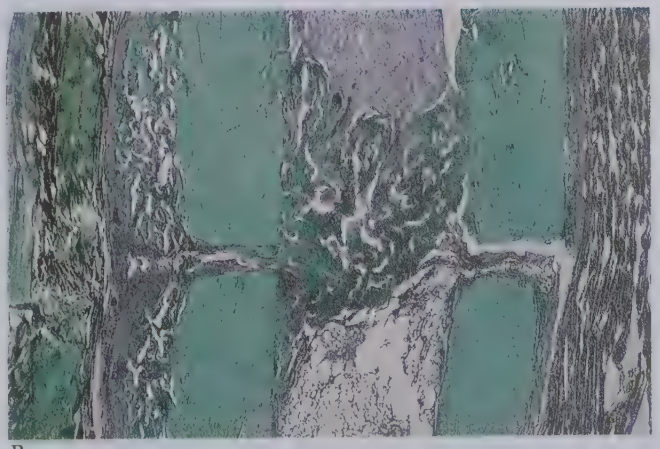
A hole in bone is a *foramen*; *foramina* are *canals* when lengthy. Large holes may be called *apertures* or, if covered largely by connective tissue, *fenestrae*. Clefts in or between bones are *fissures*. A *lamina* is a thin plate; larger laminae may be called *squamae* (e.g. the temporal squama).

Large areas on many bones are featureless and indeed often smoother than articular surfaces, but they differ from these in possessing many visible vascular foramina. Such a texture occurs where muscle is directly attached; through the foramina pass small blood vessels from bone to muscle and perhaps vice versa. Areas covered only by periosteum are similar but vessels are less numerous.

Tendons are usually attached at roughened bone surfaces; and wherever any aggregation of collagen in a muscle reaches bone, surface irregularities correspond closely in form and extent to the pattern of such 'tendinous fibres'. Such markings are almost always elevated above the general surface, as if ossification advanced into the collagen bundles from periosteal bone. However, how such secondary markings are induced is uncertain. Evidence suggests that their prominence may be related to the power of muscles involved and they increase with advancing years, as if the pull of muscles and ligaments exercised an accumulative effect. Certainly, surface markings delineate the shape of attached connective tissue structures, whether an obvious tendon, intramuscular tendon or septum, aponeurosis, or tendinous fibres mediating otherwise direct muscular attachment. Hence markings may be facets, ridges, nodules, rough areas or complex mixtures, affording accurate data of junctions of bone with muscles, tendons, ligaments or articular capsules. Numerous examples will be described with individual bones.

Note that even in the so-called 'fleshy' or direct attachment of a muscle, its myocytes do not themselves adhere directly to periosteum or bone. The route of transmission of tension from contracting muscle to bone must be through the connective tissue which pervades all muscles as perimysium and endomysium. (See *myotendinal junction*, p. 556, although details of its mechanics are uncertain.) These two forms of attachment, at the extremes of a range of admixtures, differ in the density of collagen fibres between muscle and bone. Where collagen is visibly concentrated, markings appear on the bone surface. In contrast, the multitude of microscopic connective tissue ties of direct attachment, necessarily over a larger area, do not visibly mark it. Here the bone appears smooth to unaided vision and touch. (*See* 3.5,6 for magnified views of osseous surfaces.)

The Response of Bone to Injury



After an injury such as a fracture, bone generally undergoes spontaneous regeneration, which in favourable conditions can result in virtually complete restoration of its anatomical structure before injury. Depending on the location of the injury, endochondral and/or intramembranous ossification (p. 300) may be involved. Exceptions to this occur in the calvarium, where fractures are usually repaired permanently by fibrous union and not by regeneration of new bone, and after rigid internal fixation, where bone can form directly by primary bone healing, without the preliminary development of either fibrous tissue or cartilage.

BONE HEALING WITHOUT OPERATIVE INTERVENTION

Bone healing consists of several overlapping phases: inflammation, soft callus formation, hard callus formation and remodelling. Soft and hard callus formation are collectively equivalent to the proliferative phase of wound healing (p. 84). The term 'soft callus' appears to be contradictory in that 'callus' implies hardness (Latin *callum* or *callus* = hard integument); it can be defined as the soft, collagenous, revascularizing, osteogenic blastema which unites the bone fragments and from which bone regenerates.

B

3.52 Midsagittal sections through the repairing fracture site of the lower tibia of a rabbit, held rigidly in an external fixator. Movat's hexachrome stain: undifferentiated blastemal tissue grey; cartilage turquoise; bone pale green. (Sections provided by R Brueton, Orthopaedic Research Department, Rayne Institute, St Thomas's Hospital, London; photographed by Kevin Fitzpatrick.)

A. 2 weeks after injury. A distinct fracture gap separates adjacent fragments of cortex. The mainly adipose marrow contains patches of blastemal tissue. External soft callus contains patches of cartilage; a few bone trabeculae and some cartilaginous areas are present endosteally.

B. 4 weeks after injury. A lamella of bone lies in the fracture gap. Endosteal soft callus unites the posterior cortical fragments. Periosteal soft callus is present posteriorly, but is not yet confluent across the gap, while anteriorly only fibrous tissue is present.

3.53 Midsagittal section through the remodelling fracture site of the lower tibia of a rabbit, held rigidly in an external fixator, six weeks after injury. A mass of periosteal hard callus unites the posterior cortices, while fibrous tissue is present anteriorly. Endosteal hard callus unites anterior and posterior cortices. Some soft callus lies between the fragments posteriorly. Remodelling of the marrow cavity has begun and there is a central axis of myelofibrotic material. Movat's hexachrome stain: undifferentiated blastemal tissue grey; cartilage turquoise; bone pale green. (Section provided by R Brueton, Orthopaedic Research Department, Rayne Institute, St Thomas's Hospital, London; photographed by Kevin Fitzpatrick.)

Inflammation

This begins immediately after fracture, overlaps with the phase of soft callus formation and typically lasts for about four days. It is characterized by local haemorrhage, haematoma formation, oedema and pain. Although there is some evidence that fibrin in the haematoma may stimulate the proliferation of local potentially osteogenic cells and assist in immobilizing the bone fragments, the haematoma is not generally considered to be a significant stimulator of bone healing (Heppenstall 1980).

Vascular damage causes the environment of the fracture to become hypoxic and acidic, resulting in osteocytic disruption and the release of lysosomal enzymes, followed by tissue necrosis at and close to the site of injury. Mast cells, polymorphonuclear leucocytes and macrophages appear at the site of injury and release mediators, some of which may, as in the repair of skin wounds (p. 84), stimulate the proliferation of reparative cells (here osteoblasts, endothelial cells and in some circumstances chondroblasts). The mast cells, some of the macrophages and the reparative cells are of local origin, while the polymorphonuclear leucocytes and the remainder of the macrophages are haematogenous.

During the inflammatory phase, osteoclasts and macrophages erode necrotic bone and remove tissue debris from the fracture site. Recent research suggests that macrophages also secrete factors or mediators, some of which stimulate collagen synthesis and angiogenesis in wound healing (Hunt et al 1984) and it is conceivable, though not yet demonstrated, that they act in a similar manner in the healing of bone.

As inflammation is overlapped by soft callus formation, cells near the fracture site are induced to develop into osteoblasts which produce new bone. These osteogenic cells either result from the modulation of osteocytes and osteogenic periosteal and endosteal cells, or from the division and differentiation of fibroblasts, endothelial cells, non-striated myocytes and mesenchymal cells. The inductive mechanism for modulation and differentiation is probably multifactorial and may involve a variety of interacting stimuli including mediators released from mast cells and macrophages, reduced oxygen availability and the level of bone morphogenic substance (Heppenstall 1980).

Soft Callus Formation

During this stage, which occupies approximately three or four weeks, a soft tissue blastema or soft callus develops around and between the fragments of bone, reducing their mobility (3.52A). The soft callus contains proliferating osteoblasts, fibroblasts and often chondroblasts, embedded in a matrix, rich in glycoproteins and collagen, into which new blood vessels grow. The soft callus can be subdivided into external and internal callus, the former derived from the proliferation of osteoblasts in the osteogenic layer of the periosteum, and the latter from endosteal cells. The enhanced proliferative activity of the osteogenic layer of the periosteum extends beyond the immediate fracture site, elevating the overlying fibrous component of the periosteum and producing a collar of soft external callus which unites the bone fragments. Periosteal cells located within this callus furthest from the fracture site (i.e. in a mechanically stable, well-oxygenated environment) form new osseous matrix directly but as the more mobile and poorly oxygenated fracture site is approached the cell population becomes mixed, containing chondrogenic as well as osteogenic cells, the former being the transformed progeny of the latter (Tonna & Pentel 1972). Although angiogenesis is in progress, proliferation is so rapid that cellularity outstrips vascularity, maintaining an oxygen gradient and keeping the fracture site relatively hypoxic (Wray 1963, Heppenstall et al 1975). Initially the periosteum supplies blood to the site of fracture, but later in the regenerative process the normal centrifugal flow of blood from the endosteal circulation is re-established (p. 299). The external and internal surfaces of the soft callus are electronegative throughout this stage of repair.

Hard Callus Formation

During this stage of fracture healing the external and internal soft callus are gradually converted into woven bone (3.52B) mainly by endochondral ossification, unless the bone fragments have been surgically immobilized with a compression plate, when intramembranous ossification predominates. Both cellularity and vascularity continue to increase, but in such a manner that the oxygen gradient referred to above is maintained. The pH of the matrix of the callus gradually increases to the neutral level but the external and internal surfaces of the callus remain electronegative. While both osteogenesis and chondrogenesis are in progress, osteoclasts continue to erode the matrix of any necrotic bone remaining at the fracture site. This stage of bone healing commences at about three or four weeks after injury and continues until attainment of firm bony union, about two or three months later for most adult long bones.

Remodelling

During this stage, which overlaps with the formation of hard callus and may continue for several years, the woven bone of the hard callus is gradually converted into lamellar bone. Osteoclasts remove excess bone from the exterior of the periosteal collar and remodel its endosteal aspect so that the medullary cavity is restored across the site of the fracture (3.53). As a result of changes in vascularity, the oxygen supply of the fracture site returns to normal. The surface charge of the fracture site also reverts to normal, being no longer electronegative. Remodelling can be considered to be complete, a state achieved more rapidly in children than in adults, when the site of the fracture can no longer be identified either structurally or functionally. The regenerative process is, however, extremely lengthy and, until it has been completed, the injured bone is functionally less efficient than it was before damage. The rate of regeneration can be accelerated by a number of measures, including surgical intervention and exposure to physical agents such as direct current (Friedenberg et al 1971, Brighton 1981), pulsed electromagnetic fields (Bassett et al 1974, reviewed by Barker & Lunt 1983) and ultrasound (Duarte 1983, Dyson & Brookes 1983). The mechanisms of induced acceleration of regeneration are currently under investigation.

PRIMARY BONE HEALING

In the primary bone healing which follows rigid internal fixation (Perren et al 1969), interruption of the blood supply at and near the fracture results in local destruction of osteons, and this

stimulates the regeneration of new Haversian systems across the site of the fracture. Osteoclasts assemble at the ends of Haversian canals near to the fracture site forming *spearheads* or *cutting cones* which advance at a rate of 50 to 80 μm per day across the fracture, enlarging the canals as they advance; they are closely followed by osteoblasts which form new Haversian systems in the enlarged canals which now cross the fracture site and so link the fragments of bone. The entire process only lasts about five or six weeks but has the disadvantage that the major surgical intervention required subjects the tissues to further trauma.

THE AXIAL SKELETON

Introduction

Dividing the skeleton into axial and appendicular sections is not merely a convention. The axial structures, cranium and vertebral column and associated ribs and sternum, are primary; the appendicular elements in fins, limbs or wings were subsequent though early additions. Both primary and secondary elements are concerned in elaboration of locomotion. An axial endoskeleton, first a notochord and then a vertebral column, is the basic feature of *Chordata* and their subphylum, the *Vertebrata*, including mankind. A stiff but flexible axis, in bilaterally symmetrical animals that show an early tendency to elongation, prevents telescoping of the body during waves of contraction in successive segmental muscles to produce the sinuous movements, especially in the tail, which are the basic mode of locomotion in aquatic vertebrates. A chain of bones, flexibly connected by discs of deformable substance, developed around and largely replaced the notochord. However, notochordal vestiges occur in vertebrae of many fish, amphibians and reptiles, and centrally in mammalian intervertebral discs. This replacement is repeated in every vertebrate embryo. These new vertebral elements are complex and variable in pattern in earlier vertebrates but from reptiles onwards the most basic part is the *centrum*, forming most of the vertebral body, ventral to the spinal cord (spinal medulla). In a typical vertebra a *neural arch*, encircling the spinal cord, fuses ventrally with the centrum and usually bears a median dorsal *spinous process* and paired lateral *transverse processes* just dorsal to neurocentral junctions. This enclosure isolates the spinal cord from the play of axial musculature and protects it from external forces, thus insulating its vessels from extraneous compression.

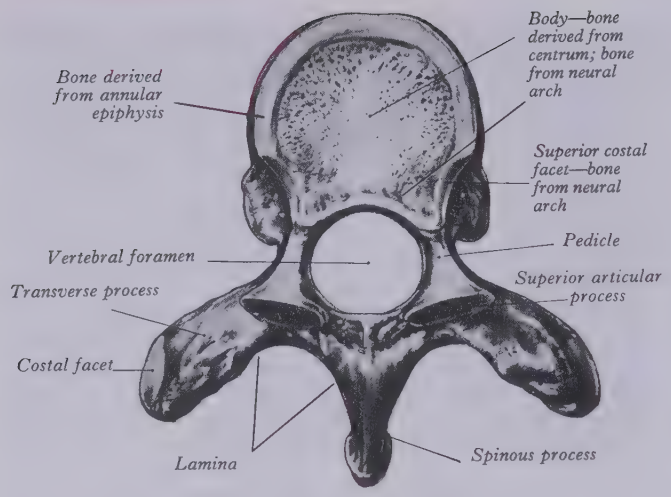
The centrum and each half neural arch ossify from separate centres; and when these extend through cartilaginous precursors to meet and fuse, the dorsolateral parts of the vertebral *body* are formed from ventral ends of the neural arch. Centrum and body are therefore *not* synonyms, nor is the *vertebral arch* exactly equal to a neural arch. A centrum is somewhat less than a vertebral body, a neural somewhat more than a vertebral arch (p. 327).

Segmental muscles flexing the vertebral axis are only in part attached to vertebrae; in connective tissue septa (*myocommata*) between adjacent myotomes ribs evolve as levers for such attachments. Such costal struts first appeared *dorsally* in the axial musculature and extended ventrally into the body wall in early vertebrates. In fish *ventral* ribs also appeared, which enclosed caudal vessels in the tail. It is generally agreed that ribs of land tetrapods correspond to the dorsal piscine series (Romer 1970).

Ribs are thus intersegmental and segmental muscles, derived basically from myotomes, bend the vertebral column; vertebrae also become intersegmental, though their embryonic pattern (p. 159) is primarily segmental. In early vertebrates dorsal ribs adjoin most vertebrae, showing little regional adaptation except in the postanal tail. In land vertebrates, with elaboration of appendages for locomotion, the vertebral column is adapted to new patterns of force in the distribution of weight and muscular tensions.

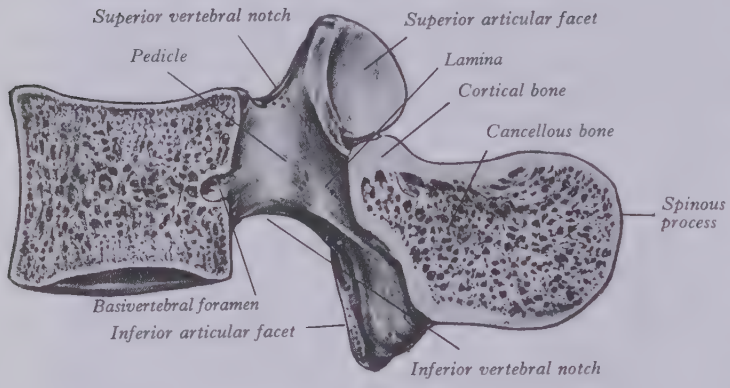
In hind limbs the pelvic girdle articulates with several vertebrae, which fuse with each other and with costal elements to form a *sacrum*. Sacral vertebrae lose *individual* movement; in mammals there are three to five *fused sacral vertebrae*, and distal to these a variable number of *caudal vertebrae*, reduced to four degenerate elements fused into a *coccyx* in adult humans. Some movement persists, however, between the fused sacral mass and neighbouring vertebrae; also between sacrum and the pelvic girdle.

Mammalian presacral vertebrae vary in number and differentiation, distinguished, however, into *cervical* (neck), *thoracic* (where ribs persist) and *lumbar* vertebrae (devoid of mobile ribs). Cervical ribs are small or 'absent' (but *vide infra*); their disappearance in cervical *and* lumbar regions is linked to the change from breathing by gills to lungs, and to development of independent movements of the head. There is no neck in fish, the postcranial region being occupied by the branchial apparatus. Caudal shift of the respiratory apparatus in land vertebrates necessarily preceded development of a neck. Cervical vertebrae were early stabilized to seven in mammals (except tree sloths and manatees), even in such extremes as whales and giraffes. With respiratory adaptation of ribs in land animals and development of a diaphragm in mammals, well-formed ribs, articulating with, but separate from vertebrae, are limited to thoracic levels. But ribs do *not* disappear completely in *cervical* and post-thoracic regions: vestigial *costal elements* are combined with transverse processes of all such vertebrae (see **2**.44, and **3**.57).



The total number of vertebrae, excluding the tail, is reduced from the lemuroid and tarsioid to the anthropoid primates. Monkeys, apes and hominids (extinct and extant) show some uniformity. The cervical, thoracic, lumbar and sacral vertebrae number respectively 7, 11 to 15, 4 to 7, and 3 to 6, human values being 7, 12, 5 and 5. Caudal vertebrae vary much in number.

Such preliminary generalizations on the origin of the human vertebral column facilitate consideration of individual elements, beginning with the form and structure of a typical vertebra. Some reference to phylogeny of the ribs and sternum will be found in subsequent sections.



General Vertebral Features

A vertebra (**3**.54) has basically a ventral *body* and a dorsal *vertebral (neural) arch*, extended by lever-like processes, together enclosing a *vertebral foramen*, occupied by the spinal cord, meninges and their vessels. Opposed surfaces of adjacent bodies are bound together by *intervertebral discs* of fibrocartilage. The complete column of bodies and discs forms a strong but flexible central axis of the body supporting, in bipeds, the full weight of head and trunk. It also transmits even greater forces due to muscles attached to it directly and indirectly. The foramina form a *vertebral canal* for the spinal cord, and between adjoining neural arches, near their junctions with vertebral bodies, *intervertebral foramina* transmit mixed spinal nerves, smaller recurrent nerves and blood and lymphatic vessels (see also p. 1124).

The cylindroid *vertebral body* varies in size, shape and proportions in different regions and even more in different species. Its junctional aspects vary from approximately flat (but not parallel) to sellar, with a raised peripheral smooth zone formed from the 'annular' epiphysial disc (p. 328), within which the surface is rough. These differences in texture are due to variations in early structure of intervertebral discs (p. 159). In the horizontal plane profiles of most bodies are convex, but concave dorsally where they complete the vertebral foramen. Most vertical profiles are concave but dorsally flat. Small vascular foramina appear on the front and sides, but posteriorly there are small arterial foramina (Willis 1949) and a large irregular orifice (sometimes double) for exit of basivertebral veins (**3**.55). The adult vertebral *body* is *not* coextensive with the developmental *centrum* (p. 327) but includes, posterolaterally, parts of the neural arch, as already noted.

3.54 Typical thoracic vertebra: superior aspect.

3.55 Median sagittal section through a lumbar vertebra.

The vertebral arch has on each side a vertically narrower ventral part, the *pedicle*, and dorsally a broader *lamina*. Projecting from their junctions are paired transverse, superior and inferior articular processes, and dorsally a median spinous process.

Pedicles are short, thick, rounded dorsal projections from the body at the junction of its lateral and dorsal surfaces and nearer the superior, so that the concavity formed by its curved superior border is shallower than the inferior one (3.55). Adjacent *vertebral notches* contribute to an *invertebral foramen* when vertebrae are articulated by the intervertebral disc and zygapophyseal joints. The complete perimeter of an intervertebral foramen consists, therefore, of the notches, the dorsolateral aspects of parts of adjacent vertebral bodies and intervening disc, and the capsule of the synovial zygapophyseal joint.

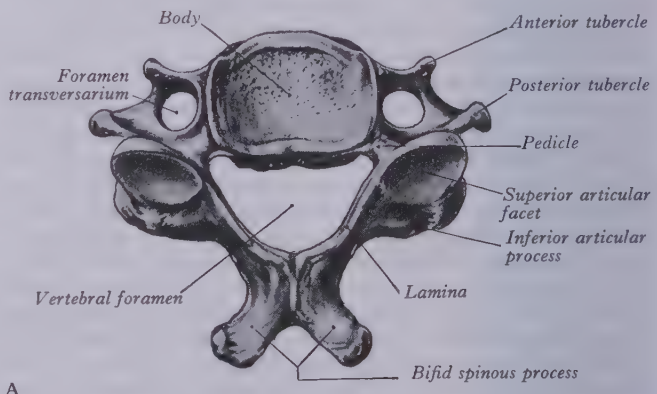
Laminae, directly continuous with pedicles, are vertically flattened and curve dorsomedially to complete, with the base of the spinous process, a vertebral foramen.

The *spinous process* or spine projects dorsally and often caudally from the laminal junction. Spines vary much in size, shape and direction. They are levers for muscles which control posture and active movements (flexion/extension, lateral flexion and rotation) of the vertebral column.

The *articular processes (zygapophyses)*, paired superior and inferior, project from the vertebral arch at pediculolaminar junctions. The *superior processes* jut cranially, bearing dorsal facets which may also have a lateral or medial inclination, depending on level. *Inferior processes* bulge caudally with articular facets directed ventrally, again with medial or lateral inclination dependent on level. Articular processes of adjoining vertebrae thus form small synovial zygapophysial joints (p. 490), forming the posterior aspect of the intervertebral foramina; these joints permit limited movement, restricted in range, between vertebrae. Mobility varies considerably with vertebral level.

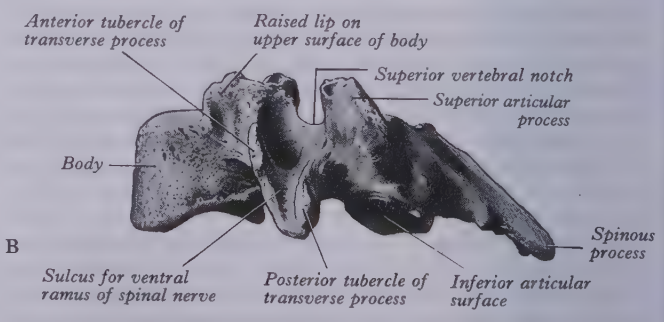
Transverse processes project laterally from pediculolaminar junctions as levers for muscles and ligaments particularly concerned in rotation and lateral flexion. (The preceding comment is a simplification. In practice the activities of spinal musculature must be considered in terms of bilateral and surrounding groups; weight-bearing and initial posture are also crucial.) The thoracic transverse processes articulate with ribs. At other levels the mature transverse process is a composite of 'true' transverse process (*diapophysis*) and an incorporated *costal element*.

Costal elements (pleurapophyses) develop as basic parts of neural arches in mammalian embryos, but become independent only as thoracic ribs. Elsewhere they remain less developed and fuse with the 'transverse process' of descriptive anatomy (3.57).



Vertebrae are internally trabecular (3.55), with an external shell of compact bone perforated by vascular foramina. The shell is thin on discal surfaces but thicker in the arch and its processes. The trabecular interior contains red bone marrow and one or two large ventrodorsal canals for the basivertebral veins.

A most interesting technique of observing vertebral geometrical dimensions (14 cervical and 14 lumbar) in radiograms has been evolved by Gilad & Nassan (1985). This involves the analysis of nine dimensions for vertebral bodies and spines, affording an exact anthropometric technique.



Ratcliffe (1981) has described arterial patterns in bodies of thoracic vertebrae at ages from 29th prenatal week to the 15th year.

The Cervical Vertebrae

The seven cervical vertebrae (3.56–63), the smallest of the movable vertebrae, are typified by a foramen in each transverse process. The first, second and seventh have special features to be considered separately. A typical cervical vertebra has a small, but relatively broad *body*; the *vertebral foramen* is large and roughly triangular, because the *pedicles* project dorsolaterally (3.56A) and *laminae* curve dorsomedially from them; the vertebral canal here accomodates the cervical enlargement of the spinal cord. Superior and inferior vertebral notches are almost equal in depth, pedicles being midway between the discal aspects of the body (3.56B). *Laminae* are long and narrow, with a thin upper border, but roughened ventrally. The *spinous process* is short and bifid, with

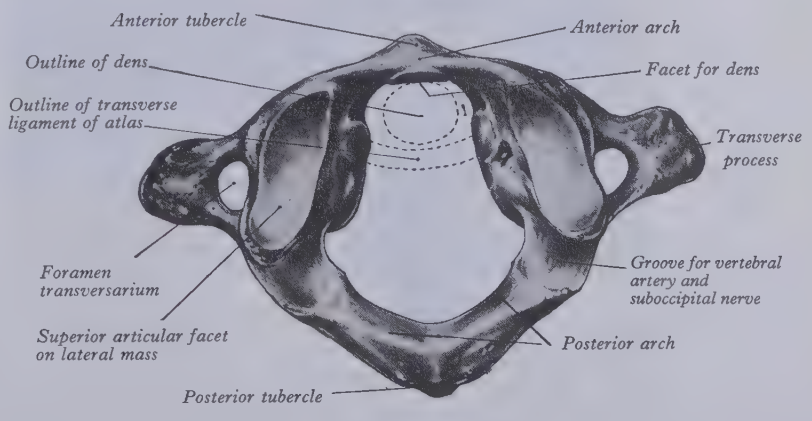
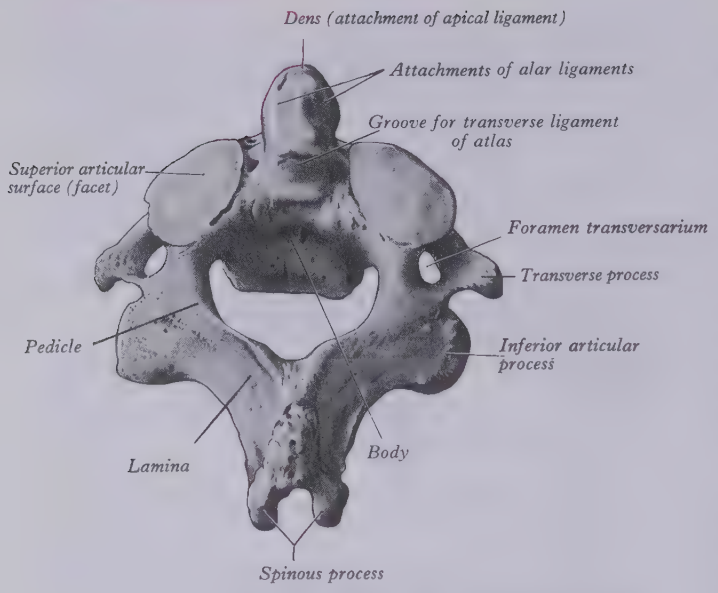
(Reproduced with permission from the author, the *Journal of Zoology* and Cambridge University Press.)



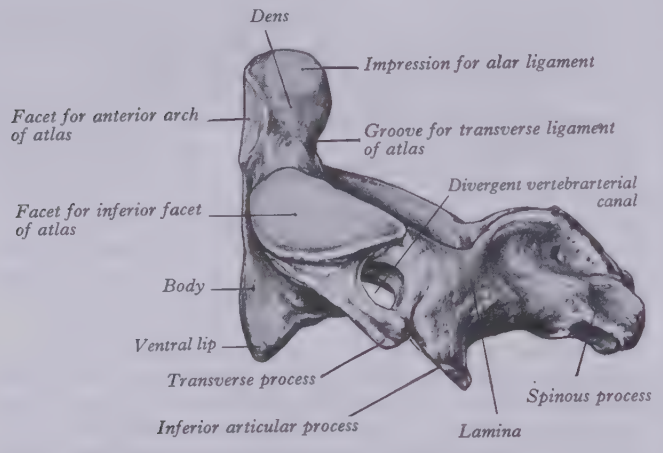
terminal tubercles often unequal in size. *Superior* and *inferior articular processes* form (when articulated) an *articular pillar*, each bulging laterally at the pediculolaminar junction. The mature '*transverse process*' is morphologically composite around the *foramen transversarium*. Its dorsal and ventral *roots* or *bars* terminate laterally as corresponding *tubercles*. The roots are connected lateral to the foramen by an *intertubercular lamella* (often incorrectly called the costotransverse bar). Of these parts all except the medial end of the dorsal root are costal vestiges and this medial moiety is the sole representative of a true transverse process (*diapophysis*) such as exists in a thoracic vertebra (3.54, 64). Cave (1975), in a morphological study of the mammalian cervical 'costal element' or *pleurapophysis*, has defined it more precisely, especially in relation to cervical ribs (3.57, and p. 161). The foramen transversarium may be divided into two or more cervical vertebra.

The body's anterior surface, convex transversely, is marked at its discal margins by attachments of the anterior longitudinal ligament, and near the midline the bilateral depressions show the points of union of the vertical part of longus colli. The flat dorsal surface displays centrally two or more large *basivertebral*, venous foramina, and to its upper and lower borders the posterior longitudinal ligament is united. The cranial discal surface is transversely concave with marked bilateral lips, its anterior rim being slightly bevelled. The inferior surface is reciprocally convex transversely and dorsoventrally concave, i.e. both discal surfaces are sellar. The lateral edges form, with lateral lips of the subjacent vertebra, small synovial joints that comprise oblique clefts which develop at about 9–10 years and are limited medially by the intervertebral disc, laterally by capsular ligaments (Cave et al 1955). Some, however, site these clefts in the disc and deny them synovial status (Töndury 1943, Orofino et al 1960). The anteroinferior rim of the body overlaps the subjacent disc. Paired ligamenta flava extend from upper borders of laminae to quite extensive lower roughened anterior *surfaces* of those above. To spinous processes are attached the ligamentum nuchae and numerous deep extensors, including semispinalis thoracis and cervicis, multifidus, spinales and interspinales.

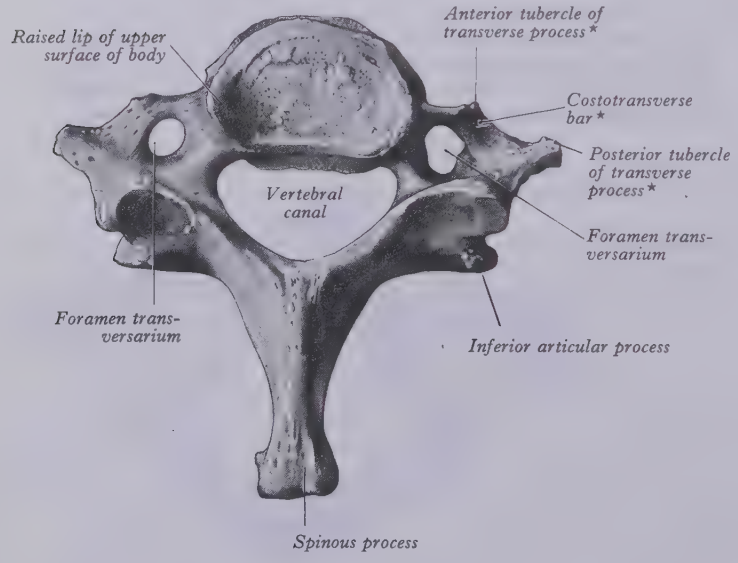


The dorsal rami of cervical spinal nerves curve dorsally close to the anterolateral aspects of the articular pillars, grooving the third and fourth pair, whose cranial facets are flat and almost oval and face craniodorsally; correspondingly similar inferior facets are anterocaudally directed. In all but the seventh cervical vertebra the transverse foramen transmits the vertebral artery and accompanying venous and sympathetic plexuses. The seventh foramen transmits accessory vertebral venous radicles and autonomic elements. Ventral parts of the fourth to sixth transverse processes end in rough tubercles for tendinous slips of scalenus anterior, longus capitis and longus colli (5.36). The tubercle of the sixth vertebra is large and the common carotid artery can be effectively compressed here in the groove between tubercle and body, hence the term *carotid tubercle*. The intertubercular lamella is oblique in the third and fourth vertebrae, descending dorsolaterally; it is increasingly grooved from the fourth to sixth by emerging anterior spinal nerve rami. The lamella of the sixth vertebra is conspicuously wide and shallow. Dorsal parts of the transverse processes also end in rounded tubercles lateral to the anterior tubercles and slightly caudal in level except in the sixth vertebra, where they are approximatey level. Attached to dorsal tubercles are splenius, longissimus and iliocostalis cervicis, levator scapulae, and scalenus posterior and medius.

The atlas, first cervical vertebra (3.58), supports the 'globe' of the head, hence its name. It is unique in lacking a body, the position of which is occupied by the *dens* of the axis, a pivot around which the atlas turns (p. 493). Moreover, it has no true spine, and consists of two *lateral masses* connected by a short *anterior* and a longer curved *posterior arch*. It is thus irregularly annular. When atlas and axis are articulated, the *dens* of the latter is retained against the anterior arch by the *transverse ligament* (4.28). Morphological and developmental studies do not favour the tradition that the atlantal centrum is fused to the axis as its dens (Jenkins 1969).



The *anterior arch* is slightly convex ventrally, and carries a rough median *anterior tubercle*. Attached to this is the median cord-like (at this level) anterior longitudinal ligament and on each side the superior oblique part of longus colli. Its upper and lower



3.58 The first cervical vertebra, or atlas: superior aspect.

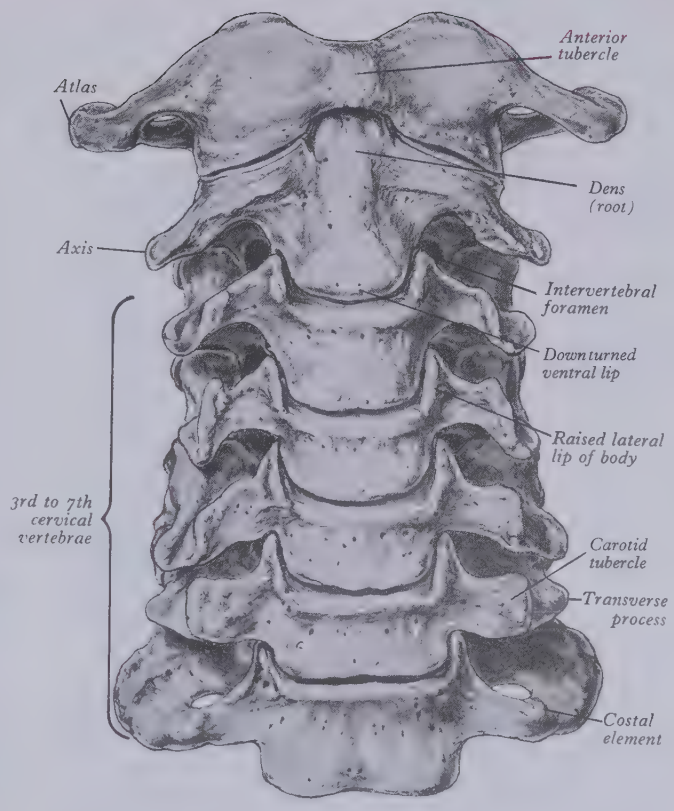
borders provide attachment respectively to the anterior atlanto-occipital membrane and diverging lateral parts of the anterior longitudinal ligament.

The roughly ellipsoidal *lateral masses* converge ventrally, each bearing an elongated, reniform, concave superior facet jointing with the corresponding occipital condyle. The facet, usually 'waisted' and sometimes divided into two (Singh 1965), faces superomedially in adaptation to nodding and lateral movements of the head at the atlanto-occipital joints. The inferior facet on each lateral mass is almost circular, flat or slightly concave, and articulates with a superior articular facet of the axis; these inferior facets face medially and slightly backwards. Attached to edges of the superior and inferior facets are articular capsules. Medially each lateral mass has a small tubercle for the transverse atlantal ligament (3.58), which is posterior to and retains the dens in place, also dividing the cavity of the atlas into a smaller, anterior part containing the dens and a larger, posterior region occupied by spinal cord, nerves, vessels and meninges. Anteriorly the lateral mass has rectus capitis anterior attached to it.

The *posterior arch* forms about two-fifths of the atlantal ring. Superiorly a wide neurovascular groove crosses behind each lateral mass, the latter overhanging the vertebral artery and venous plexus (3.58). Frequently (37% of 66 specimens) the groove is partly or wholly made a foramen by bone arching back from the superior surface of the lateral mass (Lamberty & Živanović 1973). The first cervical spinal nerve is also in the groove, between artery and bone. Posterior to the grooves the posterior atlanto-occipital membrane joins the posterior arch; its lateral border may be ossified, as mentioned, and curves to the lateral mass. The posterior arch is continuous at its lower margin with the highest pair of ligamenta flava. The posterior tubercle is a rudimentary spinous process, roughened by attachment of the ligamentum nuchae and lateral to this by the recti capitis posteriores minores.

The *transverse processes* are long (3.62): the atlas exceeds in width all cervical vertebrae save the seventh. They are strong levers for muscles rotating the head. (Maximal atlantal width ranges from 74 to 90 mm in males and 65 to 76 mm in females of European and American Caucasians—a useful criterion of sex in assessing human remains.) The apex of the transverse process is homologous with the *posterior* tubercle of typical cervical vertebrae; it is palpable between the mastoid process and mandibular angle. Anteriorly the lateral mass may bear a minute homologue of an *anterior* tubercle. An atlantal transverse process is thus equivalent to the posteror part and intertubercular lamella alone. Numerous muscles are attached to it: superiorly, rectus capitis lateralis in front of superior oblique; at the apex, inferior oblique; inferolaterally, slips of levator scapulae, splenius cervicis and scalenus medius. The first cervical ventral spinal ramus passes forwards on the lateral surface of the lateral mass and then down in front of the transverse process behind the internal jugular vein, crossed here anteriorly by the accessory nerve and occipital artery.



The axis, second cervical vertebra (3.59,60), is a pivot or axle for rotation of the atlas and head around its strong *dens* (odontoid process), projecting vertically from the body. A small oval anterior articular facet on the dens forms a synovial joint with a reciprocal facet on the back of the anterior atlantal arch; posteriorly the dens is grooved by the transverse atlantal ligament (3.59,60). The dens is conical, about 1.5 cm long and, as noted, waisted where grooved by the cartilage-covered ligament, a second, larger, synovial joint (sometimes termed a bursa) usually intervening. Its pointed apex is joined by the apical ligament (p. 495) and to its flat sides, above the groove, the alar ligaments are attached (3.59,60). The *body* contains relatively less compact bone than the dens. Above, the dens obscures the body and is flanked by two large, oval facets, extending laterally on to adjoining pedicles and articulating with the inferior atlantal facets. Unlike other superior facets, they do not form a pillar with the inferior facets, being considerably anterior to these. In front the body is hollowed on each side by attachment of the vertical part of longus colli. The anterior longitudinal ligament joins the lower discal border which projects downwards. Posteriorly the lower border affords attachment to the posterior longitudinal ligament and

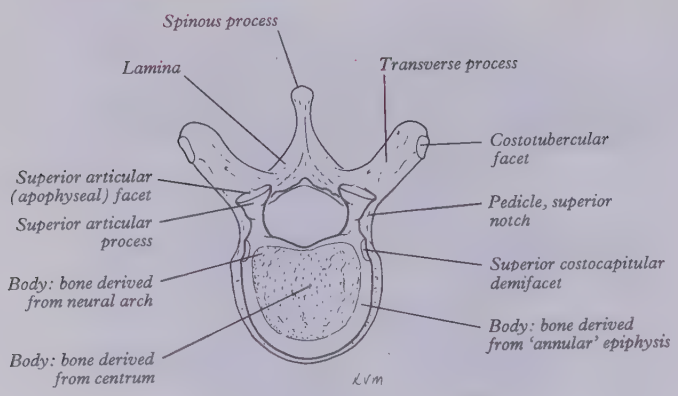
membrana tectoria (p. 494). The pedicles are thick, with deep inferior vertebral notches, the superior being shallow. The laminae, thicker than in other cervical vertebra, provide attachment to the ligamenta flava; they fuse posteriorly with the large spinous process which takes the pull of extensors, retractors and rotators of the head. The inferior obliques arise from rough areas on the lateral aspects of the spine, rectus capitis posterior major a little posterior to this. The ligamentum nuchae is attached in the apical notch in the spine with slips of semispinalis and spinalis cervicis, interspinalis and multifidus.

The *axial transverse processes* are small, blunt at their tips which are single tubercles and homologous with posterior tubercles at other levels. Small anterior tubercles are at or near the junctions of anterior parts of transverse processes and body, as in the atlas. To the tips of transverse processes are attached levator scapulae, between scalenus medius and splenius cervicis, and to their upper and lower surfaces the intertransverse muscles (p. 590). Each axial transverse foramen inclines superolaterally, because the vertebral arteries deviate laterally to traverse the more widely separated atlantal foramina. The inferior articular facets are at the pediculolaminar junctions, facing antero-inferiorly, as in typical cervical vertebrae. The vertebral foramen is large.

In a study of 60 cervical vertebral series (Krmpotić-Newmanić & Keros 1973) the longitudinal axis of the dens, relative to its vertebral body, varied with cervical curvature and also age. For discussion of homologies of transverse processes of atlas and axis and associated joints, muscles and nerves, consult Cave (1975).

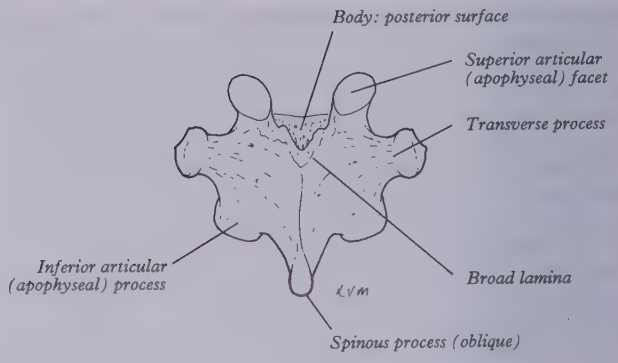
The seventh cervical vertebra (3.61), *vertebra prominens*, has a long spinous process visible at the lower end of the nuchal furrow. The first thoracic spine is usually as prominent and sometimes more so; the seventh cervical is thick, almost horizontal and ends in a single tubercle for the ligamentum nuchae. Attached apically are trapezius, rhomboideus minor, serratus posterior superior, splenius capitis, spinalis cervicis, semispinalis thoracis, multifidus and interspinales. The transverse processes are large, particularly posterior to the transverse foramina (often reduplicated), the part anterior to them being slender and shorter; it is a costal element and may be separate as a *cervical rib*. The intertubercular lamella anterolateral to the foramen (3.61) is grooved superiorly by the ventral ramus of the seventh cervical nerve; it is often partly deficient. To the prominent posterior tubercle are attached scalenus minimus (pleuralis), when present, and also an aponeurosis covering the cervical pleural dome—the suprapleural membrane (p. 1268). The first pair of levatores costarum are attached to the transverse processes.

3.62 The cervical vertebrae: anterior aspect.



The Thoracic Vertebrae

The twelve thoracic vertebrae (3.54,64A–E,65A,B,66) increase in size caudally, like other vertebrae, due to increased loading from head to sacrum. All their bodies display lateral costal facets and all but the lowest two or three transverse processes have facets, articulating respectively with costal heads or tubercles. The first and ninth to twelfth have atypical features, to be considered separately; except for relatively minor details the rest are alike. (However, for comments concerning thoracic spinal curvatures and deviations of these, also individual asymmetries, see below and p. 284.)



The *body* is typically a waisted cylinder except where the vertebral foramen encroaches, transverse and anteroposterior dimensions being almost equal. On each side are *two costal facets* (really *demifacets*), the superior pair usually larger and at the upper border anterior to the pedicles, the inferior at the lower border anterior to the vertebral notches (3.64D). The *vertebral foramen* is small and circular; thus the *pedicles* do not diverge as in cervical vertebrae; also the thoracic spinal cord is smaller and more circular. The *laminae* are hence also short, thick, broad and overlapping from above downwards. The *spinous processes* slant downwards. The superior *articular processes*, thin plates of bone, project at pediculolaminar junctions, are almost flat and face dorsally, a little superolaterally. The *inferior processes* project down from the laminae, their facets directed forwards, a little superomedially. The large, club-like *transverse processes* project from the vertebral arch at pediculolaminar junctions. They point

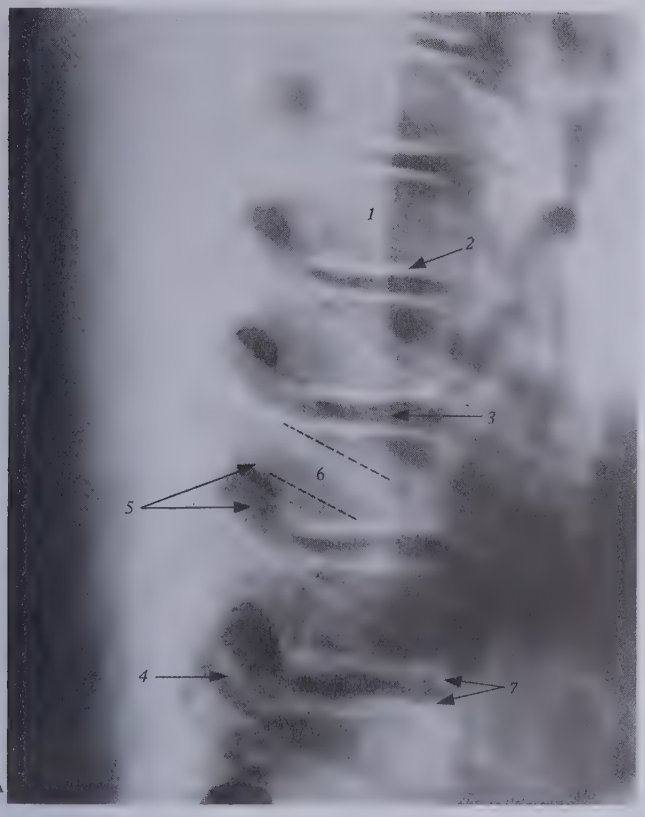
posterolaterally and bear, near their tips, anterior oval facets articulating with tubercles of corresponding ribs.

The first thoracic vertebra (3.66) shows circular upper costal facets articulating with the whole facet on first costal heads, but the inferior are smaller and semilunar; they articulate, as do most thoracic vertebrae, with a demifacet on a costal head. The spine is thick, long, horizontal and commonly as prominent as the seventh cervical.



The ninth thoracic vertebra (3.66), otherwise typical, often fails to articulate with the tenth ribs and then the inferior demifacets are absent.

The tenth thoracic vertebra (3.66) articulates only with the tenth ribs and is excluded from the eleventh costovertebral joints. Therefore only superior facets appear and are usually large and semilunar or oval when the tenth ribs fail to joint with the ninth vertebrae and intervening disc. The transverse process may or may not be facetted for the tenth rib.

The eleventh thoracic vertebra (3.66) articulates only with heads of the eleventh ribs. The circular costal facets are close to the upper border of the body and extend on to pedicles. The small transverse processes hence lack articular facets.

The twelfth thoracic vertebra (3.66) articulates with the heads of the twelfth ribs by circular facets somewhat below the upper border, spreading on to the pedicles. The body is large and transverse processes are small; the vertebra has some lumbar features (vide infra).

Bodies of upper thoracic vertebrae gradually change from cervical to thoracic type, and the lower from thoracic to lumbar type. The body of the first is cervical, its transverse diameter almost twice the anteroposterior; the second retains a cervical shape, but its breadth is less and the two measurements differ less. The third body is the smallest; its anterior aspect is convex, unlike the flattened first and second. The remaining bodies increase in size and, owing to its increased anteroposterior diameter, the fourth is

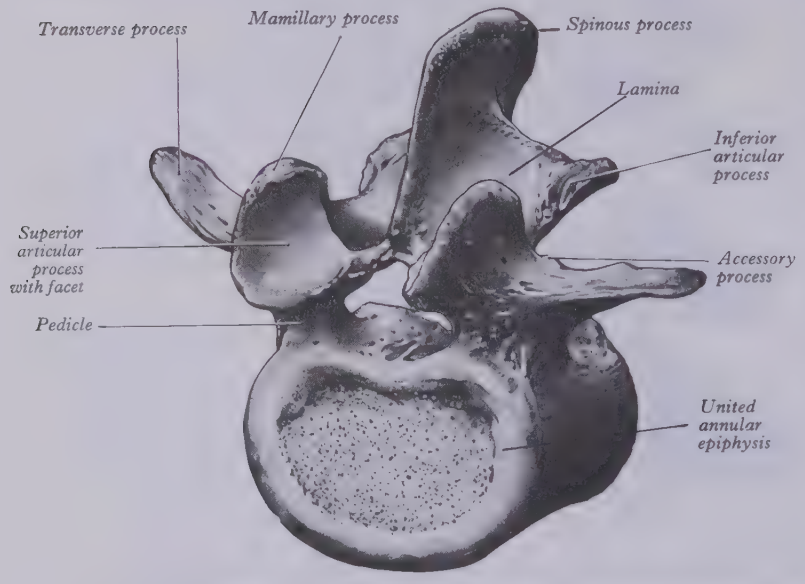
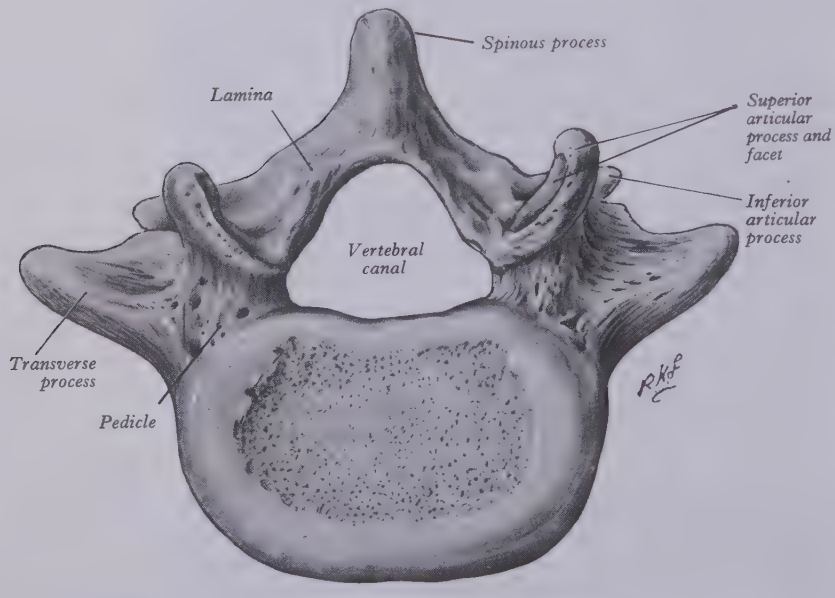
3.66 The first, ninth, tenth, eleventh and twelfth thoracic vertebra: right lateral aspect.

typically cordate ('heart-shaped'). The fifth to eighth increase in anteroposterior dimension but change little in transverse. These four, in transverse section, are *asymmetrical*, their left sides being flattened by pressure of the thoracic aorta. The rest increase more rapidly in all measurements, so that the twelfth body resembles that of a typical lumbar vertebra. Geometrical analysis suggests that these are also adaptations to a greater range of flexion-extension at the cervical and lumbar ends of the thoracic vertebral column (Veleanu et al 1972).



To borders of the bodies are attached the anterior and posterior longitudinal ligaments, and around the margins of costal facets are capsular and radiate ligaments of costovertebral joints. Longus colli arises from the upper three thoracic vertebral bodies, lateral to the anterior longitudinal ligament, and psoas major and minor from the side of the twelfth near its lower border.

Thoracic *pedicles* show a successive caudal increase in thickness. The superior vertebral notch is recognizable only in the first thoracic, but the inferior notch is deep in all. Ligamenta flava are attached at the upper borders and lower ventral surfaces of laminae, and rotatores to their dorsal aspects.



Thoracic *transverse processes* shorten in caudal succession. In the upper six (or five), the costal facets are concave and face anterolaterally; caudal to this facets are flatter and face superolaterally and slightly forwards. To the anterior surface medial to the facet is attached the costotransverse ligament, to its tuberculated apex the lateral costotransverse ligament and to its lower border the

3.69 The fifth lumbar vertebra: superior aspect.

superior costotransverse ligament. Upper and lower borders also provide attachment for intertransverse muscles or fibrous vestiges and the posterior surface for deep dorsal muscles; dorsally on the apex is the levator costae.

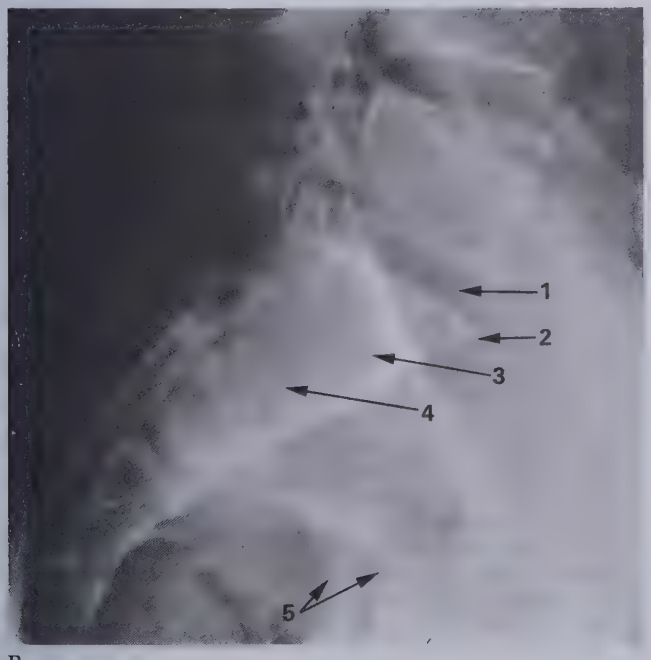
Thoracic *spines* overlap from fifth to eighth, which is the longest and most oblique. (In quadrupeds most thoracic spines slope caudally and lumbar spines cranially, the change in inclination occuring at a lower thoracic *anticlinal* vertebra; its human equivalent is the eleventh.) Supraspinous and interspinous ligaments, trapezius, rhomboideus major and minor, latissimus dorsi, serrati posterior superior and inferior and many deep dorsal muscles are attached to thoracic spines.

The first thoracic resembles a cervical vertebra in its body, both in shape and posterolateral lipping, the latter forming the anterior border of the superior vertebral notch, a distinctive feature. The upper costal facet is often incomplete, the first rib then articulating with the seventh cervical and intervening disc. Below the facet a small, deep depression often occurs.

The eleventh and twelfth thoracic spinous processes are triangular, with blunt apices, a horizontal lower and an oblique upper border. The twelfth thoracic transverse process is replaced by three small tubercles; the superior is largest, juts upwards and corresponds to a lumbar mamillary process, though not so close to the superior articular process. The lateral tubercle is the homologue of a transverse process, the inferior the homologue of a lumbar accessory process. These two vertebrae can be distinguished by the size and shape of the transverse process and the distance between the costal facet and upper border (p. 320).

A change in orientation of articular processes from thoracic to lumbar type usually occurs at the eleventh thoracic vertebra, sometimes the twelfth or tenth. In the transitional vertebra the superior articular processes are thoracic, facing posterolaterally, while the inferior are transversely convex and face anterolaterally. This vertebra marks the site of a sudden change in degree from rotational to non-rotational function (p. 492) (Davis 1955).

Ratcliffe (1981) has described in much detail by microradiography the arterial supply of thoracic and lumbar vertebral bodies, with a review of literature.



The Lumbar Vertebrae

The five lumbar vertebrae (3.67,68,69,70A–D) are distinguished by large size and absence of costal facets and transverse foramina. The *body* is wider transversely and deeper in front. The *vertebral foramen* is triangular, larger than at thoracic but smaller than at cervical levels. The *pedicles* are short. The *spinous process* is almost horizontal, quadrangular and thickened along its posterior and inferior borders. The *superior articular processes* bear vertical concave articular facets facing posteromedially, with a rough *mamillary process* on their posterior borders. The *inferior articular processes* have vertical convex articular facets facing anterolaterally. The *transverse processes* are thin and long, except the more substantial fifth pair. A small *accessory process* marks the postero-inferior aspect of the root of each transverse process. Measurement of 338 third and fourth lumbar vertebrae, from both sexes aged 20–90 years, showed that *breadth* of body increases with age; in males, posterior height decreases relatively; in both sexes anterior height of the body decreases relative to breadth (Ericksen 1976). Twomey et al (1983), in a study of 93 adult vertebral columns, observed a reduction in bone density of lumbar vertebral bodies, principally due to a reduction in transverse trabeculae (more markedly in females), associated with increased diameter and increasing concavity in their juxtadiscal surfaces. Amonoo-Kuofi (1982, 1985) compared lumbar interpedicular distances in 150 males and 140 females by radiography, expressing these as a ratio of vertebral body width. Values varied much, but the ratio (in Nigerians) was most constant. He notes racial variation, in discussing the literature. The blood supply of developing lumbar vertebral bodies, from the 29th prenatal week to the 15th year, has been detailed by Ratcliffe (1981).

The fifth lumbar vertebra (3.69) has a massive *transverse process* continuous with the *whole of the pedicle and encroaching on the body*. The body is usually the largest and markedly deeper in front, contributing thus to the sacrovertebral angle.

Upper and lower borders of lumbar *bodies* give attachment to the anterior and posterior longitudinal ligaments (p. 489). Lateral to the anterior ligament the upper bodies (three on the right, two on the left) give attachments to the crura of the diaphragm. Posterolaterally, psoas major is attached to the upper and lower margins of all lumbar bodies; between these, tendinous arches carry its attachments across their concave sides. The first lumbar *vertebral foramen* contains the conus medullaris of the spinal cord, the lower foramina the cauda equina and spinal meninges. Strong paired *pedicles* spring posterolaterally from each body near its upper border. Superior vertebral notches are shallow, inferior ones deep. The laminae are broad and short but do not overlap as much as do the thoracic. To spinous processes are attached the posterior lamella of the thoracolumbar fascia, erectores spinae, spinales thoracis, multifidi, interspinal muscles and ligaments, and supraspinous ligaments. The fifth spine is smallest, its apex often rounded and down-turned. Upper lumbar superior articular processes

are further apart than inferior ones, but the difference is slight in the fourth and negligible in the fifth. The articular facets are reciprocally concave (superior) and convex (inferior), allowing some degree of rotation as well as flexion-extension. Transverse processes, except the fifth, are dorsoventrally compressed and project dorsolaterally. The lower border of the fifth transverse process is angulated, passing laterally and then superolaterally to a blunt tip, the whole process presenting greater upward inclination than the fourth. The angle on the inferior border may represent the tip of the costal element and the lateral end the tip of the true transverse process. The lumbar transverse processes increase in length from first to third and then shorten. Thus, as noted, the fifth pair incline both *upwards* and posterolaterally. All lumbar transverse processes present a vertical ridge on the anterior surface nearer the tip which marks the attachment of the anterior layer of the thoracolumbar fascia, and separates the surface into a medial area for psoas major and a lateral for quadratus lumborum. The middle layer of the fascia is attached to the apices of the transverse processes; additionally to the first pair the medial and lateral arcuate ligaments (lumbocostal arches), and to the fifth the iliolumbar ligament, are attached. Posteriorly the transverse processes are covered by deep dorsal muscles and fibres of longissimus thoracis are attached to them. To their upper and lower borders lateral intertransverse muscle are attached. The mamillary process, homologous with the superior tubercle of the twelfth thoracic vertebra, gives attachment to multifidus and medial intertransverse muscle. To the accessory process, which is sometimes difficult to identify, is attached the medial intertransverse muscle. The costal element is incorporated in the mature transverse process. (For a discussion of homologies of all three processes consult Jones 1912.)

Applied Anatomy. Various methods of estimating the diameter of the lumbar vertebral canal, sometimes subject to stenosis, have been reviewed by Amonoo-Kuofi (1982), who considers radiographic estimation of interpedicular dimensions as a reliable technique. The same observer (1985) considers that racial variation occurs in the sagittal dimension of the lumbar vertebral canal.

The Sacrum

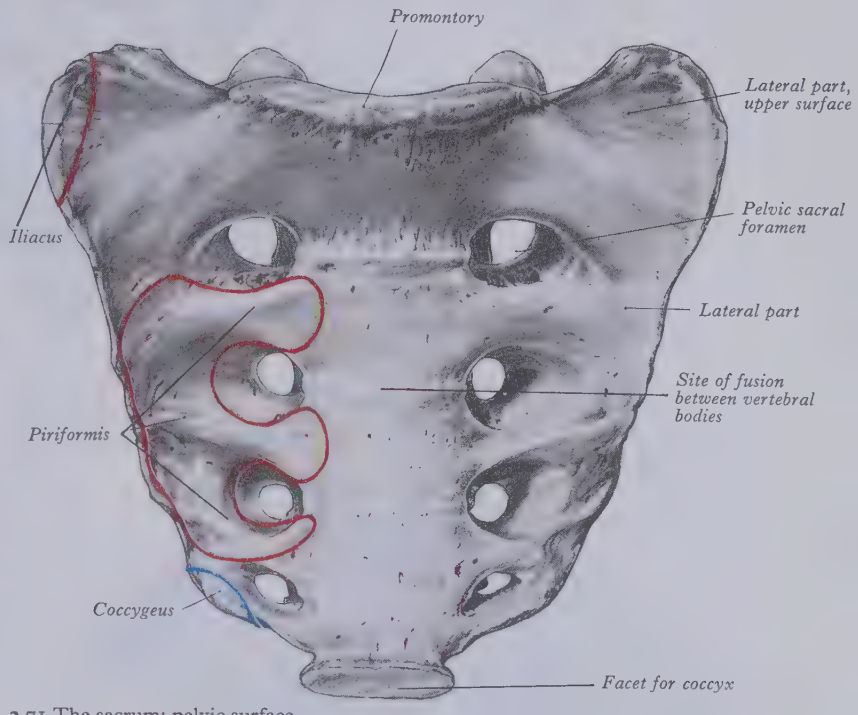
The sacrum (**3**.71–5) is a large, triangular fusion of five vertebrae and forms the posterosuperior wall of the pelvic cavity, wedged between the two innominate bones. Its blunted, caudal *apex* articulates with the coccyx and its superior, wide *base* with the fifth lumbar vertebra at the *sacrovertebral angle*. The bone is set obliquely and curved longitudinally, its dorsal surface being convex, the pelvic concave (**3**.73). This ventral curvature increases pelvic capacity. Between base and apex are *dorsal, pelvic* and *lateral surfaces* and a *sacral canal*. In childhood, individual sacral vertebrae are connected by cartilage and separable by maceration; the adult bone also retains many vertebral features.

The base (**3**.74) is the upper surface of the *first sacral vertebra*, the least modified from typical vertebral plan. The *body* is large and wider transversely. Its anterior projecting edge is the *sacral promontory*. The vertebral foramen is triangular, its *pedicles* being short and posterolaterally divergent. The *laminae* are oblique, inclining down posteromedially to meet at a *spinous tubercle*. The *superior articular processes* project cranially, with concave articular facets directed dorsomedially to articulate with inferior articular processes of the fifth lumbar vertebra. The posterior part of each process projects, bearing laterally a rough area homologous with a lumbar mamillary process. The *transverse process* is much modified; a broad, sloping mass projects laterally from the body, pedicle and superior articular process (**3**.74A,B) —a unique feature, although foreshadowed in the fifth lumbar. It consists of transverse process and costal element fused together and to the rest of the vertebra, forming the superior part of the sacral *lateral mass* or *ala*.

The pelvic surface (3.71), is antero-inferior, and vertically and transversely concave but the second sacral body may produce a convexity. Four pairs of *pelvic sacral foramina* communicate through intervertebral foramina with the sacral canal, transmitting ventral rami of the upper four sacral spinal nerves. The large area between right and left foramina, formed by flat pelvic aspects of the sacral bodies, shows their fusion by four *transverse ridges*. The bars between foramina are *costal elements*, fused to the vertebrae. Lateral to the foramina the costal elements unite together and posteriorly with transverse processes to form the *lateral part* of the sacrum (which expands basally as the ala).

The dorsal surface (3.72) is convex and dorsosuperior. It has a raised, interrupted, *median sacral crest* with four (sometimes three) *spinous tubercles* representing fused sacral spines. Below the fourth (or third) an arched *sacral hiatus* in the posterior wall of the sacral canal, due to failure of the fifth pair of laminae to meet, exposes the dorsal surface of the fifth body. Flanking the median crest the posterior surface is formed by fused laminae and lateral to this are four pairs of *dorsal sacral foramina*. Like the pelvic foramina they lead into the sacral canal through intervertebral foramina; each transmits the dorsal ramus of a sacral spinal nerve. *Medial* to the foramina and vertically below each articular process of the first sacral, is a row of four small tubercles, collectively the *intermediate sacral crest*; these, sometimes termed *articular*, represent fused articular processes. The fifth inferior articular processes project caudally and flank the sacral hiatus as *sacral cornua*, connected to coccygeal cornua by intercornual ligaments. *Lateral* to the dorsal sacral foramina is a *lateral sacral crest* formed by fused transverse processes, whose apices appear as a row of *transverse tubercles*.

The lateral surface (3.73) is a fusion of transverse processes and costal elements. Wide above, it rapidly narrows in its lower part. The broad, upper part bears an *auricular surface* for articulation with the ilium, the area posterior to this being rough and deeply pitted by attachment of ligaments. The auricular surface, borne by costal elements, is like an inverted letter L. The shorter, cranial limb is restricted to the first sacral vertebra, the caudal descending to the middle of the third. Beyond this the lateral surface is non-articular and reduced in breadth. Caudally it curves medially to the body of the fifth sacral vertebra at the *inferior lateral angle*, beyond which the surface becomes a thin lateral border. A variable *accessory* sacral articular facet sometimes occurs.



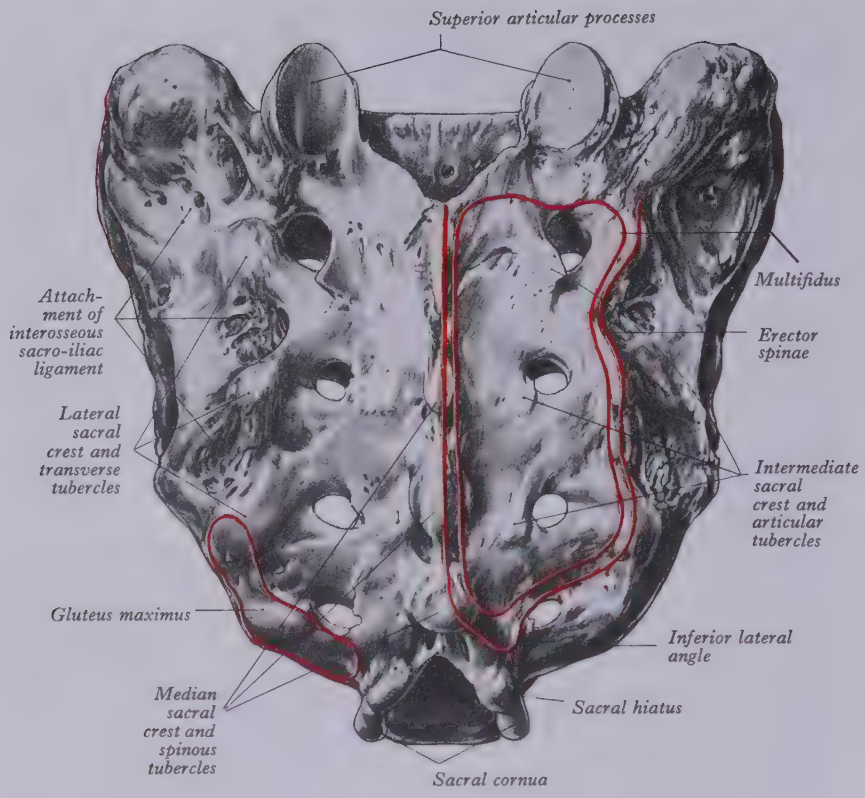
The sacral apex, the inferior aspect of the fifth sacral vertebral body, bears an oval facet for articulation with the coccyx.

The sacral canal (3.75), formed by sacral vertebral foramina, is triangular in section. Its upper, basal opening is oblique but, owing to sacral inclination, is directed cranially in the standing position. Each lateral wall presents four intervertebral foramina (3.75), through which it is continuous with pelvic and dorsal sacral foramina. Its caudal opening is the *sacral hiatus*.

To the ventral and dorsal surfaces of the first sacral body are attached terminal fibres of the anterior and posterior longitudinal ligaments. Its upper laminar borders receive the lowest pair of ligamenta flava. Superiorly the ala is smooth, medially concave and laterally rough. It is covered almost entirely by psoas major. The smooth area is obliquely grooved by the lumbosacral trunk. The rough area is for the lower band of the iliolumbar ligament (p. 492), lateral to the fifth lumbar spinal nerve and to the ventral sacro-iliac ligament. Iliacus reaches the anterolateral part of this area (3.71).

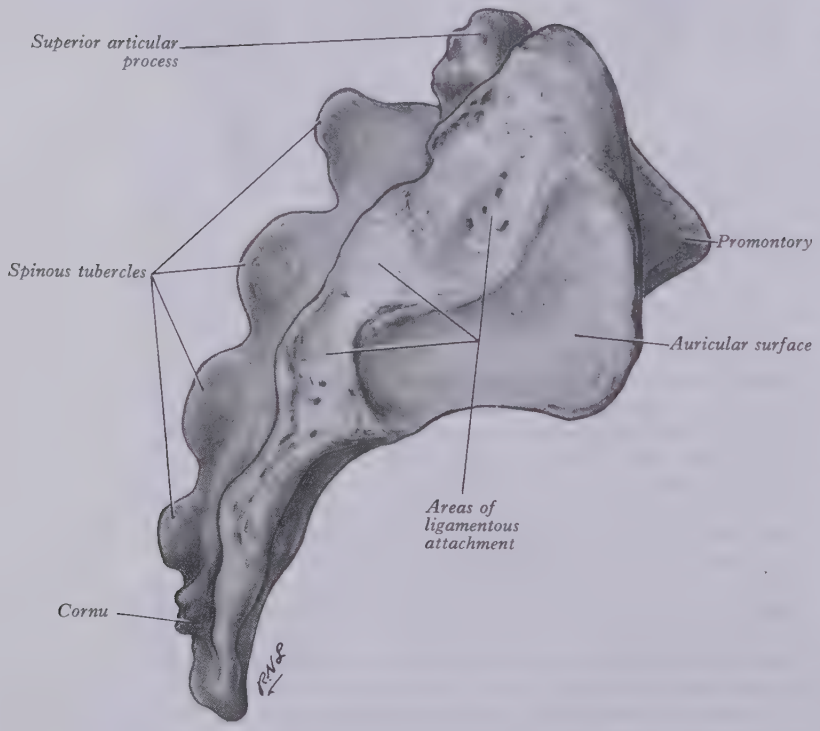
The pelvic surface gives attachment to the piriformes (3.71). Emerging from the pelvic sacral foramina the first three sacral ventral rami pass anterior to piriformis. Medial to the foramina the sympathetic trunks descend in contact with bone, as do the median sacral vessels in the midline. Lateral to the foramina lateral sacral vessels are related to bone. Ventral surfaces of the first, second and partly third sacral bodies are covered by parietal peritoneum and crossed obliquely, left of the midline, by the attachment of the sigmoid mesocolon. The rectum is in contact with pelvic surfaces of the third to fifth sacral vertebrae and with the superior rectal artery's bifurcation between the rectum and third sacral vertebra.

Colour coding of muscle attachments. The structural/functional ideas implicit in the traditional terms 'origin' and 'insertion' applied to muscle attachments do not accord with modern myokinetics; the latter envisages many more complex and flexible responses (pp. 567, 569). Nevertheless, some introductory and practical courses retain the terms, and the delineation of *all* muscle attachments by a single colour has proved an impediment to occasional groups of students. Some trunk muscles and those of the girdles and free limbs have, in this edition, a dual colour code; this facilitates their separate recognition. The axial, paraxial, or medial attachments of horizontally disposed muscles, and the proximal attachments of free limb muscles are outlined in *red* (the historical 'origin'). The lateral attachment of horizontal muscles, and the distal attachment of free limb muscles are delineated in *blue*, (the historical 'insertion'). In contrast, on a series of diagrams of the skull, multiple colour coding is used to group muscles in terms of their embryological origin and nerve supply. Above comments on red and blue lines apply in most instances; occasional exceptions may be noted in a minority of individual muscles and bones.



3.71 The sacrum: pelvic surface.

The dorsal sacral surface affords attachment to erector spinae by an elongated U-shaped area of spinous and transverse tubercles, covering multifidus which occupies the enclosed area (3.72). The upper three sacral spinal dorsal rami pierce these muscles as they emerge via dorsal foramina.



The auricular surface, covered by hyaline cartilage, is formed entirely by costal elements. It shows cranial and caudal elevations and an intermediate depression, dorsal to which, in the elderly, is a third elevation. The rough area behind the auricular surface shows two or three marked depressions for attachment of strong interosseous sacro-iliac ligaments. Below the auricular surface are attached gluteus maximus, sacrotuberous and sacrospinous ligaments and coccygeus, from behind forwards.

The **sacral canal** (3.71) contains the cauda equina (including its filum terminale) and spinal meninges. Near its mid-level subarachnoid and subdural spaces cease and lower sacral spinal roots and filum terminale pierce the arachnoid and dura maters. The filum terminale emerges at the sacral hiatus and traverses the dorsal surface of the fifth sacral vertebra and sacrococcygeal joint to reach the coccyx. The fifth sacral spinal nerves also emerge through the hiatus medial to the sacral cornua, grooving the lateral aspects of the fifth sacral vertebra.

Typical male or female sacra are easily identified but sexual differences are not always marked; identification is sometimes difficult. The female sacrum is shorter and wider, producing a

3.72 The sacrum: dorsal surface.

3.73 The sacrum: right lateral aspect.

wider pelvic cavity. Sacral width, as a percentage of length, yields a *sacral index*. The loci used in making these measurements are discussed on p. 430. The ventral concavity is deeper in females and its deepest point is usually higher than in males; curvature above this point is greater in the female. The dorsal protrusion of the second sacral vertebra (p. 432) is hence usually less prominent in males. In females the pelvic surface faces downwards more than in males, increasing the pelvic cavity and making the sacrovertebral angle more prominent. The female auricular surface is shorter but in both sexes usually extends along the first three sacral vertebrae. Owing to the great size of the fifth *lumbar* body, the first *sacral* body occupies a larger proportion of the sacral base in the male, its transverse diameter exceeding the length of an ala; the female dimensions are roughly equal.

Structure. The sacrum consists of trabecular bone enveloped by a shell of compact bone variable in thickness.

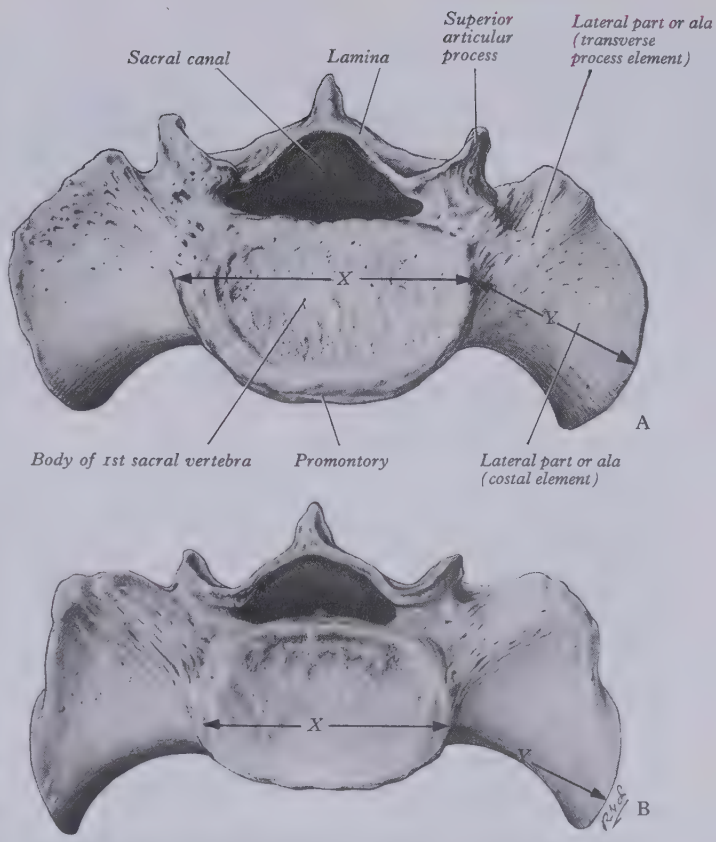
Variations. The sacrum may contain six vertebrae, by development of an additional sacral element or by incorporation of fifth lumbar or first coccygeal vertebrae. Inclusion of the fifth lumbar (*sacralization*) is usually incomplete and limited to one side. In the most minor degree of the abnormality a fifth lumbar transverse process is large and articulates, sometimes by a synovial joint, with the sacrum at the dorsolateral angle of its base. Reduction of sacral constituents is less common but *lumbarization* of the first sacral vertebra occurs; it remains partially or completely separate. The dorsal wall of the sacral canal may be variably deficient, due to imperfect development of laminae and spines. Orientation of the superior sacral articular facets (and hence the relation between the planes of the two zygapophysial lumbosacral joints) displays wide variation according to Čihák (1970): the chords of the concave sacral facets formed an angle with the sagittal plane varying from 20° to 90° in 132 sacra, the majority between 40° and 60°. Curvatures of the facets and their degree of asymmetry also varied.

The Coccyx

The coccyx (3.76A,B), a small triangular bone, usually consists of four fused rudimentary vertebrae but the number varies from five to three, the first being sometimes separate. The bone descends ventrally from the sacral apex, its pelvic surface being tilted upwards and forwards, its dorsum downwards and backwards. Orientation varies, of course, with its mobility.

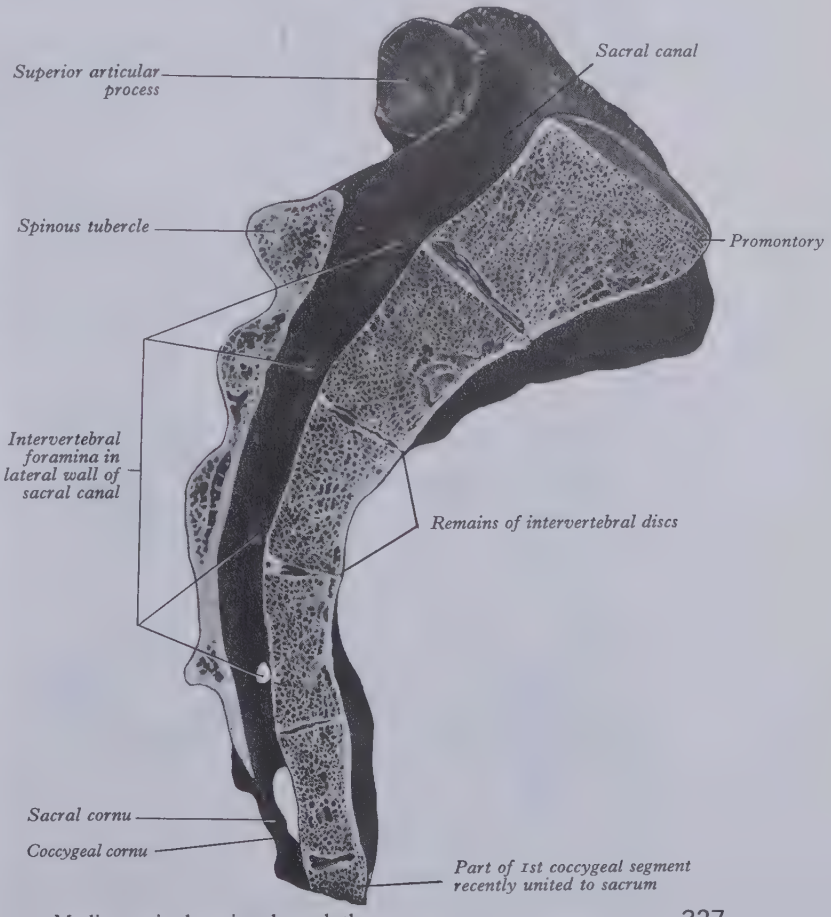
The *base*, or upper surface of the *first coccygeal vertebral body*, has an oval, articular facet for the sacral apex. Dorsolateral to this, two *coccygeal cornua* project up to articulate with sacral cornua; they are homologues of pedicles and superior articular processes of other vertebrae. A rudimentary *transverse process* projects

superolaterally from each side of the first coccygeal body and may articulate or fuse with the inferolateral sacral angle, completing the fifth sacral foramina.



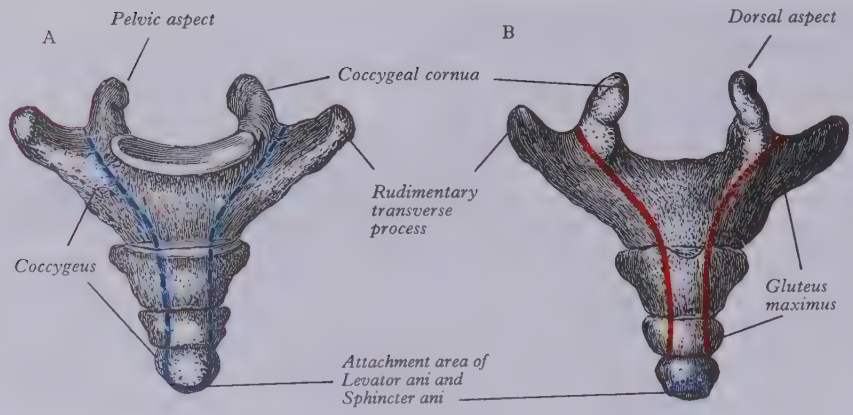
The *second* to *fourth coccygeal vertebrae* diminish in size and are usually mere fused nodules, representing rudimentary vertebral bodies, though the second may show traces of transverse processes and pedicles.

Laterally on the *pelvic surface* and including the rudimentary transverse processes, the levatores ani and coccygei are attached, as is the ventral sacrococcygeal ligament to the front of the first and sometimes second coccygeal vertebral bodies (4.56), and to the *cornua* the intercornual ligaments. The gap between fifth sacral body and articulating cornua represents, on each side, an intervertebral foramen, transmitting the fifth sacral spinal nerve, whose dorsal ramus descends behind the rudimentary transverse process, its ventral ramus passing anterolaterally between the transverse process and sacrum with, laterally, the lateral sacrococcygeal ligament which connects the process to the inferiolateral sacral angle. To the *dorsal surface* are attached the glutei maximi, at its tip the sphincter ani externus, and in its median area the deep and superficial dorsal sacrococcygeal ligaments, the superficial descending from the margins of the sacral hiatus and sometimes closing the sacral canal. The filum terminale, between the two ligaments, blends with them on the dorsum of the first coccygeal vertebra.



Ossification of the Vertebral Column

For earlier stages of vertebral development consult p. 159 and illustration 2.44.



A typical vertebra is ossified from three primary centres (2.44,3.77A), one in each half vertebral arch, one in the centrum. Centres in arches appear at the roots of transverse processes, ossification spreading back into laminae and spines, forwards into pedicles and posterolateral parts of the body, laterally into transverse processes and up and downwards into articular processes. Classically centres in *vertebral arches* are said to appear first in upper cervical vertebrae in the ninth to tenth week, and then in successively lower vertebrae, reaching lower lumbar levels at twelve weeks. However, in a radiographic study of unsexed human fetuses, of which 33 were of appropriate age (Bagnall et al 1977), a pattern was noted differing from such a simple craniocaudal sequence. A regular cervical progression was not observed. Centres first appeared in the lower cervical/upper thoracic region, quickly followed by others in the upper cervical region. After a short interval a third group appeared in the lower thoracic-lumbar region and remaining centres then appeared, spreading regularly and rapidly in craniocaudal directions. The body's major part, the *centrum*, was ossified from a primary centre dorsal to the notochord. (Centra are occasionally ossified from *bilateral* centres which may fail to unite. Suppression of one of these produces a *cuneiform vertebra*, a recognized cause of lateral spinal curvature. The condition is frequently multiple.) This centre first appears at lower thoracic levels in the ninth to tenth week, spreading craniocaudally and reaching the second cervical vertebra in the twelfth week. In the study by Bagnall et al (1977) these events were largely confirmed, but the earliest centres were in lower thoracic *and* upper lumbar regions; cranial progression was rather faster than caudal, the last centre being in the fifth sacral vertebra. (For the later and erratic ossification of the coccyx vide infra.) During early postnatal years the centrum is connected to each half neural arch by a synchondrosis or *neurocentral joint*. In thoracic vertebrae costal facets on bodies are *posterior* to neurocentral joints. At birth a vertebra consists of three ossifying elements, a centrum and two half arches, united by cartilage. During the first year the arches unite behind, first in the lumbar region and then through thoracic and cervical regions. In upper cervical vertebrae centra unite with arches about the third year, but in lower lumbar vertebrae union is not complete until the sixth. Until puberty the upper and lower surfaces of bodies and apices of transverse and spinous processes are cartilaginous but now *five secondary centres* appear, one in the apex of each transverse and spinous process and two annular epiphysial 'rings' for

3.74 Base of the sacrum in the male (A) and in the female (B). The body of the first segment (X) forms a larger part of the breadth of the base in the male than it does in the female. In the latter the body is relatively smaller and the lateral, costal part (Y), the ala, is relatively broader.

3.75 Median sagittal section through the sacrum.

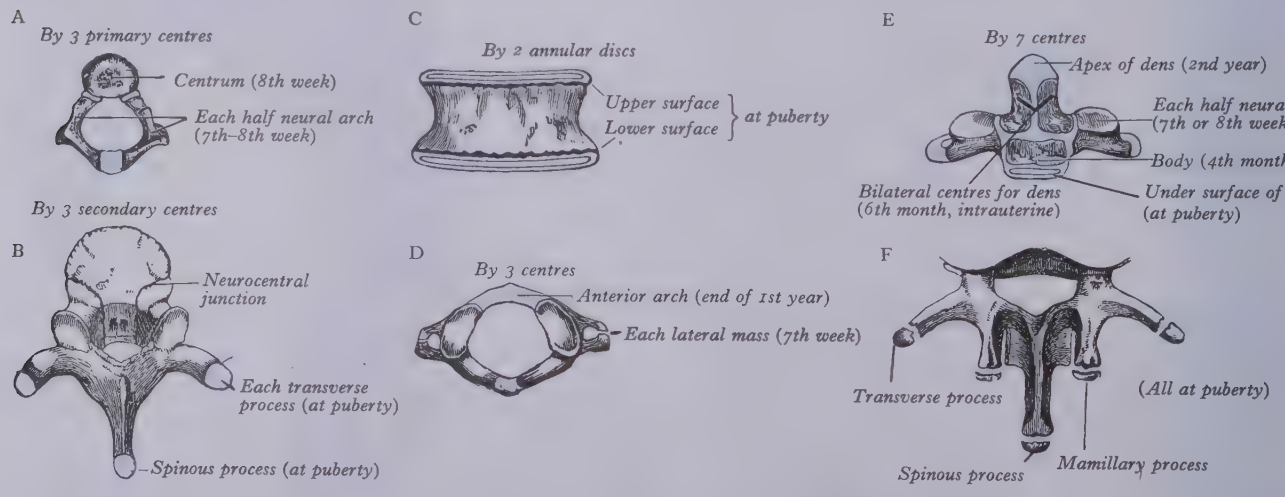
3.76 The coccyx: A. pelvic aspect; B. dorsal aspect.

circumferential parts of upper and lower surfaces of the body (2.44,3.77B,C). Costal articular facets are extensions of the annular epiphyses (Dixon 1920). These epiphyses fuse with the rest of the bone at about 25 years. In bifid cervical spinous processes there are two secondary centres. The annular 'epiphyses' of vertebrae probably cannot be equated with epiphyses of long bones. In most mammals they are complete osseous discs. For discussion consult François & Dhem (1974).

Sexual dimorphism in vertebrae has received little attention, but Taylor & Twomey (1984) have described radiological differences in adolescent humans, female vertebral bodies having a lower ratio of width to depth.

Exceptions to this pattern of ossification occur in the first, second and seventh cervical and in lumbar vertebrae.

The atlas is commonly ossified in three centres (3.77D): one in each lateral mass at about the seventh week, gradually extending into the posterior arch where they unite between the third and fourth years, directly or occasionally through a separate centre. At birth, the anterior arch is fibrocartilaginous; here a separate centre appears about the end of the first year, uniting with the lateral masses between the sixth and eighth, the lines of union extending across anterior parts of the superior articular facets. Occasionally the anterior arch is formed by extension and ultimate union of centres in the lateral masses, sometimes from two *lateral* centres in the arch itself.

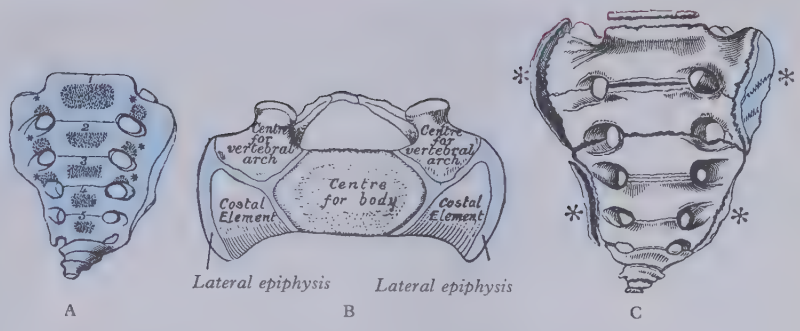


The axis is ossified from five primary and two secondary centres (3.77E), the vertebral arch from two primary, the centrum from one, as in a typical vertebra. The former appear about the seventh or eighth week, that for the centrum about the fourth or fifth month. The dens is largely ossified from bilateral centres, appearing about the sixth month and joining before birth to form a conical mass, deeply cleft above by cartilage. This cuneiform cartilage forms the apex of the odontoid process and in it a centre appears about the second year and unites with the main mass of the process about the twelfth. It has been widely regarded as a part of the cranial sclerotomal half of the first cervical segment or *pro-atlas* (Gadow 1933), but vide infra. The dens is separated from the body by a cartilaginous disc, the circumference of which ossifies while its centre remains cartilaginous until old age; in the disc possible rudiments of adjacent epiphyses of atlas and axis may occur. A thin epiphysial plate is formed inferior to the body around puberty. The dens has long been considered the atlantal centrum, secondarily fused with axis. This view was undermined by studies in a variety of mammals by Jenkins (1969), who regarded the dens as a new formation. Ganguly & Singh-Roy (1965) consider the apical centre for the dens as derived from the *pro-atlas*, which may also contribute to lateral atlantal masses.

Some observers regard the dens as the centrum of the pro-atlas.

In the seventh cervical vertebra separate centres for its costal processes appear about the sixth month and join body and transverse processes between the fifth and sixth years; they may remain separate and grow anterolaterally as cervical ribs (p. 319). Separate ossific centres may, on occasion, also occur in the costal processes of the fourth to sixth cervical vertebrae (p. 336).

The lumbar vertebrae (3.77F) have two additional centres for mamillary processes. In the fifth lumbar a pair of scale-like epiphyses usually appear on the tips of costal elements.



The sacrum (3.78A–E) resembles typical vertebrae in the ossification of its segments. Primary centres for the centrum and each half vertebral neural arch appear between tenth and twentieth

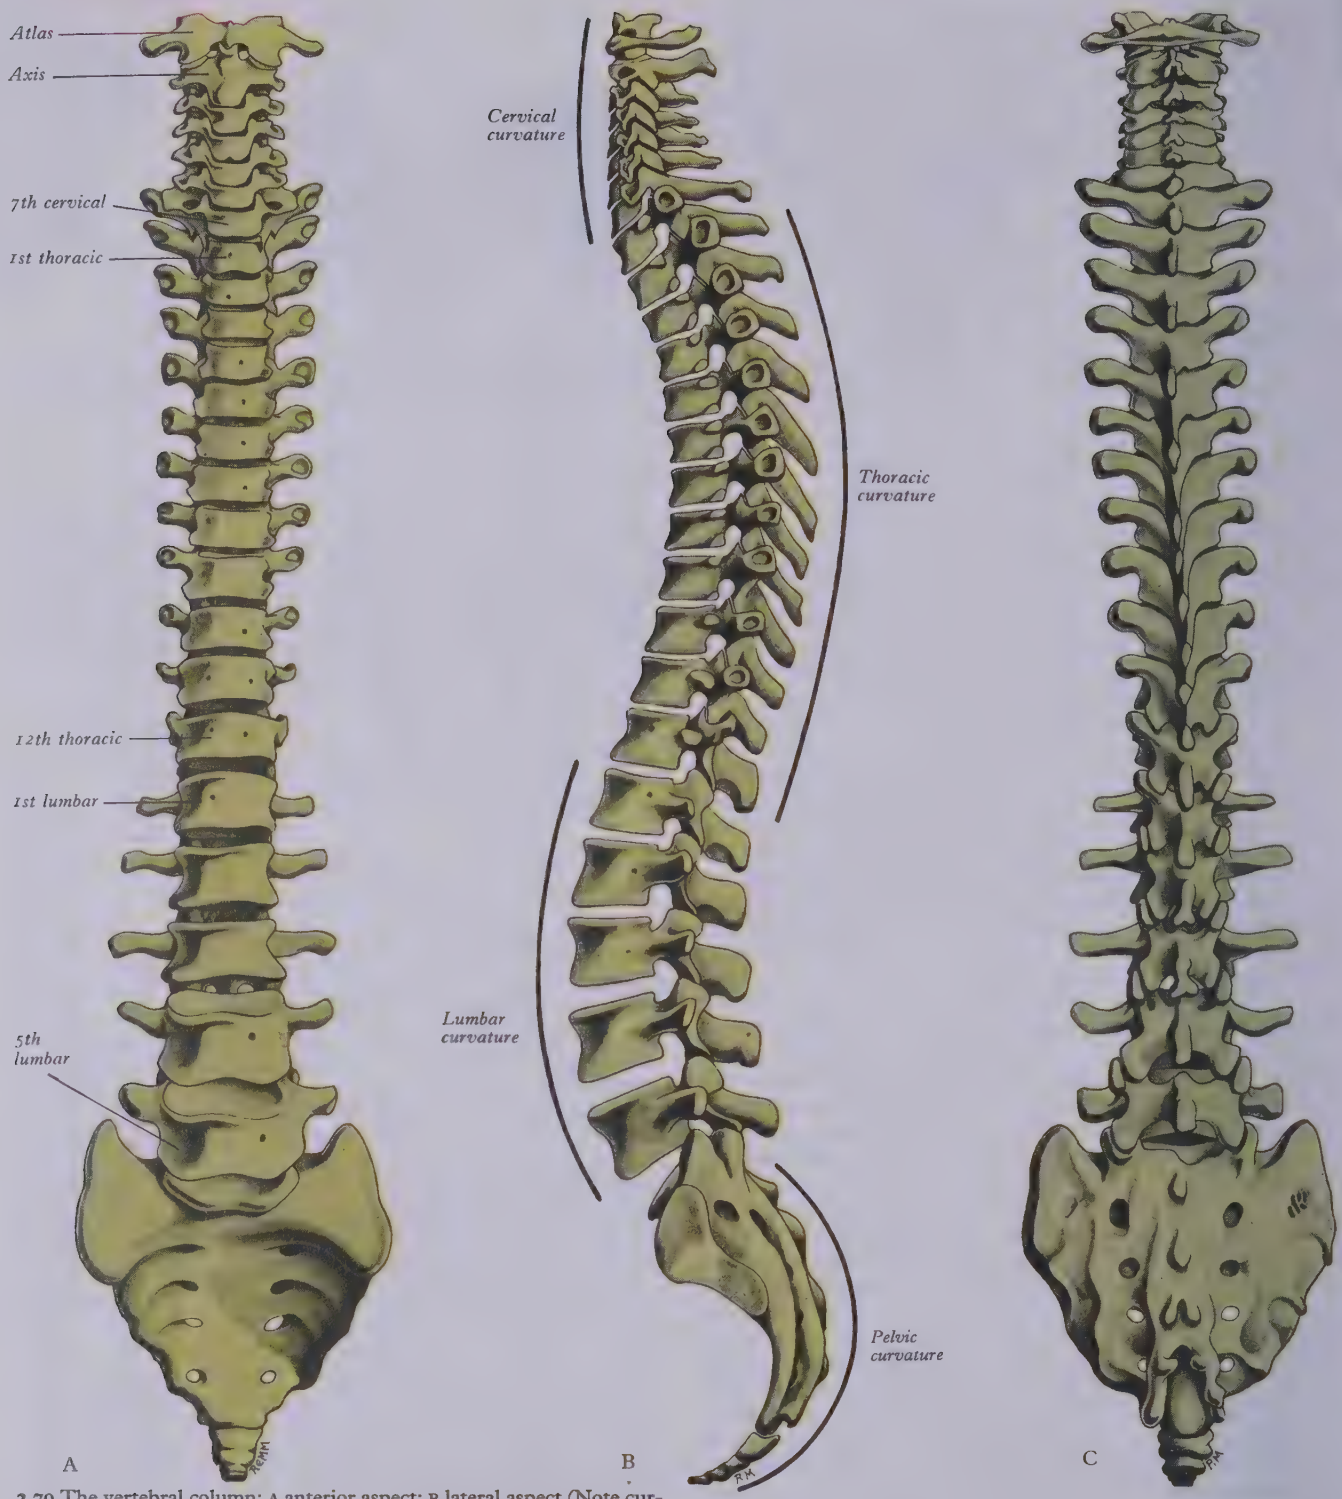
weeks. Primary centres for costal elements of the upper three or more segments appear superolateral to the pelvic sacral foramina, between sixth and eighth prenatal months. Each costal element unites with its half vertebral arch between the second and fifth years, and the conjoined element so formed unites ventrally with the centrum and dorsally with its opposite fellow at about the eighth year. Thereafter the upper and lower surfaces of each sacral body are covered by an epiphysial plate of hyaline cartilage separated by a fibrocartilaginous precursor of an intervertebral disc. Laterally, successive conjoined vertebral arches and costal elements are separated by hyaline cartilage; a cartilaginous epiphysis, sometimes divided into upper and lower parts, develops on each auricular and adjacent lateral surface. Soon after puberty the fused vertebral arches and costal elements of adjacent vertebrae begin to coalesce from below upwards. At the same time epiphysial centres develop for (1) upper and lower surfaces of bodies, (2) spinous tubercles, (3) transverse tubercles and (4) costal elements. The costal epiphysial centres appear at the lateral extremities of the hyaline cartilages *between* adjacent costal elements; two anterior and two posterior appear in each interval between first, second and third segments. Ossification spreads from these into the auricular epiphysial plates. One costal epiphysial centre appears anteriorly in each remaining interval; from these ossification spreads to the epiphysial plate covering the lower lateral surface. Sacral bodies unite at their adjacent margins after the twentieth year, but the central mass and most of each intervertebral disc remain unossified up to or beyond middle life. Available information is based on few specimens (Fawcett 1907, McKern & Stewart 1957).

The coccyx. Each segment is ossified from one primary centre but the incidence and timing are uncertain. A centre in the first segment appears about birth and its cornua may soon ossify from separate centres. Remaining segments ossify at wide intervals up to the twentieth year or later. Segments slowly unite; union between the first and second is frequently delayed until 30 years. Especially in females, the coccyx often fuses with the sacrum in later decades.

3.78A–C Ossification of the sacrum and coccyx: A at birth; B the base of the sacrum of a child of about four years of age; C at the twenty-fifth year. In C the epiphysial plates for each lateral surface are marked by asterisks.

3.78D,E The epiphyses of the costal and transverse process of the sacrum at the eighteenth year.

The Vertebral Curvatures



The vertebral column is median and dorsal in the body, the general vertebrate plan. In human males its length is about 70 cm, its cervical part approximately 12 cm, thoracic 28 cm, lumbar 18 cm and sacrum and coccyx 12 cm. In females the total length is about 60 cm.

The curves of the vertebral column viewed from the side (**3**.3,79B) are cervical, thoracic, lumbar and pelvic. The thoracic and pelvic curves are *primary*, concave ventrally during fetal life and thereafter. Cervical and lumbar curves are *secondary* or compensatory; the cervical appears before birth (vide infra) and is accentuated when the child begins to hold up its head (at 3 or 4 months) and to sit upright (about nine months). The lumbar curve appears at 12–18 months, when walking begins; it brings the trunk's centre of gravity over the legs. This change in mechanics of the lumbar region appears a potent factor in alterations in the proportions of vertebral bodies and intervertebral discs, especially in the fifth lumbar and the disc below it (Taylor 1975). The customary view that the secondary cervical curve appears around birth has been challenged (Bagnall et al 1977). Radiographic study of 195 human fetuses aged from 8 to 23 weeks, showed that 83% already possessed a cervical curve, visible as soon as the ossification permitted, i.e. at nine weeks. These observers also emphasized early onset of *fetal movements* as a factor in the emergence of an identifiable cervical curve.

In adults, the *cervical curve* is convex forwards and the least marked; it extends from atlas to second thoracic vertebra. The *thoracic curve*, concave forwards, reaching from second to twelfth thoracic vertebrae, is due to the greater posterior depth of the vertebral bodies. The *lumbar curve*, convex forwards, is greater in females; it reaches from the last thoracic vertebra to the lumbosacral angle and the convexity of the lower three segments is greater. It is mainly due to a greater anterior depth of intervertebral discs but the shape of vertebral bodies also contributes. Sexual differences in lumbar and cervical curvatures were confirmed by Knussman & Finke (1977). The *pelvic curve* extends from lumbosacral joint to coccygeal apex; its concavity is antero-inferior. In the upper thoracic region there is often a slight *lateral* curvature, convex to the right in right-handed persons, and left in the left-handed.

Viewed from the front (**3**.1,79A), the width of vertebral bodies increases from second cervical to third lumbar, in association with increase in weight-bearing. There is some variation in size of the last two lumbar bodies but thereafter width diminishes rapidly to the coccygeal apex. In the two lowest lumbar vertebrae there is an inverse relation between areas of upper and lower surfaces of bodies, and size of pedicles and transverse processes, suggesting that the latter transmit some of the vertebral compressive forces from spine to pelvis (Davis 1961). From detailed dimensional study of primate lumbar vertebrae, Rose (1975) considered that the size of bodies is as much concerned with bending as compressive stresses, emphasizing that only the *fifth* human lumbar body *regularly* displays a greater ventral depth and concluding that other factors must contribute to lumbar curvature: as noted above this is principally the intervertebral discs.

In posterior view the approximately median spines projecting dorsally are the major feature (**3**.79C). In the cervical region (except for second and seventh vertebrae) these are short, nearly horizontal with bifid ends. In the upper thoracic region they slope obliquely down; intermediate thoracic spines are long and almost vertical; finally, ones in lower thoracic and lumbar regions are nearly horizontal. They are separated by intervals in cervical and lumbar regions but closely approximated in the midthoracic region. Occasionally a spinous process may deviate from the midline, an important clinical fact, since irregularities occur also in fractures or dislocations. The seventh cervical spine can be felt at the lower end of the nuchal furrow; first and second thoracic spines are also prominent. The third thoracic is level with the scapular spine, and the seventh with the inferior scapular angle, when the arm is pendent. The fourth lumbar spine is level with the summits of the iliac crests (a point useful in lumbar puncture), and the second sacral with the posterior superior iliac spines. Lateral to the vertebral spines *vertebral grooves* contain the deep dorsal muscles; at cervical and lumbar levels the grooves are shallow and

3.79 The vertebral column: A anterior aspect; B lateral aspect (Note curvatures); C dorsal aspect. Note slight sinuous, lateral, thoracolumbar curvature visible from both dorsal and anterior aspects.

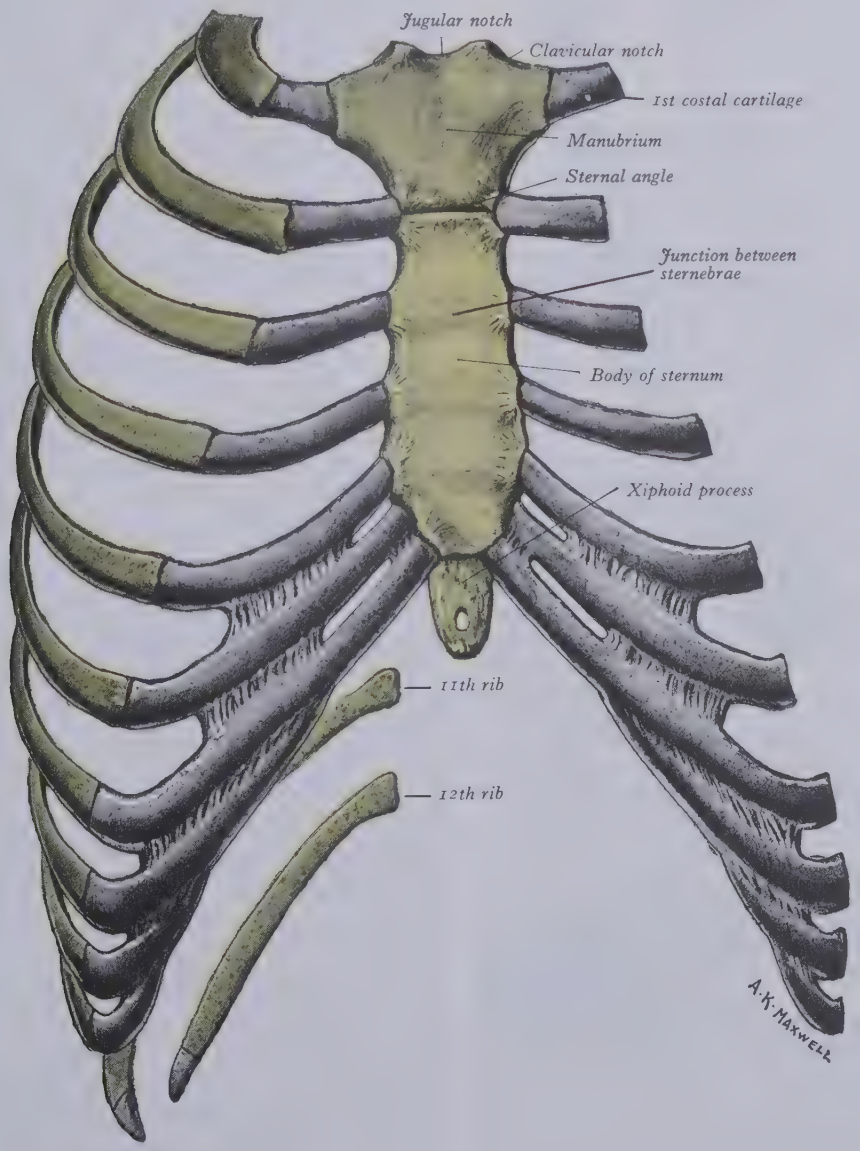
mainly formed by laminae; in the thoracic region they are deep, wide and formed by laminae and transverse processes. Lateral to laminae are articular processes and still more lateral, transverse processes. In the thoracic region the transverse processes are in a plane considerably *behind* those of cervical and lumbar processes. Cervical transverse processes are anterior to articular processes, lateral to pedicles and between intervertebral foramina. In the thoracic region they are posterior to pedicles, intervertebral foramina and articular processes. In the lumbar region they are anterior to articular processes, but posterior to intervertebral foramina. The size of the atlantal transverse processes has been emphasized (p. 318) and transverse breadth of the atlas contrasted with that of the axis. Breadth varies little from second to sixth cervical, but increases in the seventh. In thoracic vertebrae it is greatest in the first and diminishes to the twelfth, whose transverse elements are usually mere vestiges. The first lumbar vertebra is broader, the second more so, the third broadest of all, the fourth and fifth diminishing.

The *lateral aspect* of the vertebral column (3.3,79B) is arbitrarily separated from the posterior by articular processes in the cervical and lumbar regions and transverse processes in the thoracic. Anteriorly it is formed by the sides of vertebral bodies, with costal facets at thoracic level. The intervertebral foramina, behind bodies and between pedicles, are oval, smallest at cervical

and upper thoracic levels and increasing in size to the last lumbar; they contain spinal and other nerves and various vessels.

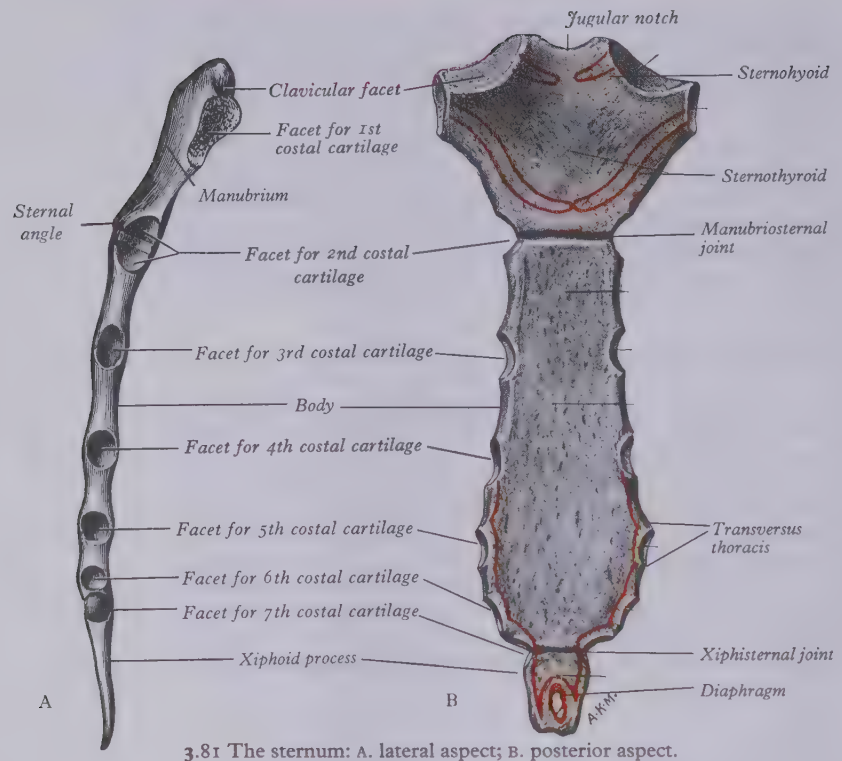
The *vertebral canal* follows the vertebral curves, is large and triangular in cervical and lumbar regions, where movement is free, but small and circular in the thoracic, where motion is less. These differences also accommodate variations in diameter of the spinal cord and its enlargements.

Although movement between adjacent vertebrae is limited, these small ranges add up to considerable degrees of bending or rotation over the whole column (p. 492). Intervertebral discs tie vertebrae together but are also the principal sites of movement. By elastic deformability they permit tilting and torsion between vertebral bodies and also add compressibility to the column. This ability to absorb stresses is augmented by the column's sinuous curvature; forces transmitted with little loss by a straight column are largely expended against the pliancy of the spinal curves. Effects of weight, muscle traction and thrust from the feet, whether trivial as in walking, or large as in running and jumping, are smoothed out by the discs and curvatures.



Despite the prominent role of intervertebral discs in spinal dynamics, regional variations in mobility also depend on the disposition, properties and geometry of intervertebral synovial joints and ligamentous complexes attached to all parts of each vertebra (p. 492).

Fractures or fracture dislocations of the vertebral column result from (1) forced flexion, e.g. by a violent blow on the back, and (2) violence transmitted along its axis, e.g. by falls on to the feet or head. In the first type injury commonly occurs at the fifth or sixth thoracic; in the second, owing to normal curvatures, injury is also a flexion fracture, often between the ninth thoracic and second lumbar.



In spondylolisthesis, present in 5% of skeletons, the spine, laminae and inferior articular processes of the fifth (sometimes fourth) lumbar vertebra are united together but separate from the rest of the bone. The condition is probably congenital and it is suggested that each half vertebral arch ossifies from two primary centres which fail to fuse, but there is no clear evidence for this.

The Sternum

The sternum is confined to land vertebrates, and aquatic mammals such as seals; it is absent in fish. The elongate human form is typical of mammals, the sternum being a plate, often composite, in amphibians and reptiles. Though associated with shoulder girdles and ribs from its earliest appearance, it is often considered axial. Its embryonic development and ossification indicate an origin separate from ribs. The human sternum (3.80, 81A,B) consists of a cranial *manubrium* (prosternum), an intermediate *body* or mesosternum and a caudal *xiphoid process* (metasternum). Its total length in males is about 17 cm, less in females (Jit 1984). The ratio between manubrial and mesosternal lengths

3.80 The sternum and costal cartilages: anterior aspect.

3.81 The sternum: A. lateral aspect; B. posterior aspect.

differs in the sexes, but racial differences have not been established. Such data are complicated by possible continuation of growth beyond the third decade and even throughout life (Ashley 1956, Rother et al 1975). In addition to the three major sections, the mesosternum in early life consists of four *sternebrae*, which from costal relations appear to be intersegmental. In natural stance the sternum slopes down and slightly forwards. It is convex in front, concave behind and broadest at the junction with the first costal cartilages, narrow at the manubriosternal joint, below which it widens to its articulation with the fifth cartilages, narrowing again below this.

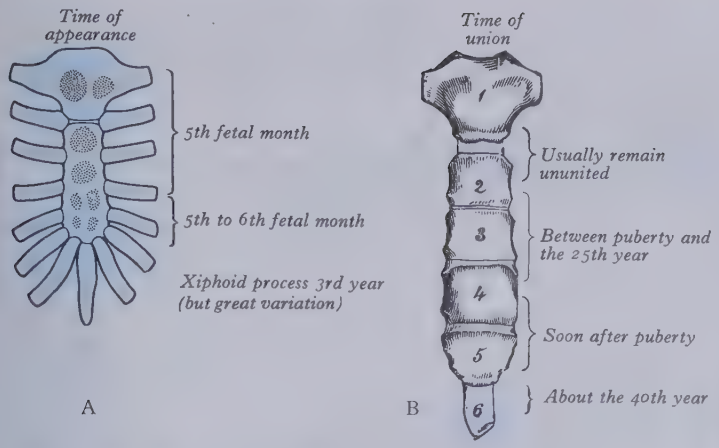
The manubrium sterni is broad and thick above, narrowing to its junction with the mesosternum. Its *anterior surface* is smooth, convex transversely, vertically concave. Its *posterior surface* is concave and smooth. The *superior border* is thick, with a central *jugular (suprasternal) notch* between two oval fossae directed up and posterolaterally for articulation with sternal ends of clavicles, hence termed *clavicular notches*. The *inferior border*, oval and rough, carries a thin layer of cartilage for articulation with the mesosternum. The *lateral borders* are marked above by a depression for the first costal cartilage and below by a small articular demifacet, which, with one on each superior mesosternal angle, joints with part of the second costal cartilage. Between these facets the narrow curved edge descends medially.

The mesosternum (body), longer, narrower and thinner than the manubrium, is broadest near its lower end. Its *anterior surface*, nearly flat, faces slightly upwards and has three variable transverse ridges at levels of fusion of its four *sternebrae* (vide infra). A *sternal foramen*, of varying size and form, may occur between the third and fourth sternebrae (p. 161). The *posterior surface*, slightly concave, also displays three less distinct transverse lines. The oval *upper end* articulates with the manubrium (*manubriosternal joint*) at the level of the *sternal angle*, an anterior ridge usually being palpable. A posterior transverse groove also marks the manubriosternal joint (3.81A). The *lower end* is narrow and continuous with the xiphoid process. On each *lateral border* (3.81B), at its superior angle, a small notch receives in part the second costal cartilage; below this, four *costal notches* articulate with the third to sixth cartilages; the inferior angle has a small facet, which, with the xiphoid process, receives the seventh costal cartilage. Between these articular depressions a series of curved edges diminish in length downwards, forming the anterior limits of the intercostal spaces.

The xiphoid process (*xiphisternum*), the smallest and most variable sternal element, may be broad and thin, pointed, bifid, perforated, curved or deflected. It is cartilaginous in youth, but more or less ossified in adults. It is continuous with the mesosternum's lower end at the *xiphisternal joint*. Anterior to its superolateral angles are demifacets for parts of the seventh costal cartilages (3.81).

The manubrium is level with the third and fourth thoracic vertebrae; the *sternal angle* is opposite the inferior border of the fourth vertebral body. To the manubrial *anterior surface* the sternal ends of the major pectoral and sternocleidomastoid muscles are attached and to its *posterior surface* the sternothyroids, opposite the first costal cartilages; above are the most medial fibres of the sternohyoids. This surface is the anterior wall of the superior mediastinum; inferiorly (approximately the vertically lower half) it is related to the aortic arch, above this to the left brachiocephalic vein and brachiocephalic, left common carotid and left subclavian arteries; laterally to lungs and pleurae. To the *jugular notch* are attached fibres of the interclavicular ligament. On the *lateral border* the manubriocostal joint (first costal cartilage) is a synchondrosis, unlike other sternocostal joints.

The mesosternum is level with the fifth to ninth thoracic vertebrae. To its *anterior surface* articular capsules of sternocostal joints and sternal fibres of pectoralis major are attached, and to its *posterior surface* the transversus thoracis (sternocostalis). Right of the median plane it is related to pleura and the thin, anterior border of the right lung, projecting between sternum and pericardium. The left half of the upper two sternebrae is related to left pleura and lung, the lower two directly to pericardium. To the *borders* the external intercostal membranes are attached between costal facets. Except for the first and sixth, the cartilages of 'true' ribs articulate with the sternum at junctions of its segments.



The xiphoid process is in the epigastrium. To its *anterior surface* are attached the most medial fibres of rectus abdominis and aponeuroses of external and internal obliques, to its *lower end* the linea alba, and to its *borders* the aponeuroses of internal oblique and transversus abdominis. To its *posterior aspect* slips of diaphragm are attached and it is here related to the liver.

The sternum contains highly vascular trabecular bone enclosed by a compact layer thickest in the manubrium between clavicular notches. The medulla contains *red bone marrow*. The internal trabecular pattern has been examined intensively by scanning electron microscopy and by computer analysis of metrical parameters (Whitehouse 1975). Centrally the bone is lightly constructed, the trabeculae being thicker and wider apart in lateral regions. No completely satisfactory explanation of these variations, or of those already noted in ribs and lumbar vertebrae, has been formulated. Pismenov & Zapetski (1977) have described the vascular supply of the sternum in detail.

Ossification (3.82A,B). The sternum is formed by fusion of two cartilaginous *sternal plates* (p. 161) flanking the median plane. Arrangement and number of ossificatory centres vary in relation to completeness and time of fusion of the sternal plates and to the width of the adult bone (Ashley 1956). Incomplete fusion leaves a *sternal foramen* (p. 161). (For incidence in Indian sterna, see Jit & Bakshi 1984.) The manubrium is ossified from one to three centres appearing in the fifth fetal month, and the first and second sternebrae usually from single centres about the same time. Centres in the third and fourth sternebrae are commonly paired and appear in the fifth and sixth months respectively, but one of either pair may be delayed until the seventh or even eighth month; the fourth sternebral centre may be absent (Paterson 1904). The xiphoid process begins to ossify in the third year or later. In some sterna all centres are single and median, in others the manubrial centre is single and the sternebral all paired, symmetrical or asymmetrical. Union between mesosternal centres begins at puberty and proceeds from below upwards; by 25 all are united (see also p. 498).

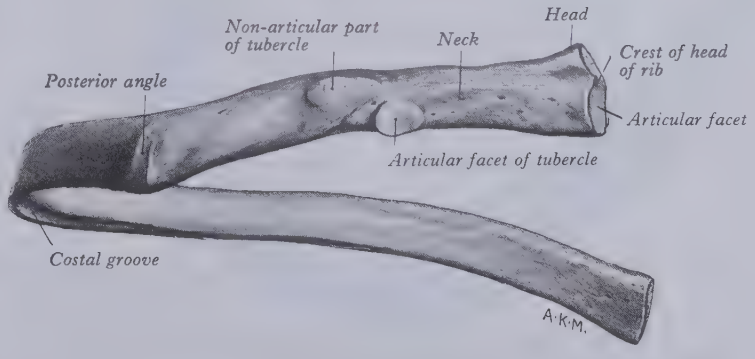
Little has been recorded of racial or sexual variation in the sternum. Jit et al (1980), and Jit and Hasjeet (1982) stated that, except in combined length of manubrium and mesosternum, sexing is not possible, the sternal angle being unreliable.

Suprasternal ossicles, paired or single, occur in about 7% of sterna. They may fuse to the manubrium or articulate posteriorly

3.82 The ossification of the sternum: A. before birth, B at puberty.

at the lateral border of the jugular notch. When well formed they are pyramidal, the base being articular. Cartilaginous at birth, they ossify during adolescence.

The Ribs

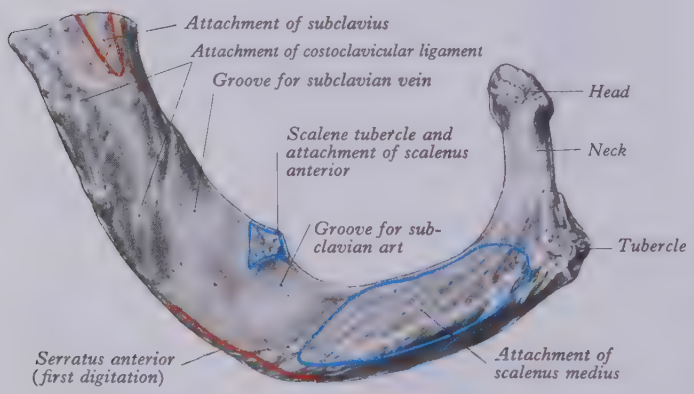


The ribs are elastic arches, connected posteriorly with the vertebral column, forming much of the thoracic skeleton. The twelve pairs may be increased by cervical or lumbar ribs or reduced to eleven by absence of the twelfth pair. The superior seven pairs are connected by costal cartilages to the sternum (3.80, 88), as *true* ribs. The remaining five are so-called *false* ribs, cartilages of the eighth to tenth joining the superjacent costal cartilage; the eleventh and twelfth, being free at their anterior ends, are sometimes termed *floating* ribs. (The tenth rib is also *usually* 'floating' in the Japanese, as also recorded in other races, see p. 336.)

Between ribs are *intercostal spaces*, which are deeper in front and between the upper ribs. Upper ribs are less oblique than the lower, obliquity being maximal at the ninth and decreasing to the twelfth. They increase in length from first to seventh, diminishing to the twelfth. In breadth they decrease downwards; in the upper ten the greatest breadth is anterior. The first two and last three present special features, the rest conforming to a common plan.

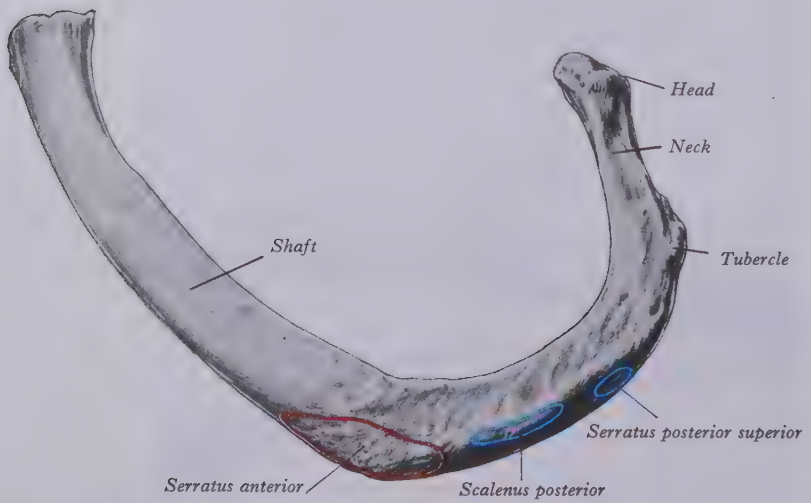
A typical rib has a shaft with anterior and posterior ends (3.83, 84). The *anterior, costal end* has a small concave depression for its cartilage's lateral end. The *shaft* has an external convexity and is grooved internally near its lower border, which is sharp, in contrast to its rounded upper border. The *posterior, vertebral end* has a head, neck and tubercle. The *head* presents two facets, separated by a transverse *crest*. The lower and larger articulates with the body of the corresponding vertebra, its crest attached to the intervertebral disc above it. The *neck* is the flat part beyond the head, anterior to the corresponding transverse process. It is oblique, facing anterosuperiorly. Its postero-inferior surface is rough and pierced by foramina. Its upper border is the sharp *crest of the neck*, its lower border rounded. The *tubercle* is postero-external at junction of neck with shaft; more prominent in upper ribs, it is divided into medial articular and lateral non-articular areas. The articular part bears a small, oval facet for the transverse process of the corresponding vertebra; the non-articular area is roughened by ligaments. The *shaft* is thin and flat with external and internal surfaces, superior and inferior borders. It is curved, bent at the *posterior angle* 5–6 cm from the tubercle, and also twisted in its long axis: the part behind the angle inclines superomedially, its *external surface* hence posteroinferior; in front of the angle it faces slightly up; it is convex and smooth, and crossed near the tubercle by a rough line, directed inferolaterally, at the *posterior angle*. The *internal surface* is smooth and marked by the *costal groove*, bounded below by the inferior border. The superior border of the groove continues behind the lower border of the neck, but terminates anteriorly at the junction of middle and anterior thirds of the shaft, anterior to which the groove is absent. (Vide infra concerning an *anterior angle*.)

3.83 A typical rib of the left side: inferior aspect.



3.84 A typical rib of the left side: posterior aspect.

The first rib (3.85), most acutely curved and usually shortest, is broad and flat, its surfaces superior and inferior, its borders internal and external. It slopes obliquely down and forwards to its sternal end. The *head* is small, round and bears an almost circular facet, articulating with the first thoracic vertebral body. The *neck* is rounded and ascends posterolaterally. The *tubercle*, wide and prominent, is directed up and backwards; medially an oval facet articulates with the first thoracic transverse process. At the tubercle the rib is bent, its head turned slightly down; angle and tubercle therefore coincide. The *superior surface* of the flattened shaft is crossed obliquely by two shallow grooves, separated by a slight ridge which ends at the internal border as a usually small, pointed, projection, the *scalene tubercle*. The *inferior surface* is smooth and ungrooved. The *external border* is convex, thick behind, thin in front. The internal *border* is concave and thin, with a scalene tubercle near its midpoint. The *anterior end* is larger than in any other rib.



The second rib (3.86) is twice the length of the first, with a similar curvature. The non-articular area of the *tubercle* is small. The *angle* is slight and near the tubercle. The *shaft* is not twisted, but at the tubercle is convex upwards, as in the first rib but less so. The *external surface* of the shaft is convex and superolaterally marked centrally by a rough, muscular impression; the latter continues posteromedially towards the tubercle as a narrow roughened ridge. The *internal surface*, smooth and concave, faces inferomedially with posteriorly a short costal groove.

The tenth rib has a single facet on its head which may articulate with the intervertebral disc above as well as the upper border of the tenth thoracic vertebra near its pedicle.

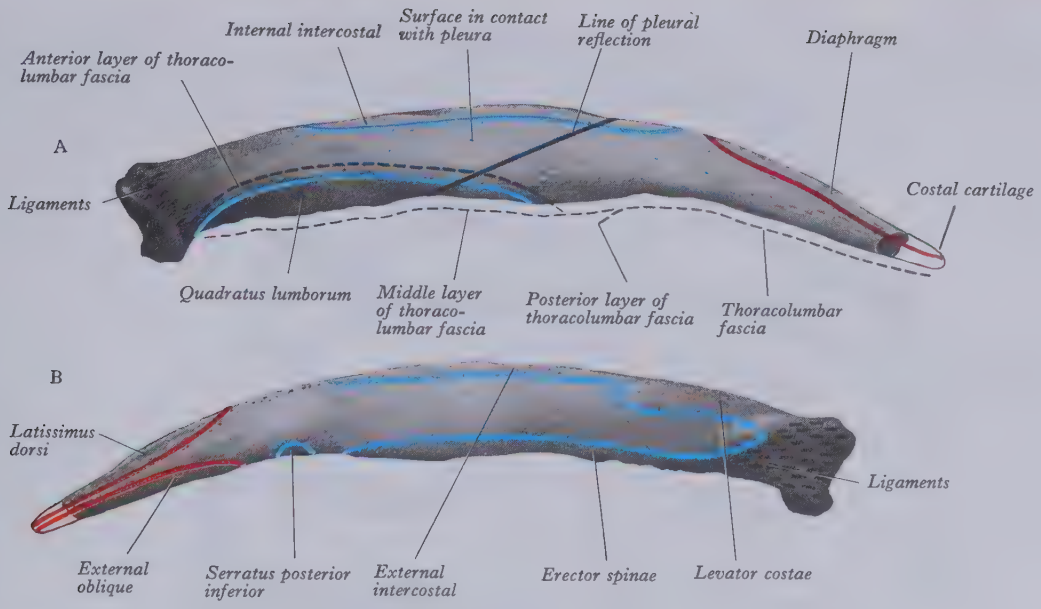
The eleventh and twelfth ribs (3.87) each have one large, articular facet on the head, but no necks or tubercles; their pointed anterior ends are tipped with cartilage. The eleventh has a slight angle and shallow costal groove. The twelfth has neither, is much shorter and slopes cranially at its vertebral end. The internal surfaces of both face slightly *upwards*, more so in the twelfth.

3.85 The first rib of the left side: superior aspect.

3.86 The second rib of the left side: superior aspect.

Attachments and Relations of Ribs

To the *head of a typical rib* the radiate ligament is attached along its anterior border, and the intra-articular ligament to its crest. Its anterior surface is related to costal pleura and in lower ribs the sympathetic trunk. The *neck's anterior surface* is divided by a faint transverse ridge for the internal intercostal membrane and continuous with the *inner* lip of the superior border of the shaft. The area above the ridge, more or less triangular, is separated from the membrane by fatty tissue; the lower, smooth area is covered by costal pleura. The *neck's posterior surface* receives the costotransverse ligament and is pierced by vascular foramina. The *crest of the neck* is for attachment of the superior costotransverse ligament and extends laterally into the *outer* lip of the shaft's superior border. The neck's rounded *inferior border* continues laterally into the upper border of the costal groove, receiving the internal intercostal membrane. The *articular area of the tubercle* in the upper six ribs is convex and faces posteromedially; in the succeeding three or four it is almost flat and faces down, back and slightly medially. To the *non-articular area* the lateral costotransverse ligament is attached.



The ridge on the shaft's *external surface* (near its posterior angle) in a typical rib receives an upward continuation of thoracolumbar fascia and lateral fibres of iliocostalis thoracis. From second to tenth ribs the distance between angle and tubercle increases. Medial to the angle the external surface affords attachment to a levator costae and is covered by erector spinae. Near this surface's sternal end an indistinct, oblique line (*anterior 'angle'*) separates attachments of external oblique and serratus anterior (or latissimus dorsi, in ninth and tenth ribs). To the *costal groove* (internal surface) is attached the internal intercostal muscle, separating bone from intercostal vessels and nerve. At the vertebral end the groove faces down, its borders in the same plane. Near the posterior angle the shaft broadens and the groove reaches its internal surface; to the groove's superior rim intercostalis intimus is attached, rarely extending to the rib's anterior fourth. Posteriorly this rim meets the neck's lower border. To the sharp inferior costal border is attached an external intercostal muscle. The superior border has posteriorly two lips: to the inner are attached both intercostalis internus and intimus, to the outer only intercostalis externus.

The first rib (3.85) has a *tubercle for scalenus anterior*, which is also attached to adjoining parts of the *upper surface*. The groove anterior to this forms a bed for the subclavian vein; and the rough area between this and the first costal cartilage receives the costoclavicular ligament and, more anteriorly, subclavius. To the groove behind the tubercle is apposed the subclavian artery and usually the lower trunk of the brachial plexus. Behind this, as far as the costal tubercle, scalenus medius is attached. The obliquity of the first ribs accounts for the appearance of pulmonary and pleural apices in the neck.

The first rib's external border is covered behind by scalenus posterior descending to the second; the first digitation of serratus anterior is, in part, attached to it, behind the subclavian (arterial) groove. To the *internal border* is attached the suprapleural membrane, covering the pleura's cervical dome.

The second rib (3.86) is marked by *serratus anterior*, its rough prominence extending from just behind the midpoint of its external surface; to this tubercle the lower part of the first and the second digitation are attached. The second intercostal nerve is between the rib and pleura in most of its course. The distinct lips of the upper border are widely separated behind; in front of the angle the outer lip receives scalenus posterior and, below this, serratus posterior superior.

The twelfth rib (3.86A,B) has numerous attached muscles and ligaments. To the lower part of its *anterior surface*, in its medial half to two-thirds, quadratus lumborum and its anterior covering layer of thoracolumbar fascia are attached, the upper part being related to the costodiaphragmatic pleural recess. At or near the

3.87 The twelfth rib of the left side. A. anterior aspect; B. posterior aspect.

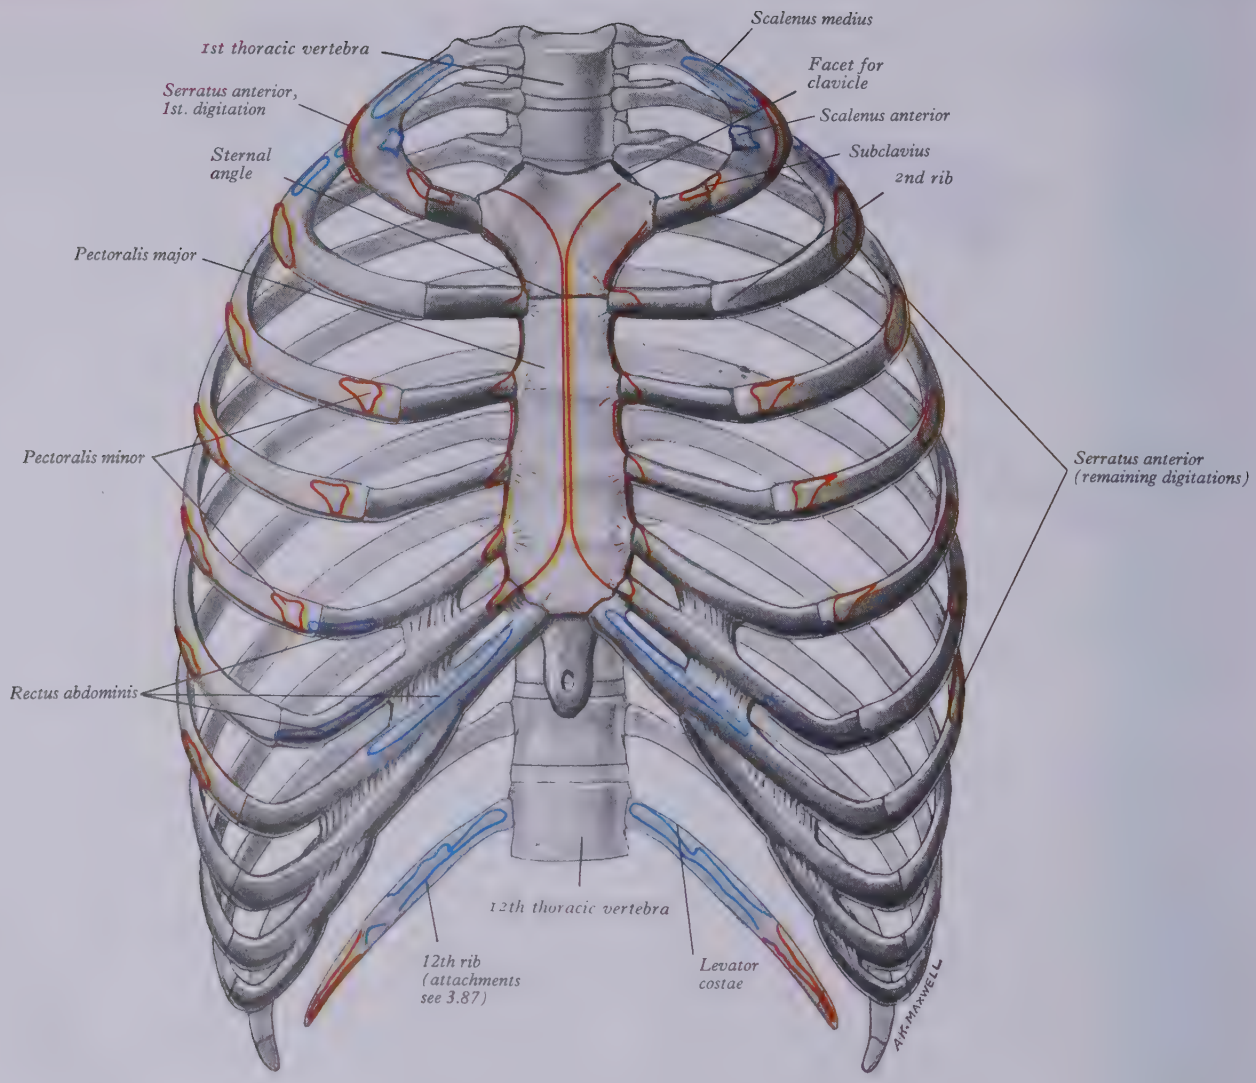
upper border are attachments of the internal intercostal medially and laterally the diaphragm. The *lower border* affords attachment to the middle lamella of the thoracolumbar fascia and, lateral to quadratus lumborum, the lateral arcuate ligament (p. 592) and posterior lamella of the thoracolumbar fascia. Posteriorly, close to the head, is attached the lumbocostal ligament (p. 497), connecting it to the first lumbar transverse process. To the *external surface* are attached the lowest levator costae, longissimus thoracis and iliocostalis in its medial half and laterally serratus posterior inferior, latissimus dorsi and obliquus externus. Along the *upper border* the external intercostal is attached. These attachments vary; those of the internal intercostal, levator costae and erector spinae merge and those of latissimus dorsi, diaphragm and external oblique may reach the costal cartilage. The lower limit of the pleural sac crosses in front of the rib, approximately where it is crossed by the lateral border of iliocostalis. Its lateral end is usually below the line of costodiaphragmatic pleural reflexion and therefore not covered by pleura.

Ribs consist of highly vascular trabecular bone, enclosed in a thin layer of compact bone and containing large amounts of red marrow (see **3**.22).

Ossification. Each rib, except the first and last two, is ossified from a primary centre for the shaft and secondary centres for the head and articular and non-articular parts of the tubercle (Fawcett 1911) but not for non-articular parts of tubercles below the sixth or seventh. The primary centre appears near the angle, late in the second month, first in the sixth and seventh ribs. Secondary centres for head and tubercle appear about puberty, uniting to the shaft soon after 20. The first rib has a primary centre for the shaft, a secondary for the head but only one for the tubercle; the eleventh and twelfth, without tubercles, have each only two centres.

The Costal Cartilages

The costal cartilages (**3**.88), flat bars of hyaline cartilage, extend from the anterior ends of ribs, contributing much to thoracic mobility and elasticity. The upper seven pairs join the sternum; the eighth to tenth articulate with the lower border of the one above; the lowest two have free pointed ends in the abdominal wall. They increase in length from first to seventh, thence decreasing to the twelfth. They diminish in breadth from first to last, like the intercostal spaces. They are broad at their costal continuity and taper therefrom; but the first and second are of even breadth and the sixth to eighth enlarge where their margins are in contact. The first descends a little, the second is horizontal and the third ascends slightly, the others being angulated and inclining up to the sternum or cartilage above, a little anterior to their ribs.



Each costal cartilage has two surfaces, borders and ends. The *anterior surface* is convex, facing anterosuperior; to it in the first cartilage are attached the sternoclavicular articular disc, costoclavicular ligament and subclavius and in the first six or seven medially is pectoralis major. The others are covered by the partial attachments of anterior abdominal muscles. The *posterior surface* is concave, and really posteroinferior; to the first cartilage is attached sternothyroid, to the second to sixth, transversus thoracis, and to the six lower ones transversus abdominis. To the concave *superior* and convex *inferior* borders are attached the internal intercostal muscles and external intercostal membranes. The inferior borders of the sixth to ninth cartilages project at points of greatest convexity and often also the fifth. Oblong facets on these projections articulate with facets on slight projections from the superior borders of subjacent cartilages. The *lateral end* of each cartilage is continuous with its rib; the *medial end* of the first is continuous with the sternum; those of the six succeeding cartilages are round and articulate with shallow costal notches on the lateral margins of the sternum; those of the eighth to tenth are pointed, each connected with the cartilage above; those of the eleventh and twelfth are pointed and free. Excepting the synchondrosis of the first rib and sternum, all these articulations are synovial (p. 497).

The tenth rib is usually united ventrally with the ninth by a fibrous joint (p. 498); but it frequently is free and pointed like the eleventh and twelfth. The incidence of a 'floating' tenth rib varies from 35% to 70% in different races (Shimaguchi 1974).

In old age costal cartilages tend to ossify superficially, losing pliability and becoming brittle. The histology (Amprino & Bairati 1933), histochemistry (Quintarelli & Dellovo 1966), and ultrastructure of such senile changes have been reviewed by Stockwell (1967), (p. 290). An increase in keratan sulphate is noted maximally in the subperichondrial zone.

The Thorax

The thoracic skeleton (**3**.88) is an osteocartilaginous frame around the principal organs of respiration and circulation. It is narrow

3.88 The skeleton of the thorax: anterior aspect.

above, broad below, flattened anteroposteriorly and longer behind. It is reniform in horizontal section due to the forward projection of vertebral bodies.

Posteriorly the thorax includes thoracic vertebrae and posterior parts of the ribs. On both sides of the vertebral column is a large groove due to the posterolateral curvature of ribs from their vertebral ends to their angles. *Anteriorly* are the sternum, anterior parts of ribs and costal cartilages and this aspect is slightly convex. *Laterally* the thorax is convex and formed by ribs alone. Ribs and costal cartilages are separated by 11 intercostal spaces, occupied by intercostal muscles and membranes, neurovascular bundles and lymphatic channels.

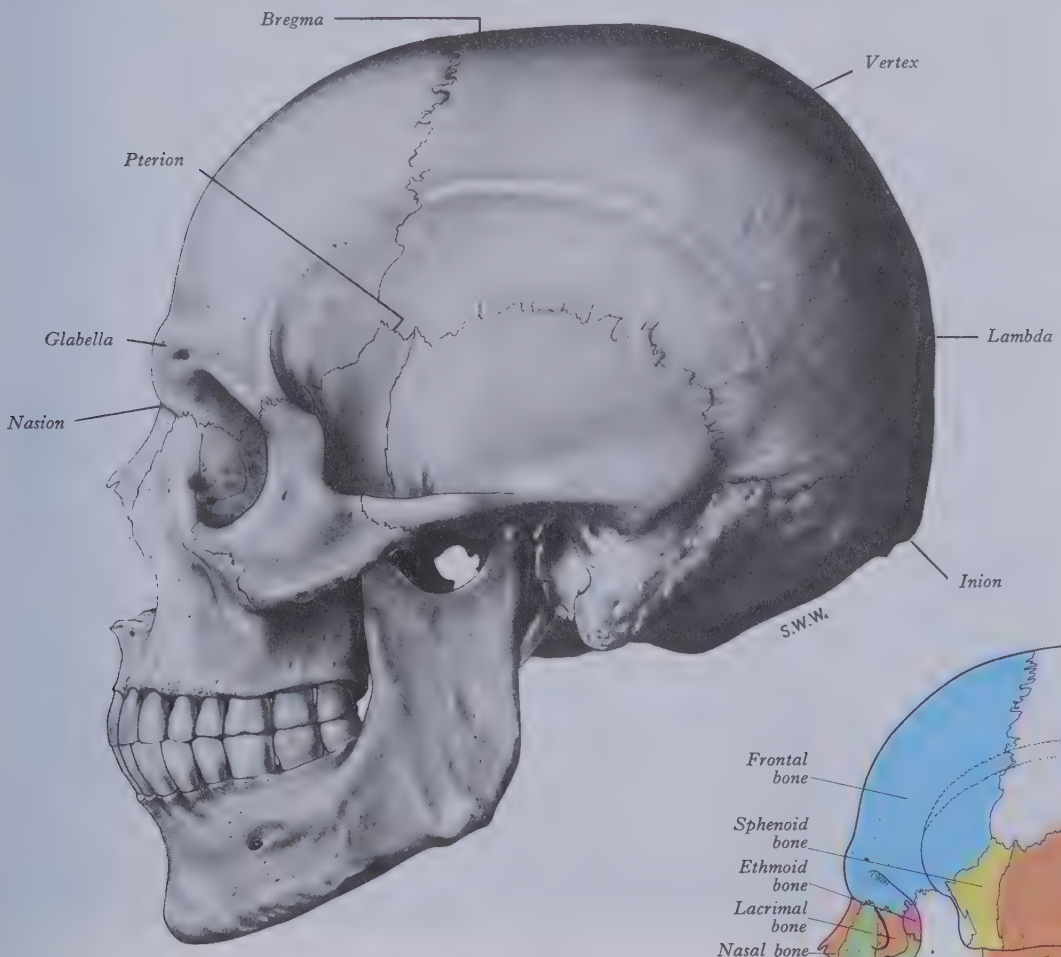
The *thoracic inlet* is reniform, about 5 cm anteroposteriorly, and transversely about 10 cm. Its plane slopes down and forwards, bounded by the first thoracic vertebral body behind, the superior border of the manubrium sterni in front and first rib on each side. The *outlet* is limited behind by the twelfth thoracic vertebral body, the twelfth and eleventh ribs laterally, and in front by the tenth to seventh ribs, which ascend to form the *infrasternal angle*. The outlet is wider transversely and oblique, sloping down towards the back, and is closed by the diaphragm which forms a floor to the thoracic cavity.

Thoracic variations in dimensions and proportions are partly individual and also linked to age, sex and race. At birth the transverse diameter is relatively less but adult proportions develop as walking begins. In females capacity is less, absolutely and proportionately, the sternum being shorter, the thoracic inlet more oblique and the suprasternal notch level with the third thoracic vertebra (second in males). The upper ribs are more mobile in females, allowing greater upper thoracic expansion. In tall thin individuals their thoraces usually show corresponding proportions, and a similar correspondence also occurs in the short and broad. Racial variations are also linked to stature and proportions in a like manner.

The prime function of the thorax is respiration (p. 498). The obvious protection afforded is fortuitous but many muscles are attached to it, not all primarily concerned with respiration, although they may assist it. Muscles of the arm, especially those acting on its girdle and humerus, those of the abdominal wall and spinal column, all have widespread thoracic attachments.

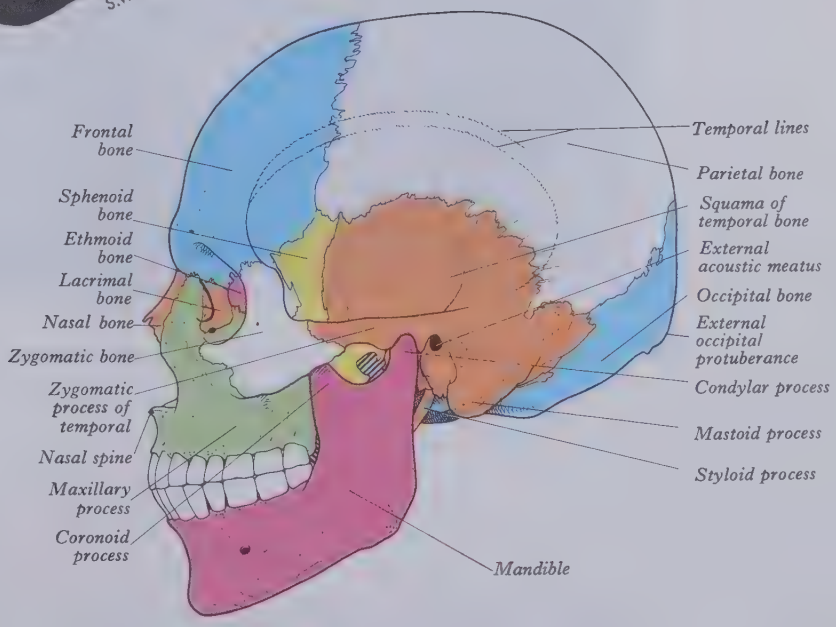
Elastic recoil of ribs, which suspend the sternum, may explain the rarity of sternal fractures. Despite their pliability, the ribs are much more frequently broken, middle ribs being most vulnerable. Since traumatic stress is usually due to compression of the thorax, the usual site of fracture is the rib's weakest point, just in front of the angle. Direct impact may fracture a rib anywhere and the broken ends of bone may be driven inwards, with possible injury to thoracic or upper abdominal viscera.

A *cervical rib*, the costal element of the seventh cervical vertebra, may be a mere epiphysis on its transverse process but more often has a head, neck and tubercle, with or without a shaft which, varying in length, extends anterolaterally into the posterior triangle of the neck, where it may end freely or join the first rib or costal cartilage, or even the sternum. It may be partly fibrous, but its effects are not related to the size of its osseous part. If it is long enough its relations are those of a first thoracic rib: the



brachial plexus (usually lower trunk) and subclavian vessels are *superior* and apt to suffer compression in a narrow angle between rib and scalenus anterior. Hence cervical ribs may first be revealed by nervous and vascular symptoms, particularly due to pressure on the eighth cervical and first thoracic spinal nerves, with motor and sensory effects in structures supplied. According to Cave (1975) a cervical rib or pleurapophysis may show synostosis or diarthrosis with either the anterior (parapophysial) or posterior (diapophysial) 'roots' of the so-called seventh cervical transverse process or, more usually, with both (**3**.57).

THE SKULL



Introduction

The vertebrate skull is the most modified part of the axial skeleton. Whatever truth may reside in the hypothesis that it is partly derived from metameric elements such as modified vertebrae, palaeontology and comparative anatomy clearly indicate that from earliest times it has been a skeletal complex adapted to support the brain and organs of special sense and to secure food. Siting of special receptors, tactile, chemical and visual, and a feeding orifice at the leading end of an elongate creature, such as a vertebrate, has advantages so obvious as to be overlooked. This concentration of functions is linked with elaboration of the fore end of the nervous system into a brain, whose size and dominance have inceased throughout vertebrate evolution. The very size of the human brain emphasizes the skull's *cerebral* function, overshadowing others. Even in this limited role the cranium cannot be considered merely protective. Sporadic protection of brain from external impacts is of undoubted value; need of a barrier against stresses due to play of powerful masticatory and axial musculature is less obvious but is continual. In addition to these extraneous forces, the rigid cranial walls provide continuous isolation for cerebral circulation. Moreover, the reputed buffering by meninges, subarachnoid space and contained fluid could only be effective within a rigid container.

The brain's extreme dependence on uninterrupted blood flow is well known; independence of cerebral arterial pressure from extracranial variations, due to some form of autoregulation as yet

3.89 The skull: left lateral aspect (Norma lateralis). Compare with Key in **3**.90; basic black line diagram is used; for greater detail see **3**.101; for muscle attachments see **3**.102.

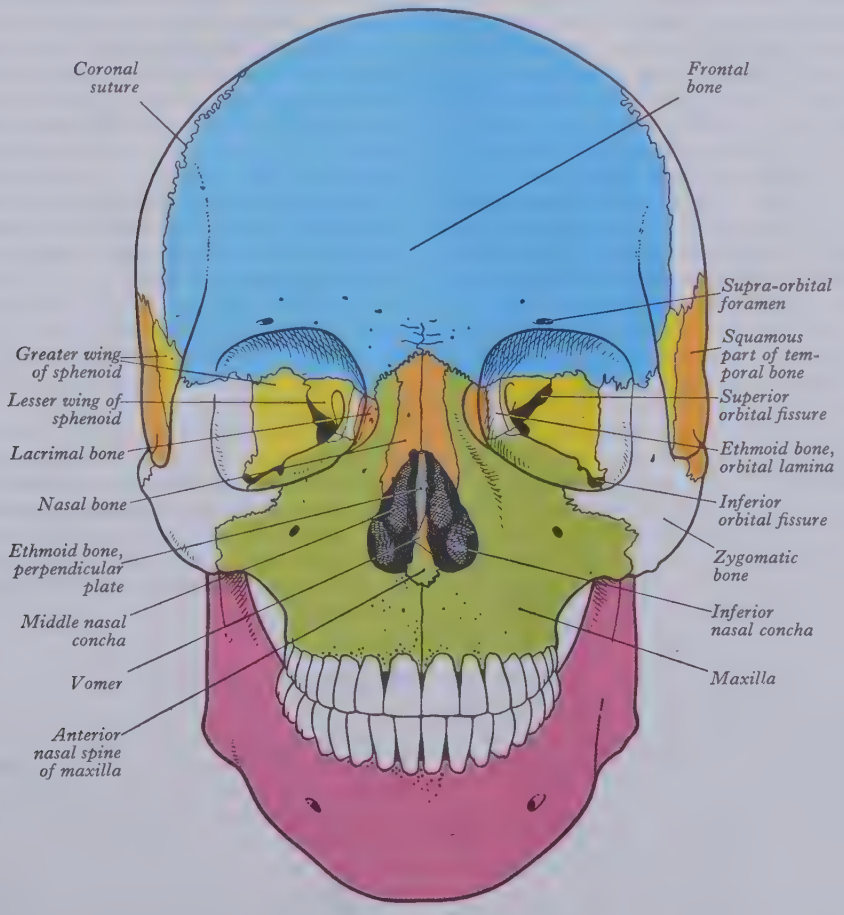
unidentified, is also established. It appears likely that siting of a brain in a rigidly maintained space is a factor in such mechanisms, despite lack of exact evidence. Of course, the cranial cavity is not closed: cerebrospinal fluid passes freely through the foramen magnum, displaceable in either direction. Even the brainstem can be displaced through the same orifice by raised intracranial pressure. Variability in volume of fluid in the cerebral ventricular system and numerous connections between intra- and extracranial veins add to the complexity of the situation. Nevertheless, it appears undeniable that enclosure of the brain in an otherwise invariable space must be a factor in control of cerebral circulation. This peculiar location of the brain entails some penalties, however well-adapted to ordinary circumstances: lesions which occupy space can raise pressure within the cranium far more easily than elsewhere and with far more devastating effects.

Even in primitive vertebrates the *neurocranium*, derived from cartilages ventral to brain, as in human embryos (p. 164), has been joined by cartilaginous supports for external nares and olfactory receptors, eyeballs and labyrinths. With the addition of jaws, of branchial origin, and dermal or 'membrane' bones, arising in subcutaneous mesenchyme over the head and jaws and in the buccal roof, the vertebrate skull is defined in all its complexity. Cartilaginous elements are usually ossified, except in minor groups such as sharks, where cartilage is considered degenerate rather than primitive. Moreover, some dermal elements are as ancient, judging by fossil records, as 'cartilage' bones, and may even have preceded them. It is misleading to regard cartilage as the primeval substance in this respect. Bone may arise by two major routes: by direct ossification in mesenchyme or indirectly in cartilage, itself derived from mesenchyme. Roof and sides of the neurocranium are developed in mesenchymal sheets, or membranes, in or subjacent to dermis; hence the terms 'membrane' or 'dermal' bone, the latter perhaps being more informative. Dermal parts of the cranial box are currently considered at least as primitive in origin as its chondrocranial base. In jaws, events appear more certain: primary cartilaginous elements, derived from the branchial apparatus, have been replaced by dermal bone.

The 'capsules', enclosing special sensory organs and integrated into the skull, are obviously protective but also confer less obvious but more basic advantages. Primitive nostrils in lower vertebrates are gustatory and olfactory; even when they lead into nasal cavities after development of a secondary palate in land vertebrates, olfactory function persists with new respiratory arrangements and both functions require open airways, whatever

sphincteric mechanisms are added. Circumocular skeletal elements have long provided sockets, more or less complete, containing not only eyeballs but also their muscles. The latter, in attachments to this optic 'capsule', have varied only in minor details since their appearance in earliest vertebrates—judging from extant forms. Their effects are largely rotatory, and it is difficult to envisage how such actions could be effective without a socket, which not only aids ocular location during rotation but also ensures stability of interocular distance, a necessary prelude to binocular vision.

The siting of labyrinths deep in cartilage or bone entails a fixed relationship between three semicircular canals; fusion of otic capsules into the cranial base determines the strict relation of all six canals both to each other and to the head itself, and without this no orderly correlation could evolve between these receptors and central nervous connections.



Axial muscles extending from the vertebral column to caudal aspects of the cranium have become more elaborate and massive in land animals with the development of necks and increasing problems of cranial suspension in quadrupeds. In all but jawless fishes (*Agnatha*, such as lampreys, a numerically insignificant class) the primitive skull is invaded by the ligamentous and muscular apparatus of the jaws, the maxillae being integrated into the skull at an early stage. These large muscles, both axial and mandibular, transmit strains to the skull which are sometimes very great and associated with extensive cranial modifications to resist and absorb stress. Even in humans, with modest masticatory and neck musculatures, the whole body can be suspended from the bite of the teeth. In other mammals, especially quadrupeds, greater relative size of jaws and weight of head lead to development of large plates, bars and buttresses, which owe little in origin to the protection which they fortuitously offer. A perfect example is the high cranial dome of elephants, which is associated with production of a large attachment for massive extensor muscles necessary to suspension of so heavy a head. Perhaps enough has now been said to emphasize the diversity of cranial function beyond its obvious protectiveness; exclusive emphasis upon protection, characteristic of anatomical texts, is purblind and belittles the skull's multifunctional adaptations.

General Cranial Features

The term *cranium* is sometimes reserved for the skull without its mandible but this strict usage is not adhered to here. Its upper part is a box enclosing the brain, often termed the *calvaria*, the remainder being the *facial skeleton*; its upper part is immovably fixed to the calvaria, the lower being the mobile mandible. The skull is clearly of greater practical interest, viewed as a whole, than its constituent bones. Nevertheless, the general positioning of these must first be considered (3.89A,B,90,91A,B,92A,B).

The skull may be viewed from above (*norma verticalis*), below (*norma basalis*), behind (*norma occipitalis*), the front (*norma frontalis*) and the side (*norma lateralis*). The calvarial roof or *calva* (skull cap) must be removed to examine its interior. In the erect attitude the lower margins of orbital openings and upper margins of external acoustic meatuses are near the same horizontal (Frankfurt plane), an important convention of orientation in description.

The forehead is formed by the *frontal bone* (3.89A,B,90,92A,B), passing back in the vault of the skull to the *coronal suture* to meet the anterior borders of the *parietal bones*, right and left, which form most of the cranial vault, articulating together at the median,

3.92B The skull: anterior aspect (Norma frontalis). Key to 3.92A. Blue = frontal bone; yellow = sphenoid bone; green = maxillae; brown = lacrimal, nasal, temporal bones and vomer; *magenta* = mandible; uncoloured = parietal, zygomatic and ethmoid bones.

serrated, *sagittal suture*. Posteriorly they meet the *occipital bone*, which forms the back of the skull (occiput). The suture between parietal and occipital bones is called *lambdoid*, after the Greek capital letter lambda, Λ, which it resembles in shape. Each parietal bone curves down as the side of the vault to the upper limit of the *greater wing* of the *sphenoid bone* in front, and the *squamous part* of the *temporal bone* behind. When the *calva* is removed, the saw cuts through the frontal and usually across the lower part of the parietal bones but may involve the temporal *squamae*; posteriorly the section cuts the occipital bone. The calva thus consists of a large part of the frontal bone, most of the two parietals, possibly small parts of temporal squamae and part of the occipital. When it is removed, the *calvarial floor or base of the skull* is revealed. It shows natural subdivision into three regions: anterior, middle and posterior *cranial fossae* (**3**.109A,B). These are considered in detail on pp. 361, 362, 364; here, as a preliminary, is a brief synopsis of their principal osseous boundaries.

The anterior cranial fossa, a little less than the base's anterior third, is limited behind by a sharp edge on each side. Note that it roofs the orbits and between them the nasal cavity. On each side an *orbital part* projects back from the *frontal bone* forming most of the orbital roof, these two plates being separated by a narrow interval occupied by a perforated strip, the *cribriform plate* of the *ethmoid bone*, forming much of the nasal roof; the rest of the ethmoid is in the lateral walls and septum of the nasal cavity. The cribriform plate bears a median *crista galli* on its upper surface. Posteriorly the floor of the anterior fossa is formed by parts of the *sphenoid bone*, the front of whose *body* meets the cribriform plate; on each side a narrow *lesser wing* projects laterally from it to the posterior margin of the orbital plate of the frontal, forming a sharp posterior border, the posterior limit of the floor of the anterior cranial fossa. These borders are adapted to the lateral cerebral fissures (p. 1023).

The middle cranial fossa (**3**.109A,B) immediately behind the anterior is of small median extent but expanded posteriolaterally on both sides. The narrow median region is formed by the sphenoid body and its cranial aspect presents a hollow for the hypophysis cerebri (pituitary gland). The lateral parts are formed by the *greater wings of the sphenoid* in front and the *petrous temporal bones* behind. Each greater wing curves from the side of the body in the base, then the side of the skull to the parietal's anteroinferior angle. Posterior to this the anterior surface of the petrous temporal bone continues laterally into the squama.

The posterior cranial fossa (**3**.109A,B), almost circular and occupying about two-fifths of the cranial base, is largely *occipital bone*. Through its large *foramen magnum* the brainstem and spinal cord are continuous. The anterior region is the *basilar part* of the occipital bone, fused in front with the body of the sphenoid. On each side the fossa is formed by the posterior surface of the petrous temporal bone above and *lateral (condylar) part* of the occipital bone below. The temporal's *mastoid part*, posterolateral to the petrous, joins the occipital squama to complete the fossa.

In frontal view (*norma frontalis*) **3**.92A,B,95) the *orbits* and *anterior nasal aperture* are apparent. Inferiorly is the *mandibular body*; above this are the *maxillae*, or upper jaws, separated by the teeth. The maxillae form much of the buccal roof and the inferolateral margin of the anterior nasal aperture; each forms the inferomedial orbital margin (completed laterally by the zygomatic bone) and a *frontal process* ascends to the frontal in the medial orbital margin. Between the bilateral maxillary frontal processes are two *nasal bones*, the upper boundary of the nasal aperture.

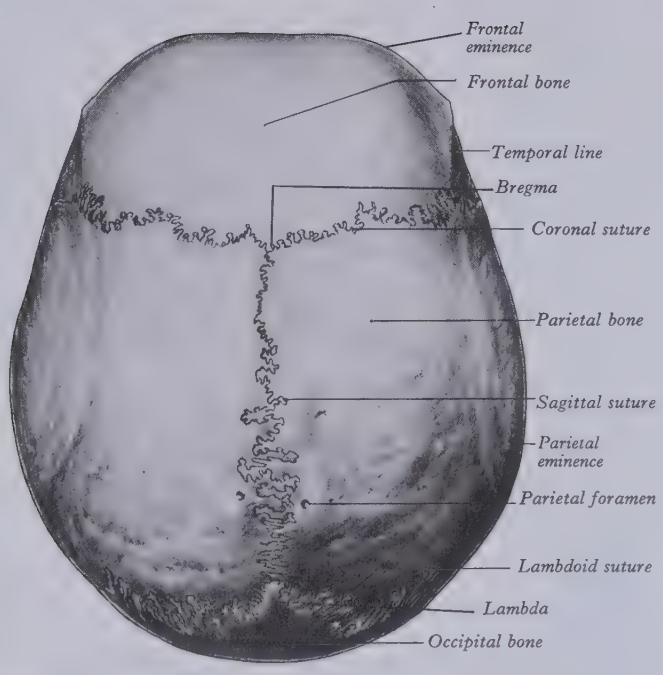
In lateral view (*norma lateralis*) (**3**.89A,B,91) the *mandibular ramus* ascends from the posterior end of its body to the cranial base. The *mandibular head*, surmounting the posterior border of the ramus, fits the *articular fossa* on the inferior aspect of the temporal squama. It is separated from the *external acoustic meatus* by the temporal *tympanic plate*. Anterosuperior to the meatus the temporal *zygomatic process* reaches to the zygomatic bone, forming the *zygomatic arch*, or *zygoma*, separated widely from the side of the skull. The *zygomatic bone* forms the prominence of the cheek and inferolateral orbital margin, ascending in the lateral orbital margin to the frontal bone.

With mandible removed (**3**.103A,B,C) it is easier to see behind the maxilla, the *pterygoid process* projecting down from the sphenoid at the root of its greater wing as a large *lateral pterygoid plate* reaching dental level, and a smaller *medial plate* ending as a hamulus. The plates are walls of the *pterygoid fossa*.

The inferior cranial aspect (*norma basalis*) (**3**.103A,B,104A,B), the exterior of its base, shows posteriorly the *occipital bone* and foramen magnum, lateral to which the occipital articulates with *mastoid parts* of the temporal bones and anterolaterally with their *petrous parts*, extending forwards almost to the roots of the pterygoid processes. Anteriorly the *osseous palate*, part of the buccal roof, lies within the maxillary dental arch; both maxillae and palatine bones contribute to it, its anterior three-fourths formed by maxillary *palatine processes*, meeting in the midline, the posterior fourth by palatine *horizontal plates*. The *perpendicular palatine plates* ascend from the horizontal plates as parts of the lateral nasal walls.

The *lacrimal bones*, anterior in the medial orbital walls, the *vomer*, a large part of the nasal septum, and the *inferior conchae*, in the lateral nasal walls, can be seen effectively when orbits and nose are examined (pp. 346, 365).

THE EXTERIOR OF THE SKULL



Norma Verticalis

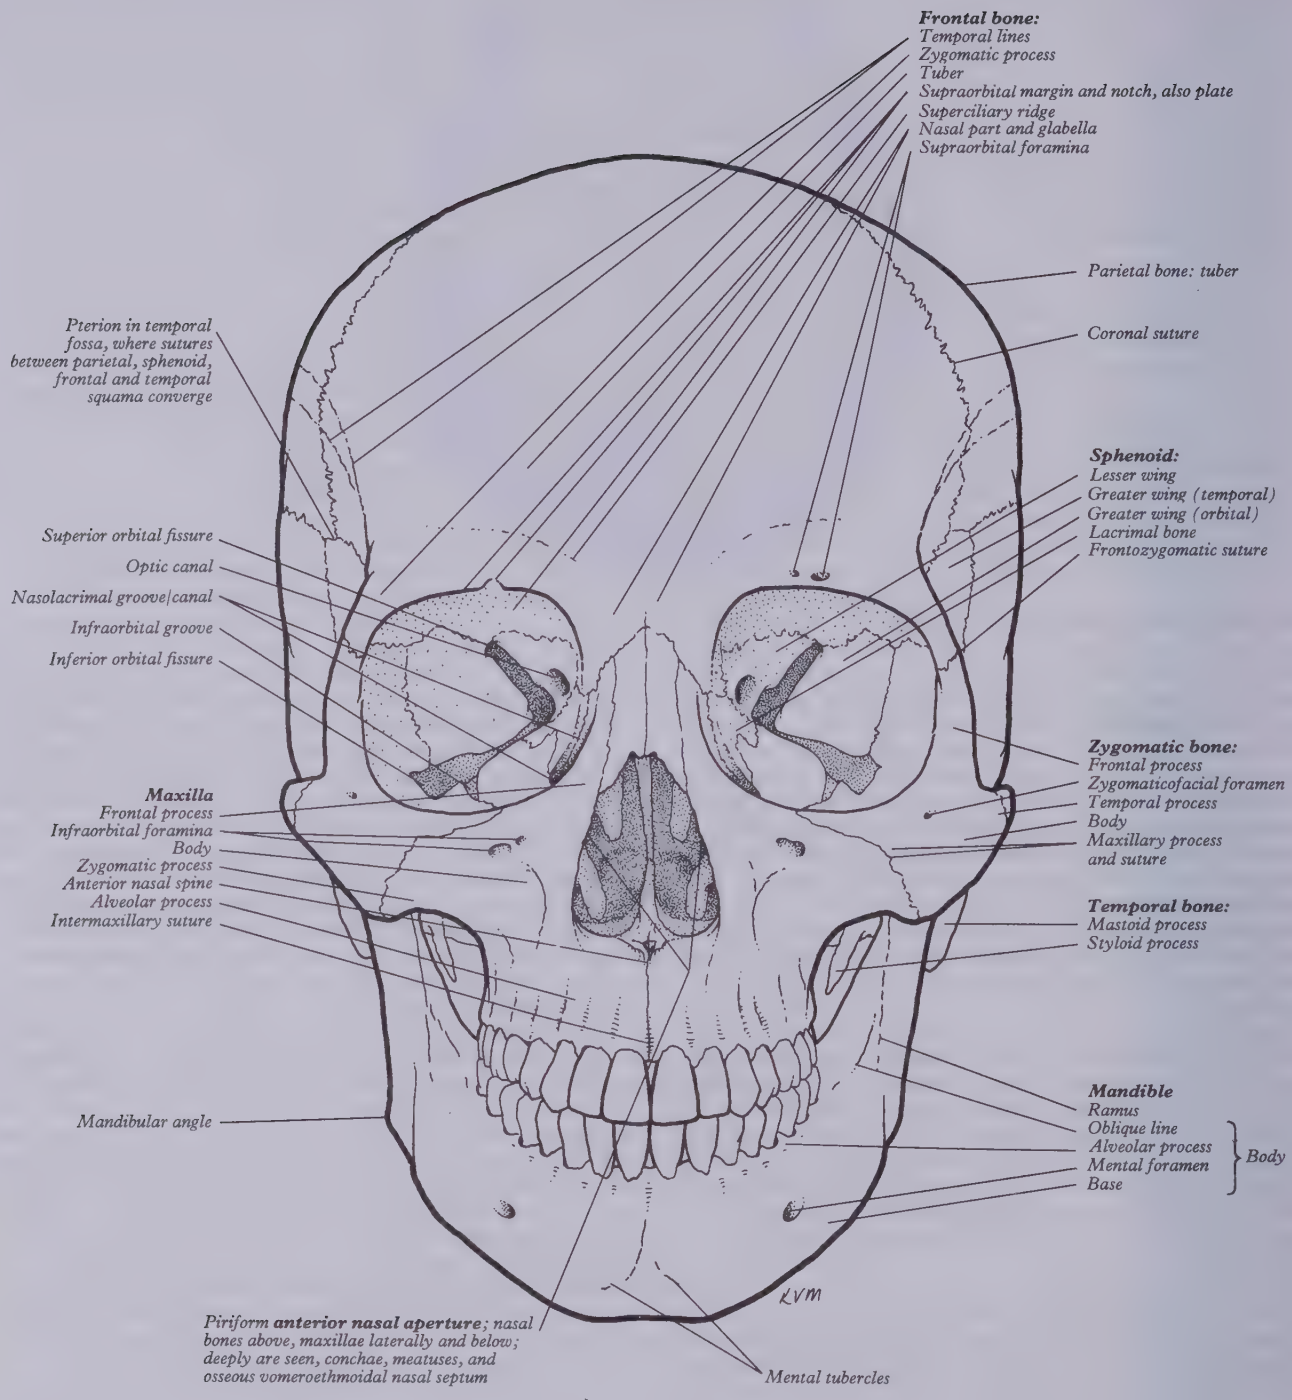
Seen from above (**3**.93), cranial contour varies greatly but is usually ellipsoid (strictly, a modified ovoid), its greatest width nearer to its occipital pole; it displays three sutures: (1) the *coronal suture* is the junction of posterior frontal margin with anterior borders of the parietal bones, descending around and forwards across the cranial vault; (2) the *sagittal suture* is median between the interlocking medial parietal borders; (3) the *lambdoid suture* joins posterior parietal borders to the superior occipital margin, descending laterally and across the cranial vault. The coronal and sagittal sutures meet at the *bregma* and in the fetal skull (together with the temporary interfrontal suture) they form the boundaries of a diamond-shaped membrane-filled *anterior fontanelle* (p. 393). The latter persists until about 18 months after birth. The *lambda* is at the junction of sagittal and lambdoid sutures, the site of a similar *posterior fontanelle* (p. 393) which closes more rapidly.

Maximal parietal convexity is the palpable *parietal tuber (eminence)*, on each side, where norma verticalis passes into norma lateralis and occipitalis without distinct demarcation. A *parietal foramen*, often absent, pierces each parietal bone near the sagittal suture about 3.5 cm anterior to the lambda. It transmits a small emissary vein from the superior sagittal sinus. An incidence of about 40–60% (in different races) is ascribed to this foramen (p. 331). Anteriorly the norma verticalis slopes into norma frontalis.

Norma Frontalis

From the front (**3**.92A,B,93,95) the skull appears roughly oval, wider and smooth above in its frontal region, but below this irregular and interrupted by the orbits and anterior nasal aperture. Superomedial to each orbit is a rounded *superciliary arch*, better marked in males, and between the two is a median elevation, the *glabella*, below which, where nasal bones meet frontal, is a depression at the root of the nose. The junction of internasal and frontonasal sutures is the *nasion*. Above each arch is a slightly elevated *frontal tuber* or tuberosity. These features are palpable and useful to both surgeon and anthropologist.

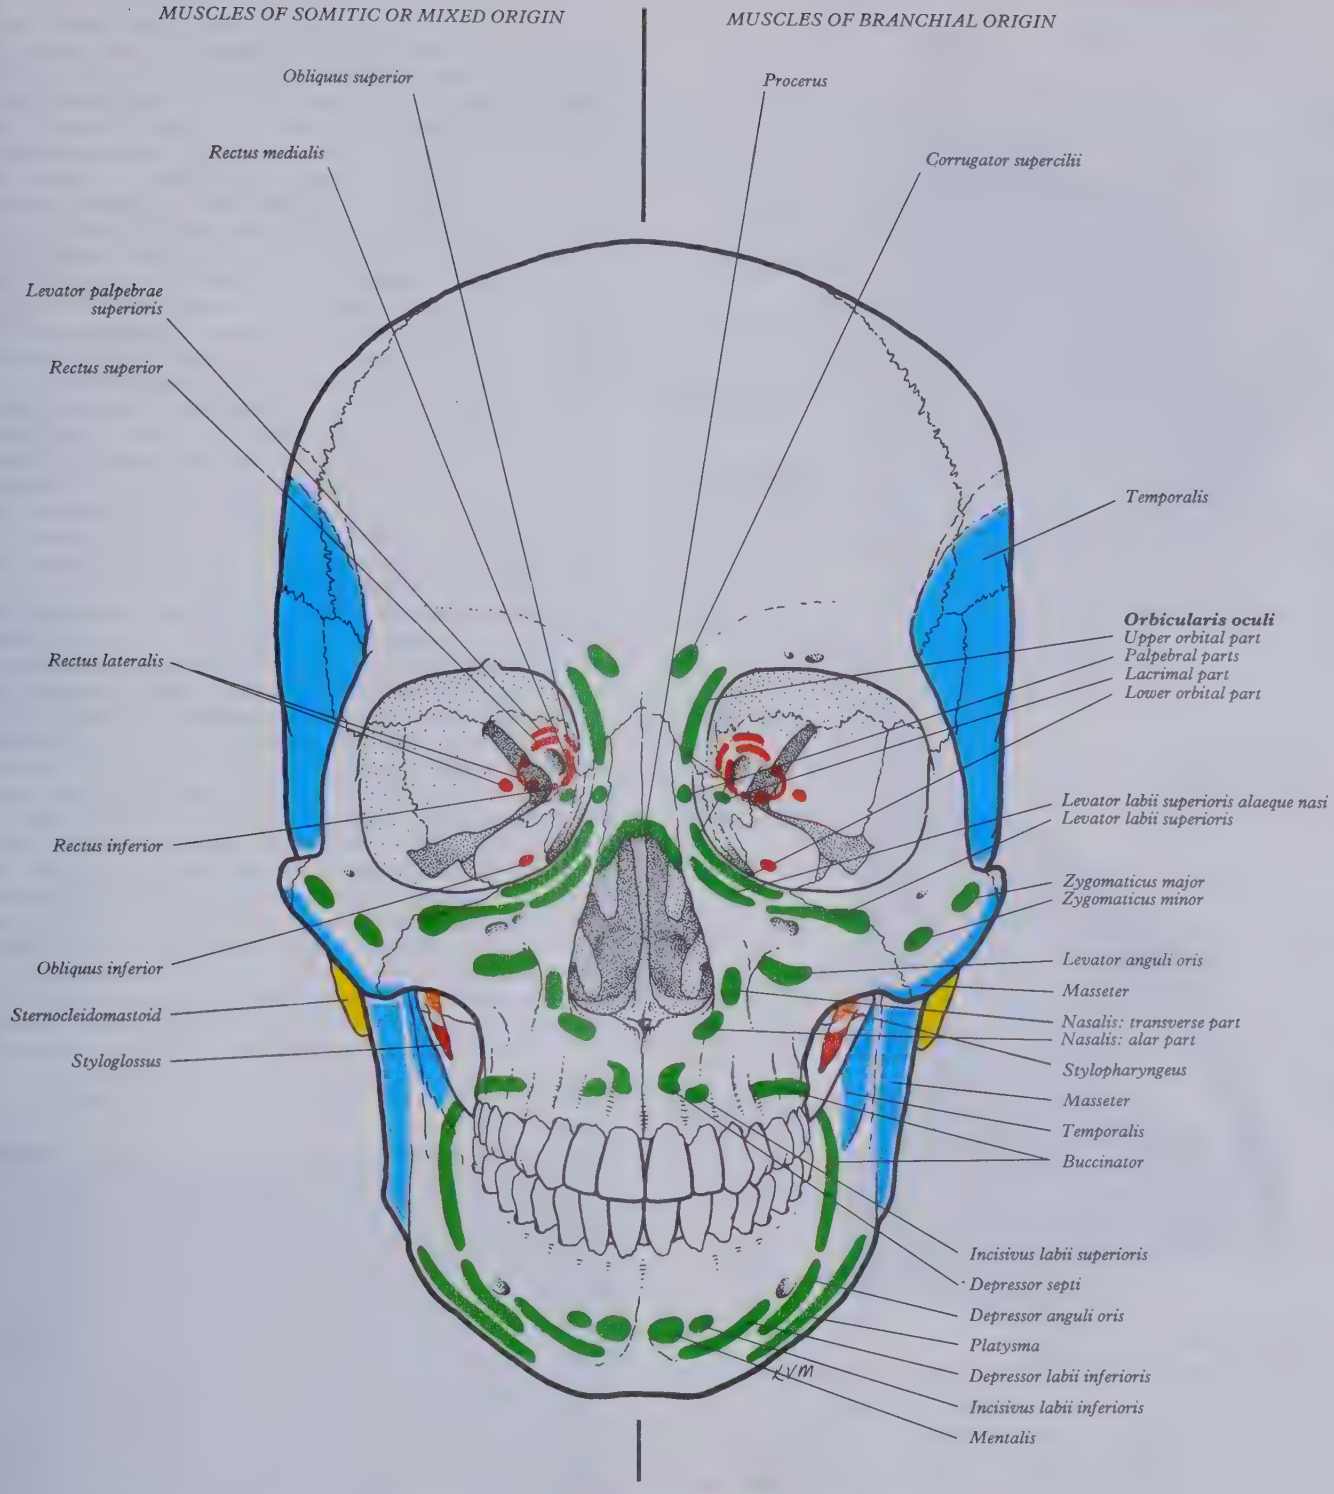
3.93 The skull; superior aspect (Norma verticalis).



The orbital opening is somewhat quadrangular, its *supraorbital margin* formed entirely by the frontal bone, interrupted at the junction of its sharp lateral two-thirds and rounded medial third by the supraorbital notch (or foramen), which transmits the supraorbital vessels and nerve. The *lateral margin* is largely the frontal process of the zygomatic bone, completed above by the zygomatic process of the frontal bone; the suture between them is a palpable depression. The zygomatic bone laterally and maxilla medially form the *infraorbital margin*. Both these margins are sharp and palpable. The *medial margin*, not so obvious, is formed above by the frontal bone, below by the lacrimal crest of the maxillary frontal process, sharp and distinct only in its lower half.

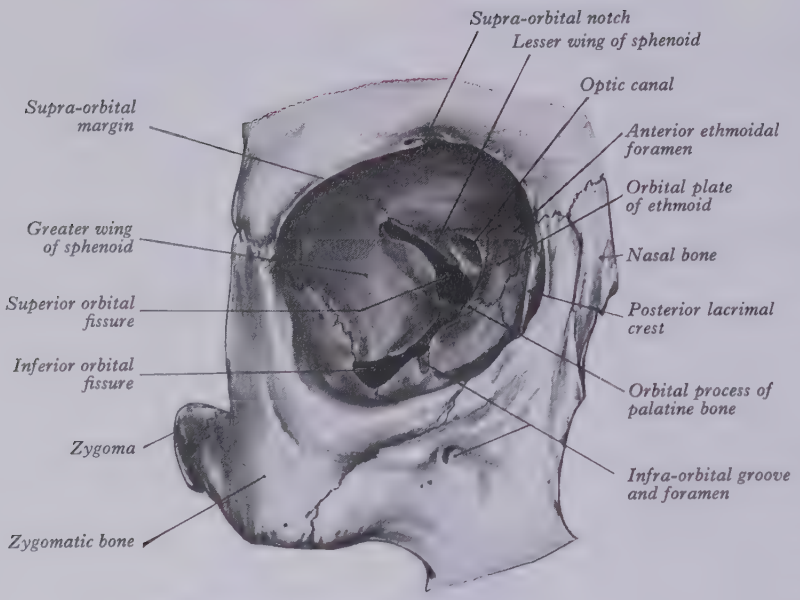
The anterior nasal aperture is piriform, wider below, and bounded by nasal bones and maxillae; these articulate with each other, with their contralateral fellows and with the frontal bone above. Each nasal bone articulates behind with a maxillary frontal process; its lower border, to which the lateral nasal cartilage is attached, is the upper boundary of the nasal aperture (**3**.92A,B). The nasal cavities are, of course, *bilateral*; a *single* anterior nasal aperture presents in the macerated skull because various cartilages (septal, lateral nasal, major and minor alar) are lost during preparation.

The maxillae predominate in the facial skeleton, and their growth elongates the face between six and 12 years. Only the anterior surface is visible in norma frontalis, with a medial well-marked *nasal notch* (the lower and partly lateral border of the nasal aperture). The prominent *anterior nasal spine* marks the intermaxillary junction in the aperture's lower boundary. It is palpable in the nasal septum. About 1 cm below the infraorbital margin is the *infraorbital foramen*, for infraorbital vessels and nerve; it is on or near a vertical through the supraorbital notch. The maxillary *alveolar process* contains sockets for upper teeth, best seen in basal view (p. 389). The short, thick *zygomatic process* from the superolateral region of the anterior surface has an oblique upper surface forming, with the zygomatic bone, a zygomaticomaxillary suture. The inferior border of the process meets the body above the first molar tooth and is palpable through cheek or buccal vestibule. The maxillary *frontal process* ascends posterolateral to the nasal bone to reach the frontal.



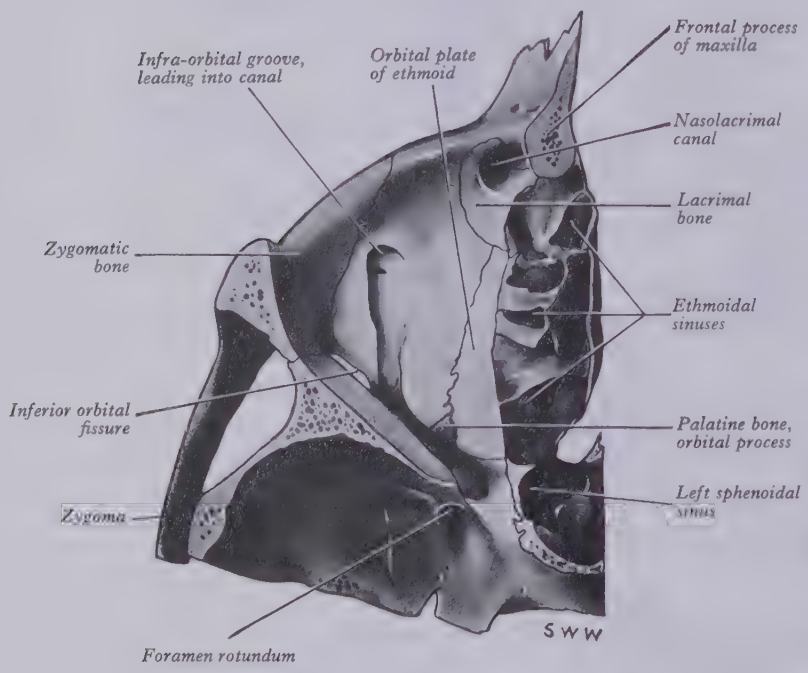
The *glabella* may show remains of the interfrontal suture, which ascends in about 9% of skulls to the coronal, indicating the frontal bone's formation by fusion of two halves, ossifying independently. To the medial part of the *superciliary arch* corrugator supercilii is attached; to the nasal part of the frontal bone and frontal process of the maxilla, the orbital part of orbicularis oculi. Between these the medial palpebral ligament is attached to the maxillary frontal process (**3**.95), and procerus to the nasal bone near the midline. The lower margin of the nasal bone usually bears a small notch, converted by the lateral nasal cartilage into a foramen for the external nasal nerve. In front of orbicularis oculi the levator labii superioris alaeque nasi is attached to the maxillary frontal process and, more laterally, levator labii superioris to the maxilla between infraorbital margin and foramen.

Norma Frontalis



3.94 (*above*) The skull: anterior aspect (Norma frontalis).

3.95 (*opposite*) The skull: anterior aspect (norma frontalis) showing muscle attachments, colour coded to indicate embryological origin and innervation. Refer to table; roman numerals indicate which cranial nerve is involved. For spinal nerve sources consult individual muscles and peripheral nerves.



COLOUR CODING OF ATTACHMENTS OF MUSCLE GROUPS BASED ON DERIVATION AND INNERVATION

Caudal arches & unsplit postbranchial lateral plate mesoderm (Nvs. X+XI complex)			*Cervical or cervicothoracic somites (Corresponding spinal Nvs.)*

3.96 The right orbit: anterior aspect.

3.97 Horizontal section through the left orbit and nasal cavity viewed from above.

A *canine eminence*, due to the tooth's large root, appears between the lateral *canine* and medial *incisive fossae*. Levator anguli oris is attached in the canine fossa whilst, to the surface bordering the nasal notch, nasalis and depressor septi and below them the incisive muscle gain attachment.

In the zygomatic bone, near the junction of inferior and lateral orbital margins, is a small *zygomaticofacial foramen* (3.99B, 164), sometimes duplicated, for the so-named nerve and artery; below the foramen are attached zygomaticus minor and, more laterally, zygomaticus major. The foramen was absent in 12–30% of different populations in a series of 580 crania (p. 396).

The Orbital Cavity

The orbits (3.96,97,99A,B) contain the eyes, associated muscles, vessels and nerves, lacrimal apparatus, fascial strata and soft fat. Each is pyramidal, with a base at the orbital opening and a long, posteromedially directed axis. It has a roof, floor, medial and lateral walls, a base and apex.

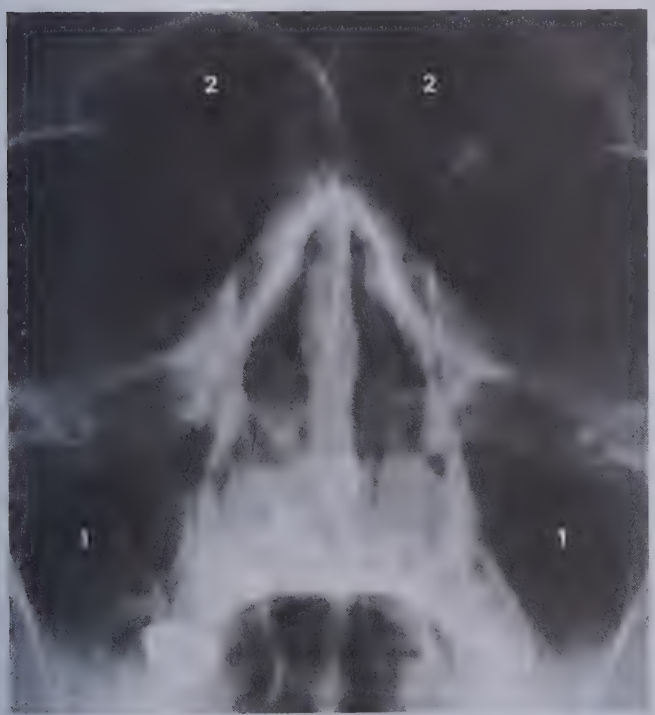
The superior wall or roof is a thin, frontal plate, gently concave on its orbital aspect which lies largely between orbital contents and brain in the anterior cranial fossa. Anteromedially it is bilaminated by the frontal sinus (q.v.); here it presents the *trochlear fovea* or spine where the annular pulley for obliquus oculi superior is attached (p. 383, 1208). Anterolaterally is a deep *lacrimal fossa* for the lacrimal gland's orbital part. Posteriorly, at the junction of its roof and medial wall, the *optic canal or foramen* connects orbit to the middle cranial fossa and transmits the optic nerve and ophthalmic artery. Near superior, medial and lower margins of the orbital opening of the canal the *common tendinous ring* of the four recti is attached to bone (7.329).

The medial wall (3.99A) is exceedingly thin except posteriorly and curves inferolaterally into the floor. Anterior is the vertical *lacrimal groove* for the lacrimal sac, opening below into the nasal cavity via the laterally inclining *nasolacrimal canal*, little more than 1 cm long. The floor of the groove separates orbital and nasal cavities, but more posteriorly ethmoidal sinuses intervene. The medial wall is related most posteriorly to the anterior region of the sphenoidal sinus, forming its lateral wall.

The inferior wall or floor (3.97) is thin and largely roofs the maxillary sinus (3.99A,B). Not quite horizontal, it ascends a little laterally. Anteriorly it curves into the lateral wall; posteriorly they are separated by the *inferior orbital fissure*, connecting the orbit posteriorly to the pterygopalatine fossa, and more anteriorly to the infratemporal fossa. The maxillary nerve traverses the fissure, whose medial lip is notched by the *infra-orbital groove*, passing forwards and sinking into the floor to become the *infra-orbital canal*, opening at an *infra-orbital foramen*. Groove, canal and foramen contain the infra-orbital nerve. The inferior orbital fissure transmits a connection between inferior ophthalmic vein and pterygoid plexus in the infratemporal fossa. The infra-orbital foramen is sometimes double, even multiple (Harris 1933), *accessory* foramina being usually smaller and recorded at incidences of 2–18% in various populations (p. 396).

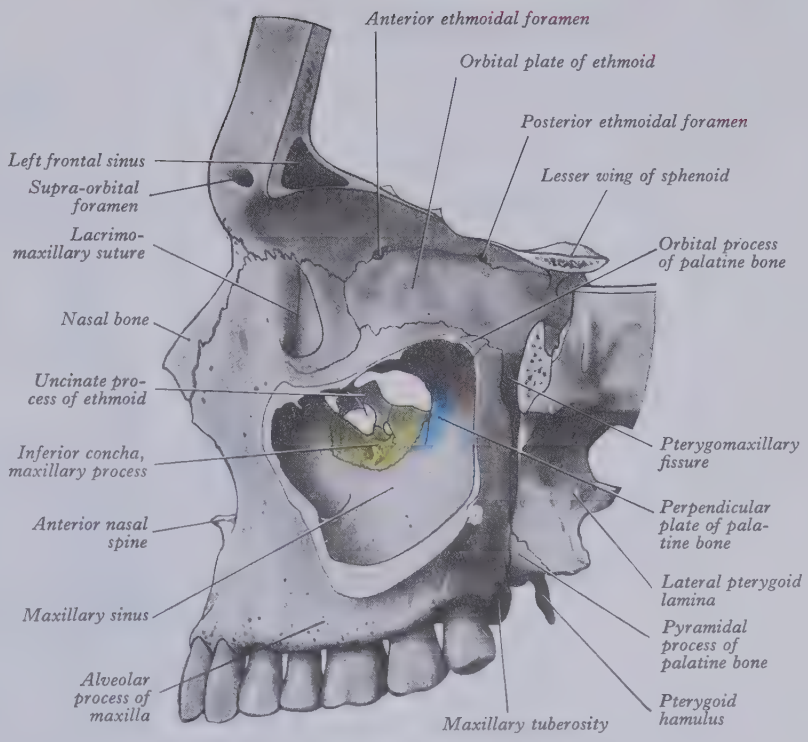
The lateral wall (3.99B) is thickest, especially posteriorly where it separates the orbit from the middle cranial fossa. Anteriorly it separates the orbit and temporal fossa. Lateral wall and roof are continuous anteriorly but separated posteriorly by the *superior orbital fissure*, tapering laterally but widened at its medial end (3.96), its long axis descending posteromedially. It communicates with the middle cranial fossa and transmits the oculomotor, trochlear and abducent nerves, branches of the ophthalmic nerve and the ophthalmic veins. Where the fissure begins to widen, its inferolateral edge shows a projection, often a spine, for the lateral attachment of the annular tendon (p. 7.329). Royle (1973) has described an *'infra-orbital' sulcus*, in 22 of 64 orbits, from the superolateral end of the superior orbital fissure towards the orbital floor, associated sometimes with an anastomosis between the middle meningeal and infra-orbital arteries; this feature has been confirmed in 45% of 100 orbits by Santo Neto et al (1984).

The boundaries of the *orbital opening* have already been described (p. 343). The *apex* of the orbit is near the medial end of the superior orbital fissure. Further details of the orbital walls are appended here.



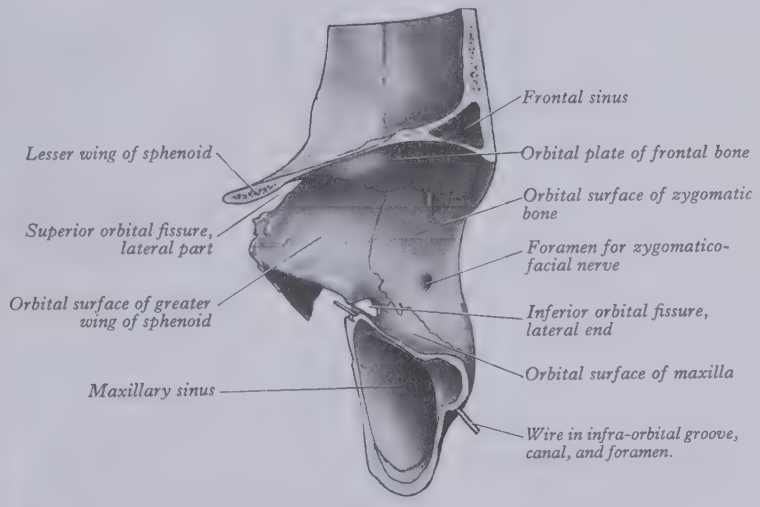
The roof, almost entirely frontal orbital plate, includes posteriorly a part of the inferior aspect of the lesser sphenoidal wing. The suture between these is almost horizontal. The *optic canal* is between the roots of the lesser wing, bounded medially by the sphenoid body. As noted, near the junction of roof and medial wall, close to the orbital opening, a *trochlear fovea* or *spine* marks attachment of the fibrous loop for the superior oblique's tendon.

To the medial wall (3.99A), limited in front by the *anterior lacrimal crest* on the maxilla's frontal process, orbicularis oculi and lacrimal fascia are attached. Behind this crest is a maxillolacrimal suture in the *lacrimal groove's* floor. The *nasolacrimal canal's upper opening* is completed laterally by the *lacrimal hamulus*, curving anteromedially to the lower part of the anterior lacrimal crest. To the groove's *posterior lacrimal crest* (mostly lacrimal bone) are attached the lacrimal part of orbicularis oculi (p. 571) and lacrimal fascia, bridging the groove. Posteriorly



the lacrimal's orbital surface is flat and articulates by a vertical suture with the the ethmoid labyrinth's orbital plate. The fronto-lacrimal and lacrimomaxillary sutures limit the medial wall in front; the ethmoid *orbital plate* contributes most to it. Almost rectangular, it is very thin, forming lateral walls to ethmoidal sinuses. Above, it articulates with the medial edge of the frontal orbital plate at a suture interrupted by *anterior* and *posterior ethmoidal foramina*, whose canals transmit their vessels and nerves (the posterior is often absent); they lead into the anterior cranial fossa at the lateral edge of the cribriform plate. Below, the ethmoid plate articulates with the medial edge of the maxilla's orbital surface and posteriorly with the palatine orbital process. Posteriorly it articulates with the sphenoid's body which forms the orbit's medial wall posteriorly, separated from the orbital roof by the optic canal. Analysis of racial and sexual variation in position and incidence of ethmoidal canals in 580 crania from several populations (p. 396), showed the anterior foramen lay outside the fronto-ethmoidal suture in 10–20% of several modern races and 62% out of 53 Peruvian crania.

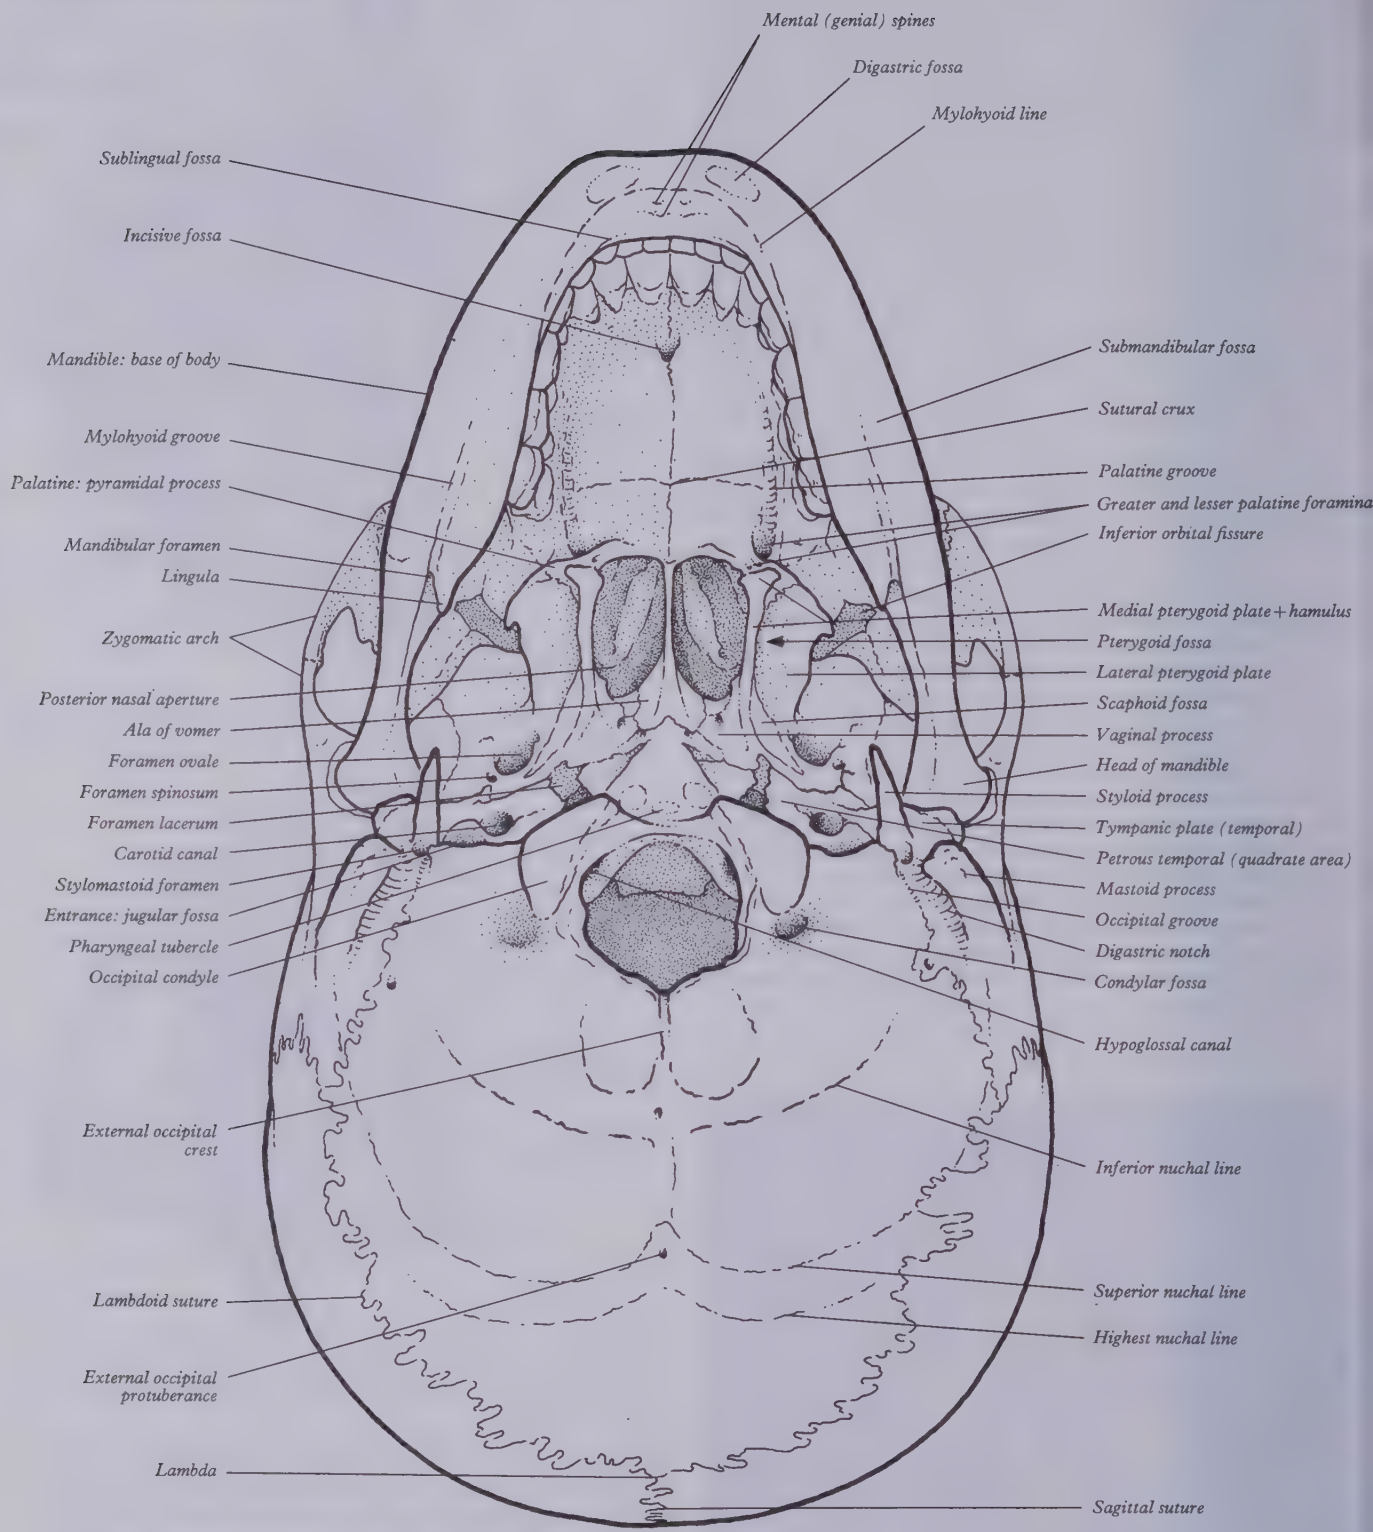
The floor of the orbit (3.97), mostly formed by maxilla and zygomatic bone anterolaterally, contains posteromedially, adjoining the medial wall, a triangular area from the palatine orbital process. The *inferior orbital fissure* transmits the maxillary nerve, infra-orbital vessels, zygomatic nerve and rami of the pterygopalatine ganglion; it is bounded above by the greater sphenoidal wing, below by the maxilla and the palatine orbital process and laterally by the zygomatic bone or zygomaticomaxillary suture. In 35–40% of skulls, maxilla and sphenoid meet at the fissure's anterior end, excluding the zygomatic. Anteromedially, lateral to the lacrimal hamulus, a small maxillary depression may mark the attachment of the inferior oblique muscle.



The lateral wall (3.99B) is formed by orbital surfaces of the greater sphenoidal wing and anteriorly by the zygomatic bone's frontal process, meeting at the sphenozygomatic suture. This zygomatic surface has openings of minute canals for zygomatico-facial and zygomaticotemporal nerves, the former near the junction of floor and lateral wall, the latter at a slightly higher level, sometimes near the suture. The *superior orbital fissure* lies between the greater wing (below) and lesser wing (above) of the sphenoid, its body being medial. For contents see p. 346 and 7.347.

3.98 Radiograph of adult skull: frontal view. 1. Maxillary sinus. 2. Frontal sinus. Both infra-orbital canals are shown.

3.99A Oblique parasagittal section through the anterior part of the skull, showing the medial wall of the left orbit and the medial wall of the left maxillary sinus.



3.99B The lateral wall of the left orbit, viewed from the medial side. Compare with 3.99A, which represents the opposite part of the same section of the skull.

Norma Occipitalis

The skull's posterior aspect is convex above and laterally flatter below. The *lambdoid suture*, entirely visible, is deeply serrated but less so inferolaterally. Inferiorly it meets *occipitomastoid* and *parietomastoid sutures* at the posteroinferior parietal angle (3.89,90). Sutural bones are common at the *lambda* (meeting of lambdoid and sagittal sutures) and along the lambdoid suture (pp. 373, 386). The main feature is the *external occipital protuberance* (3.89) and associated ridges. This is median and may overhang, being easily palpable at the upper end of the median posterior nuchal furrow. The *superior nuchal lines*, often sharp, pass laterally from the protuberance at the junction of scalp and neck; the

Norma Occipitalis

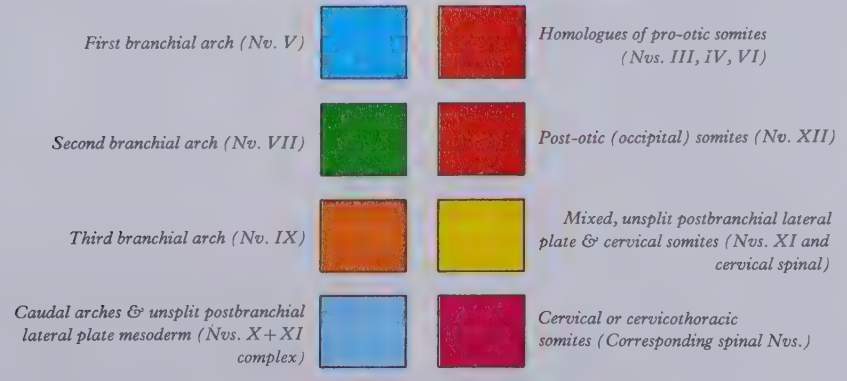
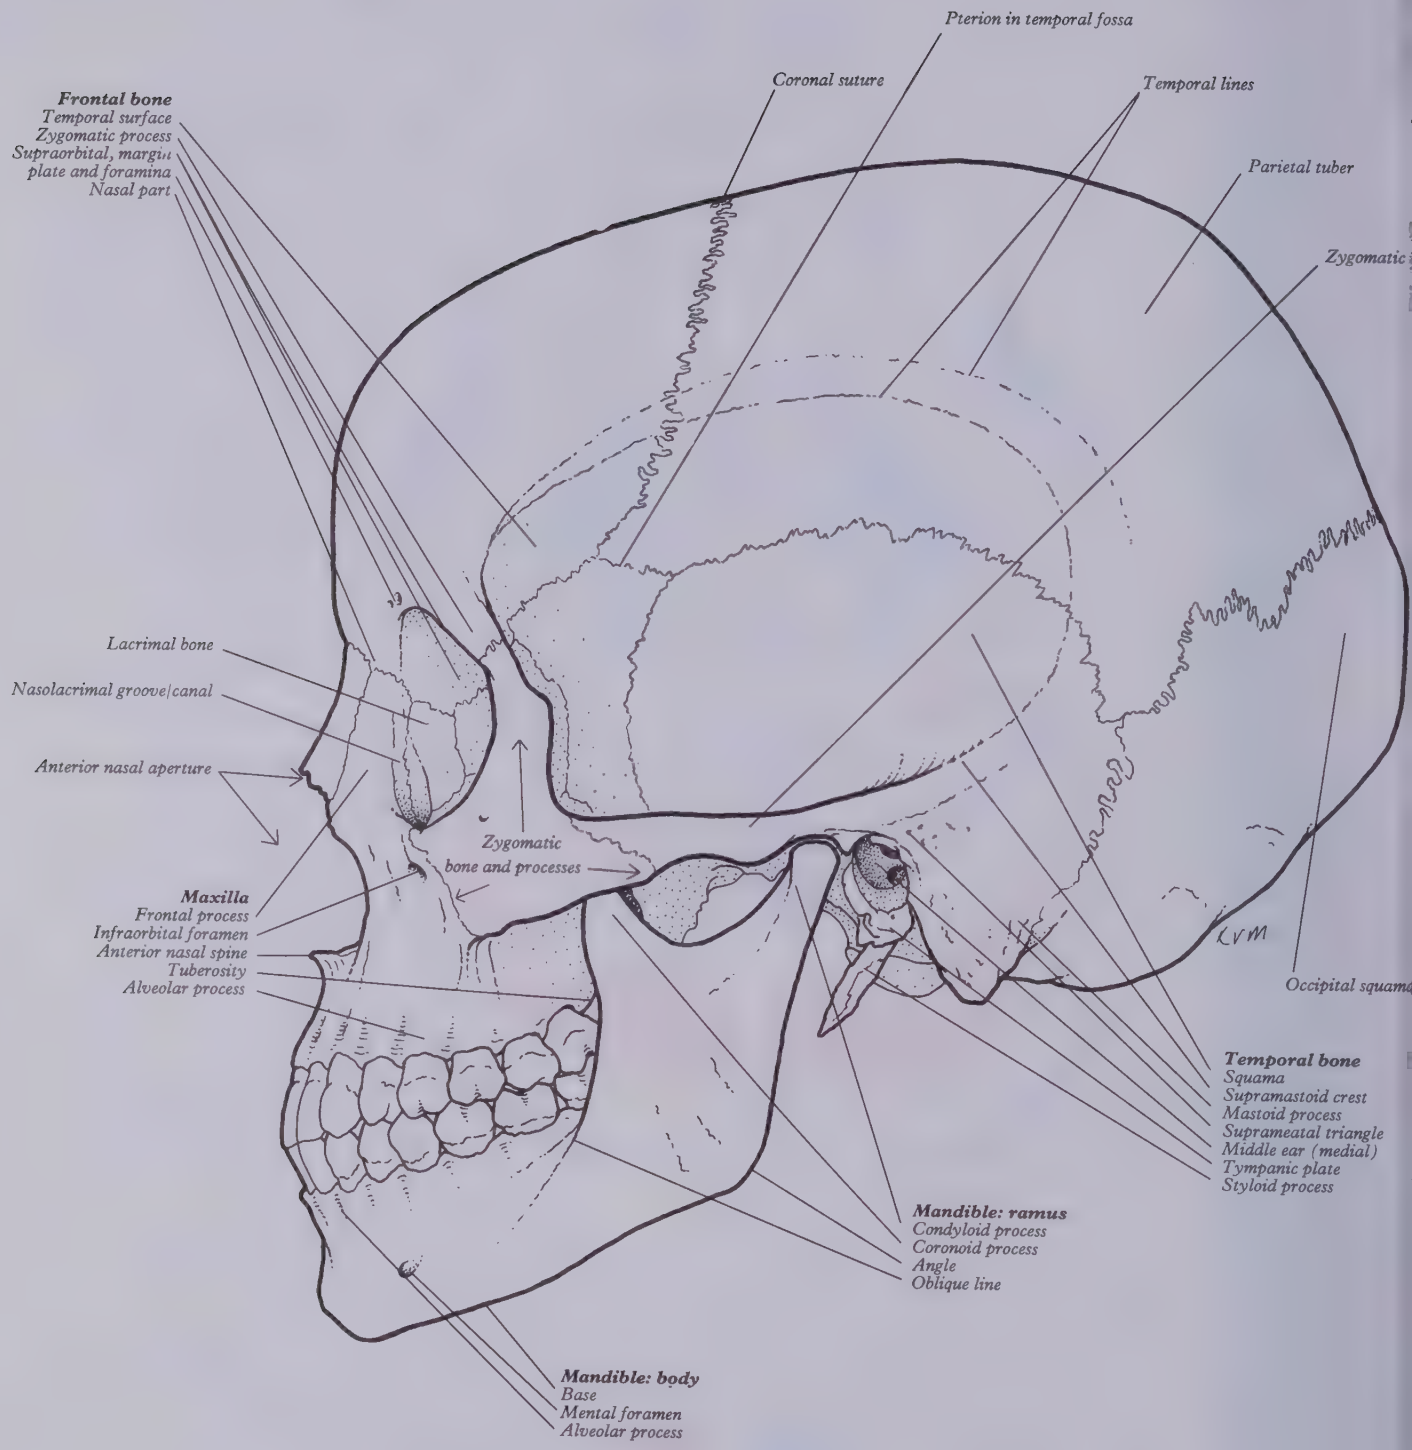
3.100B (*opposite*) The skull: norma occipitalis and norma basalis with the mandible in situ showing muscle attachments.



occipital region below them appears foreshortened and is seen better in norma basalis. The *highest nuchal lines*, when present, curve laterally from the protuberance, about 1 cm above the superior, and are more arched. In various ethnic groups their incidence varies from 3.6 to 40% (p. 395).

(Temporomastoid regions are inferolateral and examined more satisfactorily in norma lateralis, vide infra.)



The *inion* is the summit of the external occipital protuberance, to whose lower part are attached the ligamentum nuchae and to its upper part, fibres of trapezius. The latter fibres spread to the *superior nuchal line*, to which laterally (**3**.104B,123) are attached posterior fibres of sternocleidomastoid and, below this, splenius capitis. To the *highest nuchal line* are attached the galea aponeurotica and laterally the occipital belly of occipitofrontalis.

Norma Lateralis

Much of the side of the skull (3.89,90,101,102) has already been described from other aspects, but not its central features. Above is the *temporal line*, arching up and back from the frontal's zygomatic process across the coronal suture to the parietal bone. Salient and palpable in front, it is less distinct on the parietal and usually becomes *two curved ridges*, enclosing a smooth strip. Posteriorly the superior line fades away, but the inferior again becomes more prominent as it curves down across the temporal squama above the mastoid process, where, as the *supramastoid crest*, it continues into the processes forming the zygomatic arch. The temporal line marks the periphery of the temporalis muscle and its fascia, the muscle attachment being limited by its inferior ridge, the temporal fascia by the superior ridge.

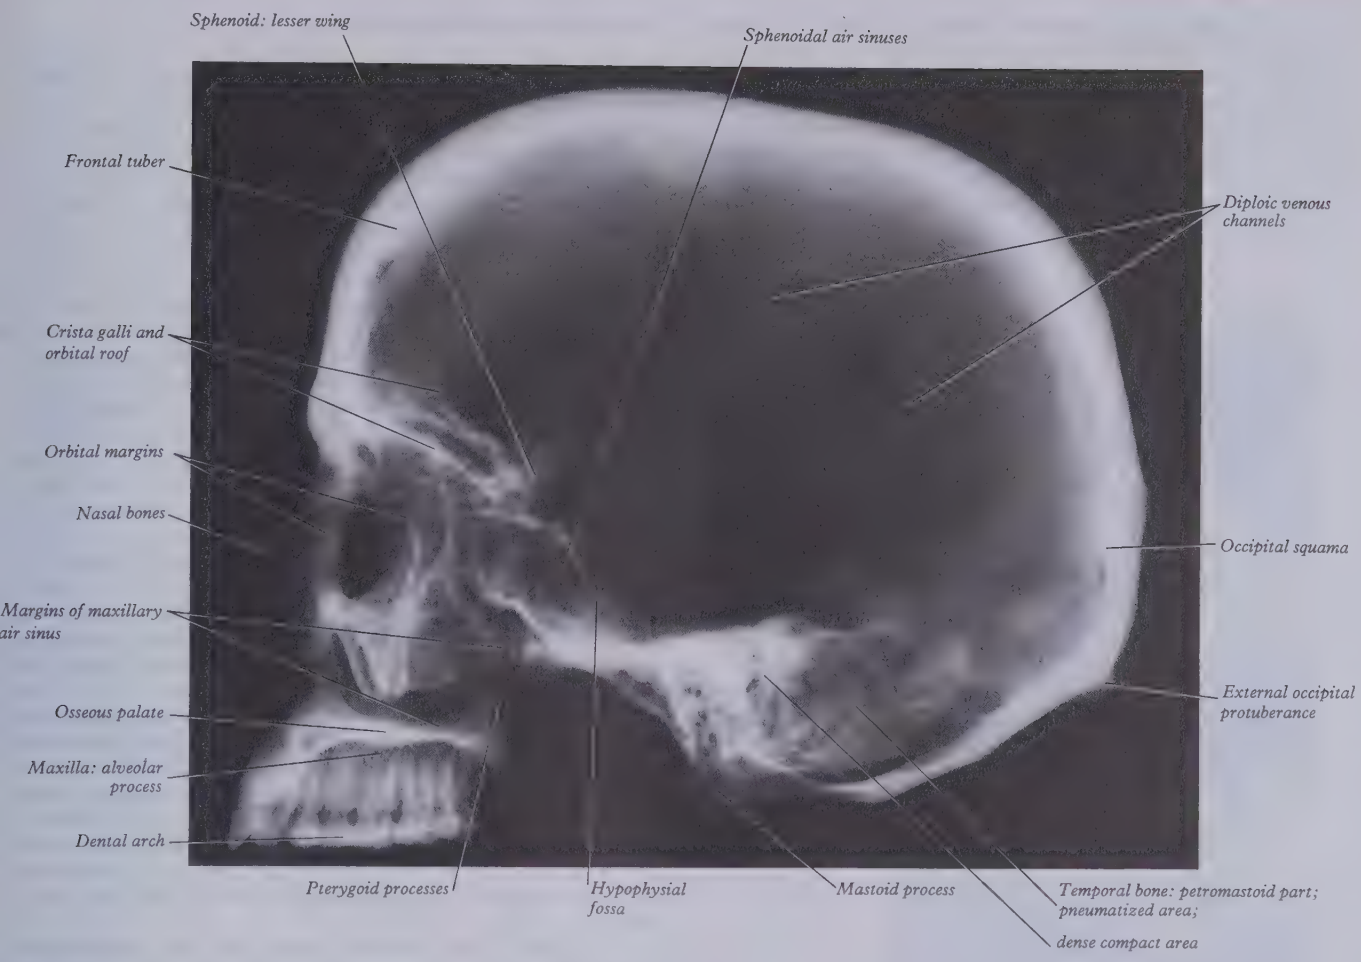
The temporal fossa is delineated by the zygomatic arch, temporal line, frontozygomatic processes and supramastoid crest; to its floor temporalis is attached. An irregularly H-shaped meeting of sutures in the fossa has as a horizontal limb the suture between the antero-inferior parietal angle and the apical border of the greater sphenoid wing. The frontal, sphenoid, parietal and temporal squama are here all close together (3.89A): a small circular area includes parts of all four and is termed the **pterion**, whose centre, an important surgical landmark, is on average 4.0 cm above the zygomatic arch and 3.5 cm behind the frontozygomatic suture (3.89A). It marks the anterior middle meningeal arterial ramus and the axial position of the lesser wing of the sphenoid; the latter is lodged in the stem of the lateral (Sylvian) cerebral fissure. Hence the term *Sylvian point*. The fossa's anterior wall is the temporal surface of the zygomatic bone, adjoining part of the greater sphenoid wing and a small area of frontal bone. These structures separate the fossa from the orbit; inferiorly the fossa merges with the infratemporal fossa between zygomatic arch and cranial wall; here the tendon and some fibres of temporalis descend to the mandible (p. 368).

The zygomatic arch (formed by temporal and zygomatic processes) is palpable and visible where cheek and temple meet. Its sharp upper border is obscured by attachment of temporal fascia, the lower by masseter; the latter is also attached to its medial aspect. The gap between arch and temple is deeper anteriorly; here the arch is crossed obliquely down and back by the zygomaticotemporal suture.

3.102B The right infratemporal fossa: seen in norma lateralis after detachment of mandible and removal of zygomatic arch. Blue = frontal bone; yellow = sphenoid and lacrimal bones; brown = temporal and nasal bones; green = maxilla. The parts shown of the parietal, zygomatic, ethmoid and palatine bones are uncoloured.

The *zygomatic process* of the temporal bone widens as it approaches the squama, dividing into: an *anterior root* passing medially in front of the *mandibular fossa* to the smooth *articular tubercle*, the anterior boundary of the fossa; and a *posterior root* passing back, lateral to the fossa, its upper border continuing into the supramastoid crest.

The external acoustic meatus, below the posterior zygomatic root, has rough margins, especially antero-inferiorly, for attachment of meatal cartilage. Posterosuperiorly the margin is formed by the temporal squama, the rest by the temporal's *tympanic plate*. The squamotympanic suture is anterosuperior, the posterior meatal (tympanomastoid) suture usually obliterated in adults, except for a canaliculus for the auricular branch of the vagus. Below the meatus the tympanic plate projects as a rough triangular area. Posterosuperior is often a small depression with a *suprameatal spine* in its anterior margin; within is a *suprameatal triangle*, bounded above by the supramastoid crest, in front by the posterosuperior meatal margin and behind by a posterior vertical tangent to the meatal margin. This triangle is the lateral wall of the mastoid (tympanic) antrum (p. 377) and is hence of surgical interest.



The mastoid part of the temporal bone, posterior to the meatus, is continuous above with squama in front. Its upper border forms behind this with the postero-inferior parietal angle a *parietomastoid suture* and, by its posterior border with the occipital squama, an *occipitomastoid suture*. These two meet the lateral end of the lambdoid suture at the *asterion*. The *mastoid process* (3.89), a breast-like inferior projection from the mastoid temporal bone, is postero-inferior to the external acoustic meatus and palpable under the ear's lobule. The *mastoid foramen* is near or in the occipitomastoid suture; it transmits an emissary vein from the sigmoid sinus. Sutural ossicles may appear in the parietomastoid suture, often at or near the asterion, the site of a *posterolateral fontanelle* (Le Double 1903), but also elsewhere along the suture.

The styloid process (3.89), a slender spike attached to the skull's base, is better viewed in norma lateralis. Anterior and medial to the mastoid process, its base partly ensheathed by the tympanic plate, it descends anteromedially medially, its tip usually reaching a point medial to the posterior margin of the mandibular ramus. The styloid process is, however, very variably developed, ranging in length from a few millimetres to a few centimetres, often approximately straight, but on occasion curved; a ventromedial concavity is more common, a dorsal concavity is infrequent. From its apex the stylohyoid ligament descends forward to the hyoid's lesser cornu (p. 370) as a cranial suspension.

The infratemporal fossa (3.103A) is an irregular, postmaxillary space, communicating with the temporal fossa between the zygomatic arch and lower temple. Medially its roof is the infratemporal surface of the sphenoid's greater wing and part of the temporal squama. Here the greater wing displays the foramina ovale and spinosum. Medial is the lateral pterygoid plate, described in norma basalis (p. 355). Behind, below and laterally the fossa is open. Its anterior and medial walls converge below but are separated above by the *pterygomaxillary fissure*, through which the infratemporal and pterygopalatine fossae connect. The fissure is continuous above with the *inferior orbital fissure's* posterior end, by which route the infratemporal and pterygopalatine fossae connect with the orbit (p. 347).

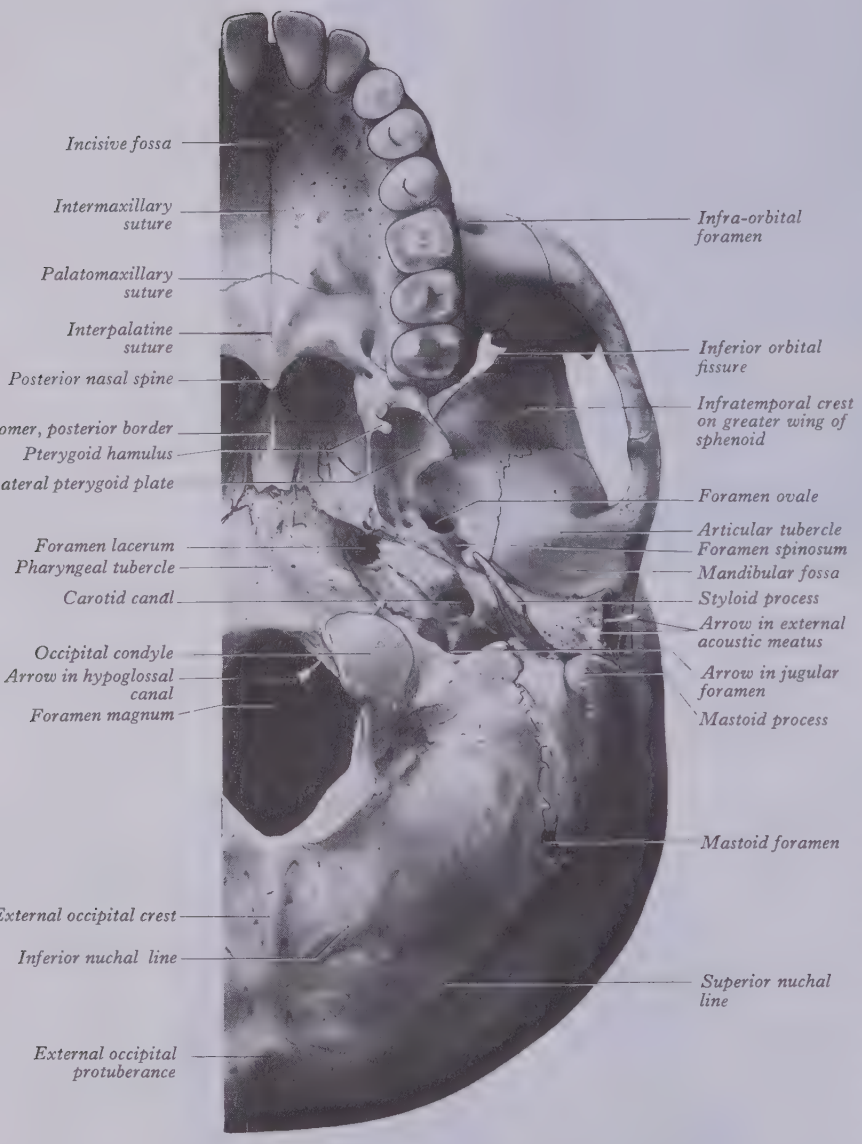
The pterygopalatine fossa is a small pyramidal space below the orbital apex; it communicates with the infratemporal fossa via the pterygomaxillary fissure, with the nasal cavity by the sphenopalatine foramen and the orbit by the medial end of the inferior orbital fissure. The foramen rotundum, in its posterior wall, is traversed by the maxillary nerve.

Further details. The floor of the *temporal fossa* bears a few vascular furrows, the most constant above the external acoustic meatus produced by middle temporal vessels. In its anterior wall the *zygomaticotemporal foramen* opens up and backwards from the zygomatic bone's posterior surface, and it transmits the zygomaticotemporal nerve and a minute artery. The tendon of temporalis descends and the deep temporal vessels and nerves ascend, deep to the muscle, between zygomatic arch and cranial wall. The temporal bone's zygomatic process bears a small *tubercle*

3.102C Lateral radiograph of adult female skull, with mandible omitted. (Supplied by P J Liepins; photography by Sarah Smith.)

of the anterior root of the zygoma, to which the lateral temporomandibular ligament is partly attached (**4**.20). It is palpable in front of the mandibular head. Behind the mandibular fossa the postglenoid tubercle descends from the zygoma's posterior root to meet the tympanic plate anterosuperiorly at the external acoustic meatus (**3**.132); its anterior aspect is a small part of the mandibular fossa.

The posterolateral surface of the *mastoid process* and its apex are attachments of sternocleidomastoid, splenius capitis and longissimus capitis, from before backwards (**3**.102,104B). Anterior and parallel to this area partially obliterated remains of the squamomastoid suture may be visible. Hence the suprameatal triangle's floor, and therefore the lateral wall of the mastoid antrum, is formed by temporal squama. The tympanomastoid fissure is on the base of the process; the mastoid canaliculus (**3**.136), which transmits the vagal auricular branch, opens in the fissure.



The *styloid process* is related laterally to the parotid gland, medially to the internal jugular vein. The stylohyoid is attached by a slender tendon to its posterior aspect near the base, styloglossus to the tip and adjacent anterior aspect, stylopharyngeus medially to its base and the stylomandibular ligament laterally near its tip. Behind its base the facial nerve emerges from the stylomastoid foramen crossing lateral to the process in the parotid gland.

The *infratemporal fossa* (**3**.103A) contains temporalis as it reaches the mandibular coronoid process and adjacent ramus; the maxillary artery and its rami, and the pterygoid venous plexus lie medial to the muscle and usually lateral to the lateral pterygoid. Deepest are the medial pterygoid, mandibular nerve and chorda tympani, the mandibular nerve entering the fossa through the foramen ovale in its roof to divide into terminal rami medial to the lateral pterygoid; these leave the fossa for other regions. The chorda tympani enters the fossa medial to the sphenoidal spine to join the lingual nerve. The maxillary nerve appears in its upper part between the pterygopalatine fossa and inferior orbital fissure. The anterior wall is pierced by small foramina for posterior superior alveolar vessels and nerves and is limited below by the maxilla's alveolar part behind the molar teeth. Here a strip of maxilla is covered by gingival mucosa and above this are attached upper fibres of buccinator, extending back on to the maxillary tuberosity. The fossa's medial wall, the lateral pterygoid plate, is completed below by the palatine bone's pyramidal process wedged between maxillary tuberosity and the plate. The superficial head of medial pterygoid is attached to the pyramidal process but also spreads to the maxillary tuberosity.

The *pterygomaxillary fissure*, between maxilla and pterygoid process, admits the maxillary artery to the pterygopalatine fossa; its uppermost part contains the maxillary nerve (p. 354).

The *pterygopalatine fossa* (**3**.103A) is bounded *behind* by the root of the pterygoid process and adjoining sphenoidal greater wing's anterior surface, *medially* by the palatine bone's perpendicular plate with its orbital and sphenoidal processes, *anteriorly* by the superomedial part of the maxilla's posterior surface. *Laterally* it connects with the infratemporal fossa via the pterygomaxillary fissure. Its main contents are the maxillary nerve, pterygopalatine ganglion and terminal rami of the maxillary artery. The pterygoid canal inferomedial to foramen rotundum transmits the pterygoid nerve and artery from the anterior wall of the foramen lacerum to the pterygopalatine ganglion; inferomedially the palatovaginal canal transmits the pharyngeal nerve and artery from the ganglion to the pharyngeal roof. In the medial wall the *sphenopalatine foramen* (**3**.115) is bounded above by the sphenoid's body, elsewhere by parts of the palatine bone, in front by its orbital

process, behind by its sphenoidal process, and below by the upper border of the palatine bone's perpendicular plate. It carries into the nasal cavity the nasopalatine nerve and vessels. A fifth foramen, placed inferiorly at the junction of anterior and posterior walls, leads into the *greater palatine canal* and descends between maxilla and palatine perpendicular plate. This canal transmits anterior, middle and posterior palatine nerves and greater and lesser palatine vessels, which emerge on the bony palate (vide infra).

3.103A The inferior surface of the left half of the base of the skull with mandible removed (Norma basalis). Compare with Key, 3.103B.

Norma Basalis

The inferior cranial aspect is complex (3.103–107) extending from upper incisor teeth to superior nuchal lines of the occiput. Laterally are the post-incisor teeth, zygomatic arches and their posterior roots and mastoid processes (which reach the lateral limits of the superior nuchal lines). It is conveniently divided into anterior, middle and posterior parts, the anterior being the hard palate and alveolar arches, on a lower level than the rest, the rest being arbitrarily divided into middle and posterior parts by a transverse plane through the foramen magnum's anterior margin.

Anterior Part of Norma Basalis

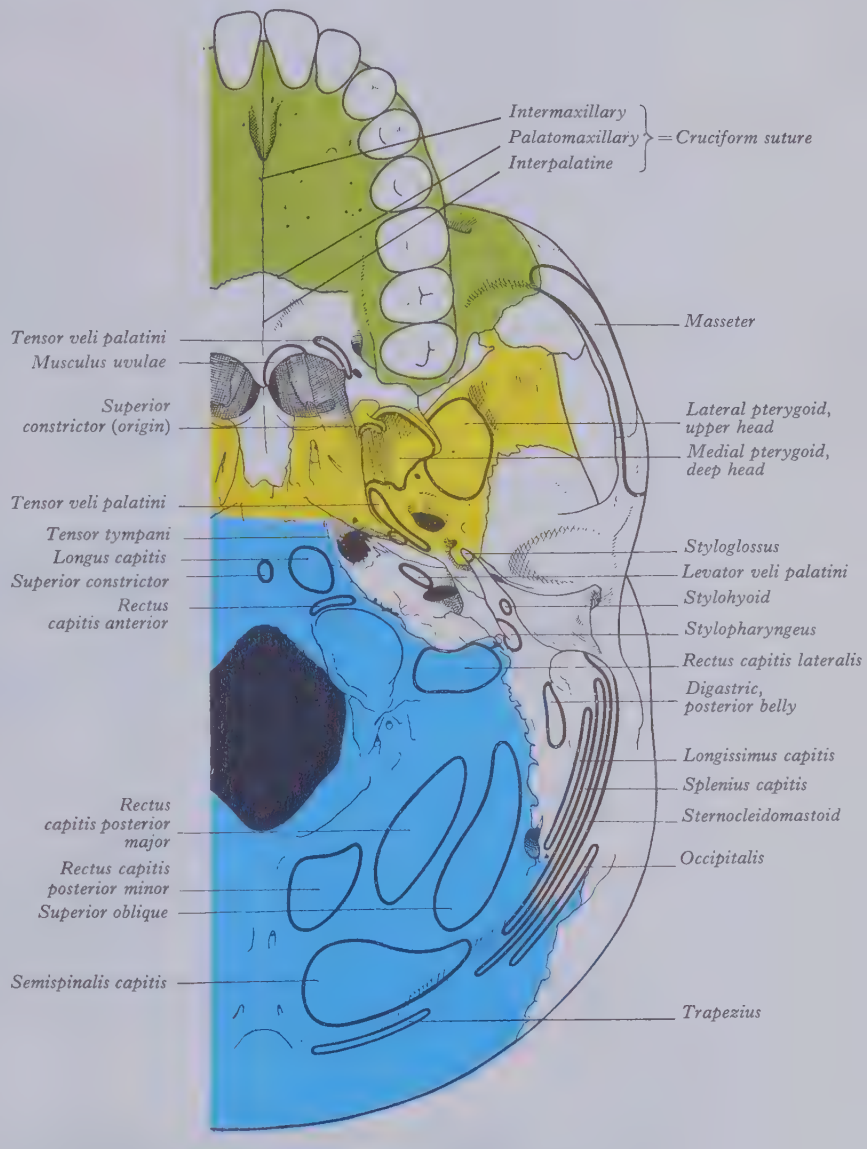
The *bony palate* (3.106), within the superior dental arch, is formed by the maxillary palatine processes and palatine horizontal plates, meeting at a *cruciform suture* formed of intermaxillary, interpalatine and palatomaxillary sutures. The palate is arched sagittally and transversely, its depth and breadth variable but always greatest in the molar region. The *incisive fossa* is anterior and median; the *lateral incisive foramina*, via which incisive canals pass to the nasal cavity (p. 366), are in its lateral walls and the *median incisive foramina*, present in some skulls, open on its anterior and posterior walls. The *greater palatine foramen* is near the lateral palatal border behind the palatomaxillary suture (3.106), and a vascular groove, deep posteriorly, leads forwards from it. The *lesser palatine foramina*, usually two, behind the greater, pierce the *palatine pyramidal process* wedged between the lower ends of the medial and lateral pterygoid plates. (Accessory lesser foramina have a high incidence, with racial and sexual variation from 30–70%; see p. 396). The palate is pierced by many other small foramina and marked by pits for palatine glands. Near its sharp, gently arched bilaterally posterior border, also slightly curved, variably prominent *palatine crests* extend medially from behind the greater palatine formina. The posterior border projects back as a median *posterior nasal spine*. The *alveolar arch* has 16 sockets or *alveoli* for teeth, varying in size and depth, some single, some divided by septa in adaptation to dental roots. The lateral incisive foramen transmits terminal rami of the greater palatine vessels and nasopalatine nerve. When median incisive foramina occur, the left nasopalatine nerve traverses the anterior and the right posterior foramen. The lateral foramina are, some claim, in the line of fusion of an os incisivum (premaxilla) with the maxilla proper, as a primitive bucco-nasal communication. In young skulls a dubious bilateral suture between os incisivum and maxilla may extend from the posterior part of the incisive fossa to septa between roots of lateral incisor and canine teeth (but see p. 390).

The greater palatine nerve and vessels traverse their foramina, the vessels grooving the palate towards the incisive fossa. The lesser palatine foramina, usually two but sometimes three, contain lesser palatine nerves and vessels. To the palatine crest is attached part of the tendon of tensor veli palatini, to the posterior palatine border the palatine aponeurosis and to the posterior nasal spine musculus uvulae. These collagenous elements, although often described separately, are in fact blended as the osseous surfaces are approached. Margins of the median palatal intermaxillary suture are sometimes raised into a *palatine torus*, variably smooth, pitted or rough. A similar longitudinal *maxillary torus* may appear on the alveolar process, palatal to the upper molar roots.

Middle Part of Norma Basalis

This (3.103–107) extends posteriorly from the osseous palate to an arbitrary line through the anterior margin of the foramen magnum. Anteriorly the *posterior vomerine border* separates two *posterior nasal apertures*, behind which a posterior area of inferior sphenoid surface is continuous with that of the *basioccipital bone*, forming a broad bar sloping down to the foramen magnum. Convex transversely, wider behind, it bears, in front of the foramen, a small midline *pharyngeal tubercle*, the highest attachment of the superior pharyngeal constrictor.

The pterygoid process, descending behind the third molar tooth from the junction of the sphenoid's greater wing and its body, has medial and lateral pterygoid plates, separated by a cuneiform *pterygoid fossa*, facing posterolaterally. Anteriorly the plates are fused, except below, where they are separated by the palatine's *pyramidal process*; sutures are usually discernible. Anteromedially the processes articulate with the posterior border of the palatine's perpendicular plate, forming a flat area in the posterior nasal aperture's lateral wall and nasopharynx. Laterally they are separated from the posterior maxillary surface by the pterygomaxillary fissure (3.103A). The *medial pterygoid plate* is narrower and projects directly back, its medial surface covered by mucous membrane of the posterior nasal aperture's lateral rim and part of nasopharynx. Its posterior border is sharp, with a small projection near midpoint, above which it is curved and

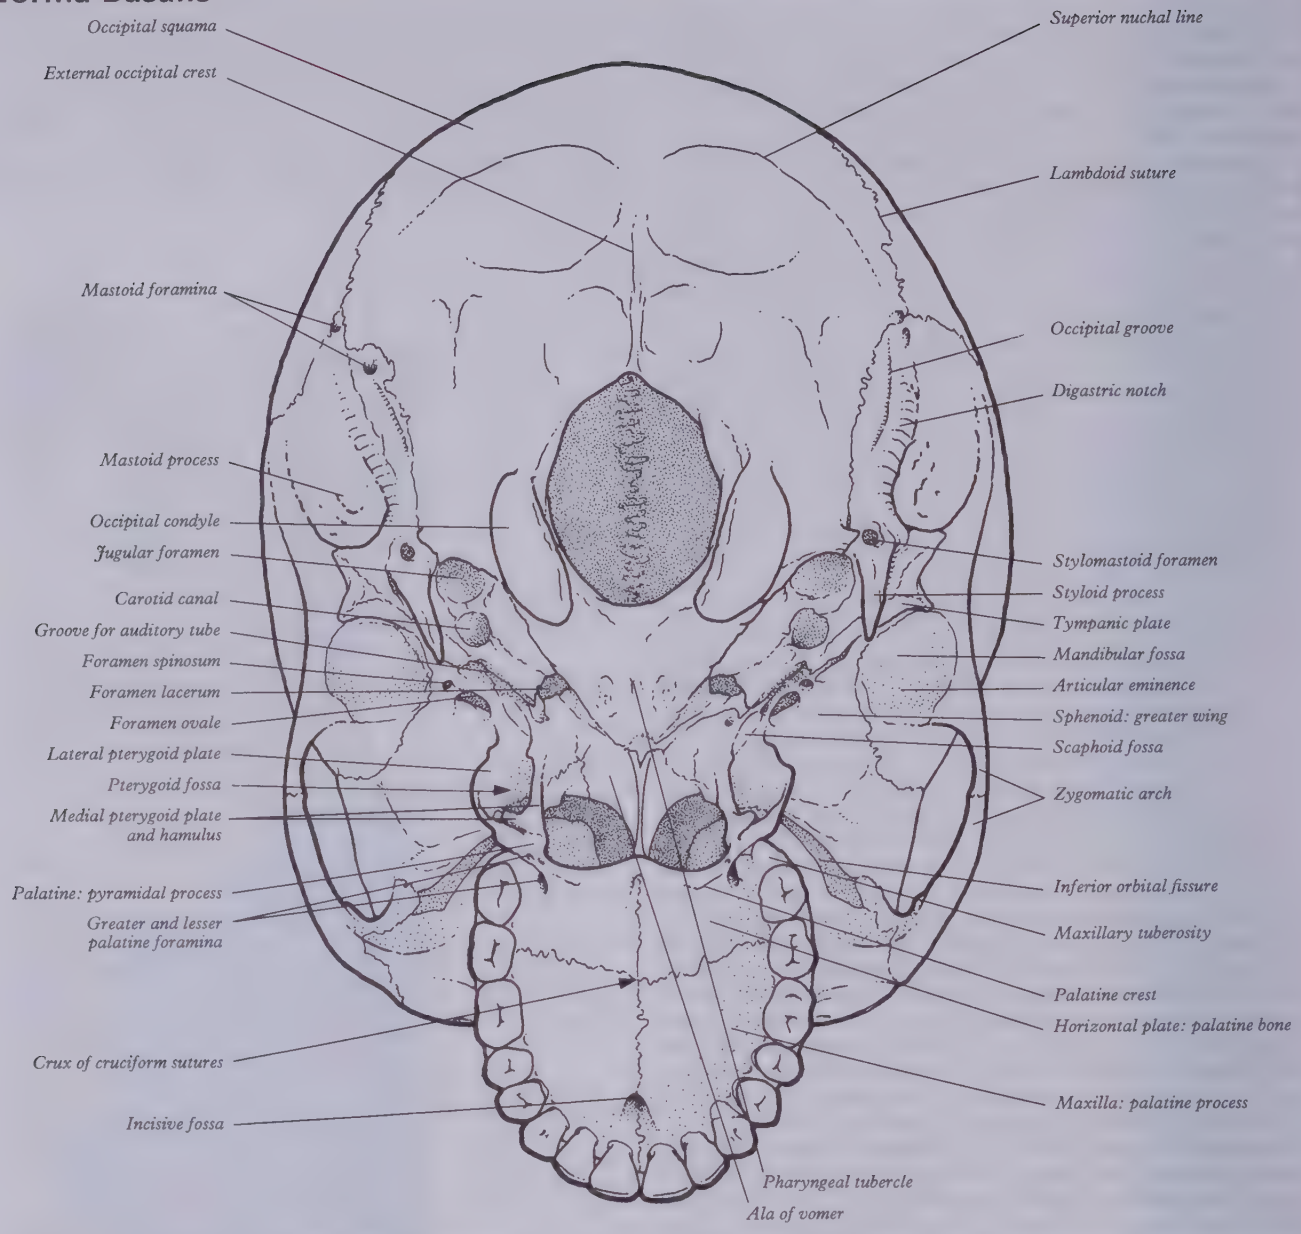


attached to the pharyngeal end of the auditory tube; superiorly it divides to enclose the *scaphoid fossa* (3.104,127); below, it projects as a slender *pterygoid hamulus*, which curves laterally and is grooved anteriorly by the tendon of tensor veli palatini. The *lateral pterygoid plate* projects posterolaterally; its lateral surface is the medial wall of the infratemporal fossa. Superiorly it is continuous with the *infratemporal surface of the sphenoid's greater wing*, anterior in the roof of the infratemporal fossa. This surface, inferolateral, is almost pentagonal; anterior is the posterolateral border of the inferior orbital fissure, anterolateral the infratemporal crest. Laterally it articulates with the temporal squama; medially it is continuous with the pterygoid process and side of the sphenoid's body; posteromedially it articulates with the petrous part of the temporal bone.

The foramina ovale and spinosum, on the greater wing's infratemporal surface, transmit some large structures as follows (for further details vide infra): the *foramen ovale*, near the lateral pterygoid plate's posterior margin, transmits the trigeminal mandibular division. Posterolateral to it the *foramen spinosum* transmits the middle meningeal artery to the middle cranial fossa; it is much the smaller and circular. Posterolateral to it projects the irregular *spine of the sphenoid* whose medial surface is flat and forms, with the adjoining posterior border of the greater wing, the anterolateral wall of a groove, completed posteromedially by part of the petrous temporal bone. This groove contains the cartilaginous *pharyngotympanic (auditory) tube* and leads posterolaterally into an osseous canal for the tube in the petrous temporal bone and also anteromedially to the medial pterygoid plate's superior border. In the roof of the groove the posterior border of the greater wing and the anterior border of the petrous temporal meet at a petrosphenoidal suture. Occasionally the foramina ovale and spinosum are confluent, frequency varying from 0.7–10.4% in modern populations. Similarly, the foramen spinosum's posterior edge may be defective, with an incidence of 2–17% (p. 396). Posteromedial to this groove is the *inferior surface of the petrous temporal* between the sphenoid's greater wing and the basi-occipital bone. Anteriorly the surface is rough, its apex separated from the posterolateral aspect of the sphenoid's body by an irregular *foramen lacerum*. Behind this rough area and posterolateral to foramen lacerum, a large, almost circular foramen opens into the *carotid canal*, which ascends then turns anteromedially to reach the posterior wall of the foramen lacerum. Emerging from the canal the internal carotid artery turns up into the cranial cavity. Inferiorly the foramen lacerum is filled by fibrocartilage; this is not traversed by large structures.

Further details. From the sphenoidal spine's base the *squamotympanic fissure* runs posterolaterally between the tympanic plate and mandibular fossa, usually reaching the anterior margin of the external acoustic meatus but sometimes obliterated near its lateral end. The *mandibular fossa*, deeply concave sagittally, and transversely gently concave, is wider laterally. It contains the head of the mandible when the jaw is elevated. Anteriorly the articular surface invades a transverse rounded *articular tubercle*, continuous laterally with the zygoma's anterior root. In front is the part of the temporal squama in the roof of the infratemporal fossa. Behind the squamotympanic fissure the *temporal tympanic plate*, separating mandibular fossa and external acoustic meatus, is roughly triangular, its apex at the medial end of the fissure near the sphenoidal spine's root. Its lower border skirts the anterolateral margin of the inferior opening of the carotid canal, extending posterolaterally to the root of the styloid process. There it forms a *sheath of the styloid process*, longer and prominent laterally where the tympanic plate is fused with the rest of the temporal bone below and behind; it is free above, forming the anterior border of the external acoustic meatus.

The upper border of the *vomer*, applied to the inferior aspect of the sphenoid's body, expands into an *ala* on each side (3.104A,153), a median groove between them fitting the sphenoid's *rostrum*. The lateral border of each ala reaches a thin *vaginal process* projecting medially from the medial pterygoid plate. The two may merely touch or the alar edge may be overlapped inferiorly by the vaginal process, whose inferior surface bears an anteroposterior groove, converted into a canal anteriorly by the superior aspect of the sphenoidal process of the palatine bone. This *palatovaginal canal*, opening anteriorly on the pterygopalatine fossa's anterior wall, transmits a pharyngeal branch of the pterygopalatine ganglion and a pharyngeal ramus from the third part of the maxillary artery. A second, *vomerovaginal canal*, medial to the palatovaginal, may exist between ala and vaginal process, leading into the anterior end of the palatovaginal canal.



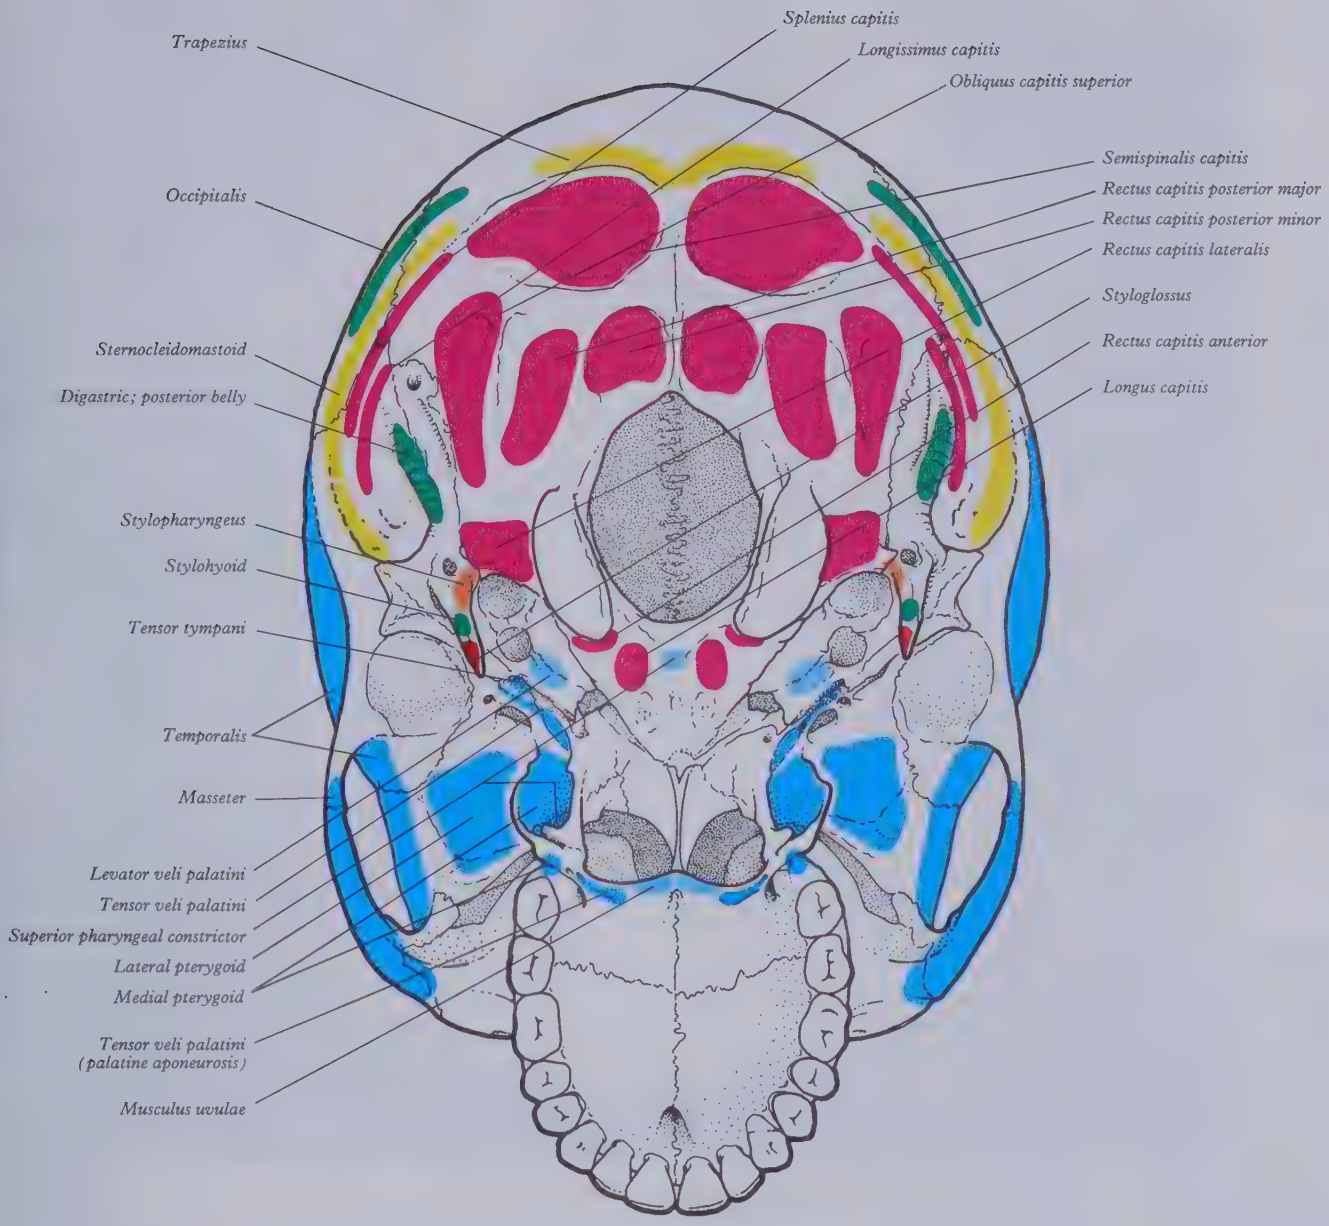
Anterior to the pharyngeal tubercle the basi-occipital bone is related to the roof of the nasal part of the pharynx and the

3.103B Outline drawing of norma basalis showing the attachments of named but unclassified muscles. Key to 3.103A. Blue = occipital bone; yellow = sphenoid bone; green = maxilla. For muscle groups see 3.104A,B.

pharyngeal tonsil. Anterolateral to the tubercle, longus capitis is attached and posterior to this rectus capitis anterior, immediately ventral to the occipital condyle and medial to the hypoglossal canal. At the root of the posterior border of **the medial pterygoid plate** the *scaphoid fossa* receives anterior fibres of tensor veli palatini, which descend along the plate's lateral surface and posterior border to reach the *hamulus*, around the anterolateral aspect of which the muscle's tendon twists medially into the soft palate. To the plate's posterior border, notched above by the auditory tube (p. 376), is attached the pharyngobasilar fascia, to its lower part the ventral highest fibres of the superior pharyngeal constrictor; these curve up and medially to the pharyngeal

Norma Basalis

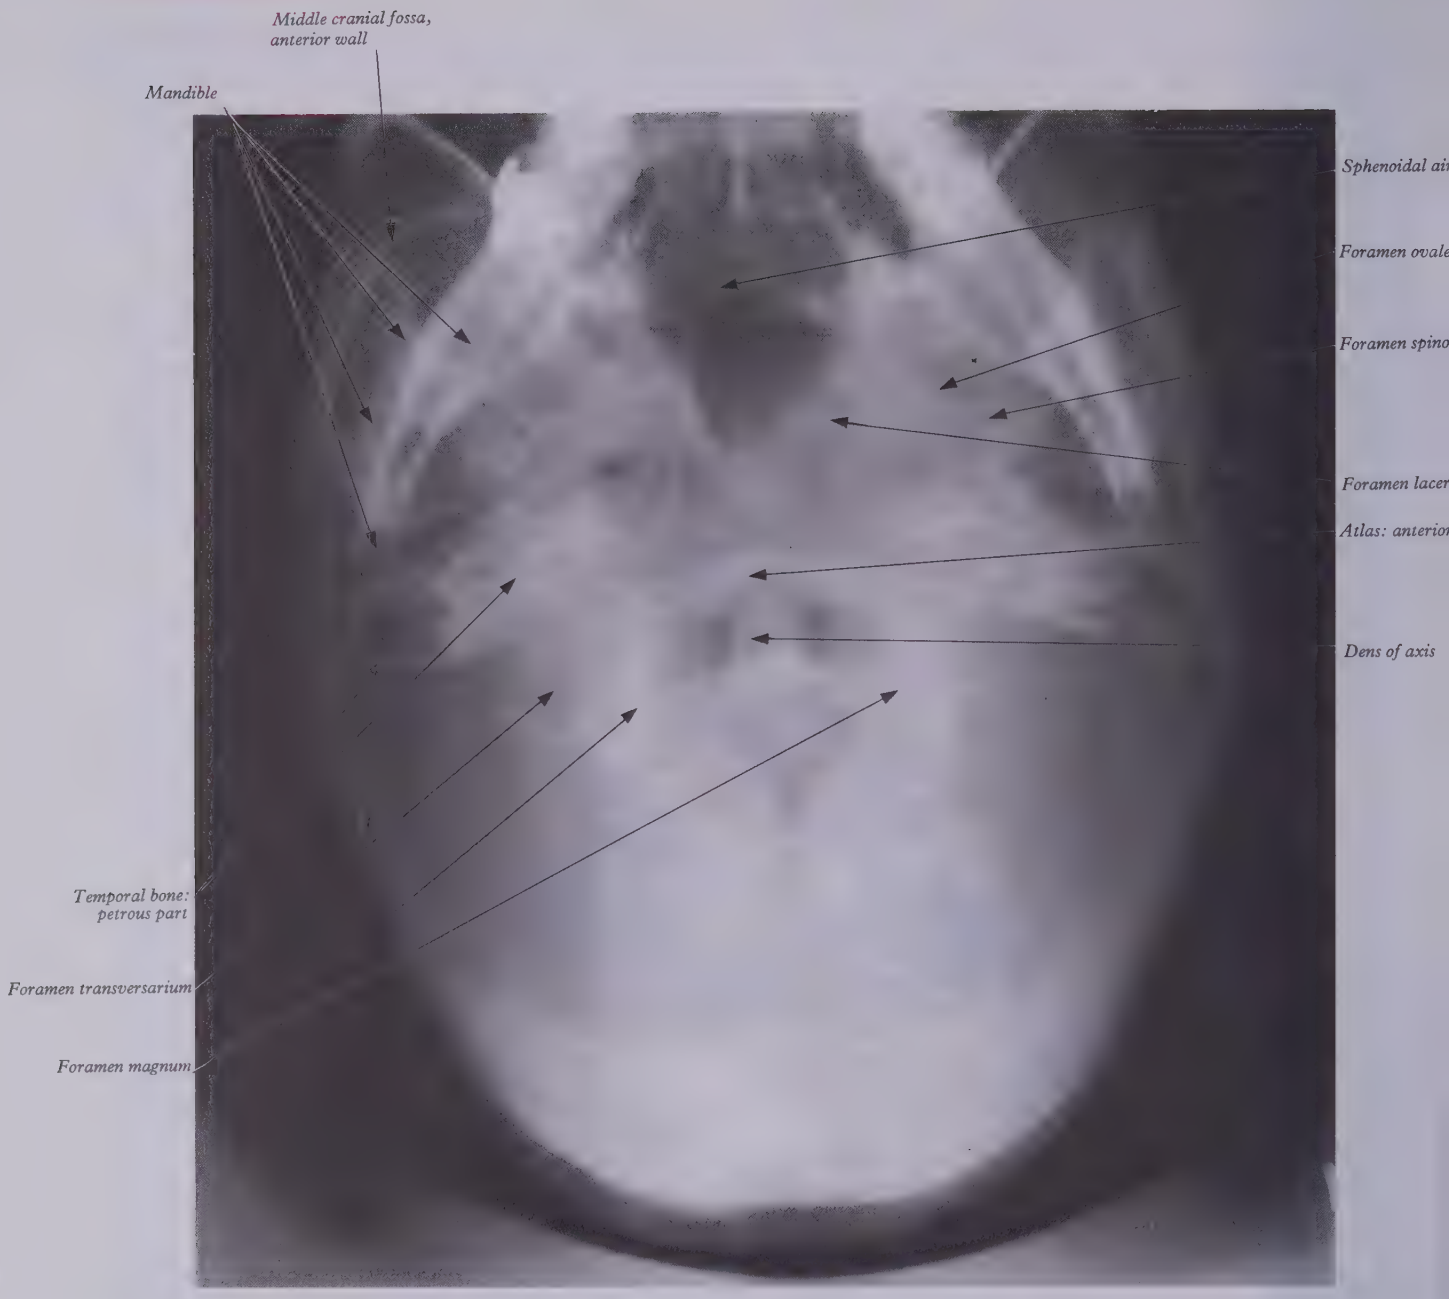
3.104A (*above*) The skull: norma basalis without mandible.



3.104B (*opposite*) The skull: norma basalis without mandible, showing muscle attachments.

tubercle. To the tip of the hamulus the pterygomandibular raphe is attached. High on the plate's posterior border a small tubercle, medial to scaphoid fossa, projects back below the posterior opening of the *pterygoid canal*, which opens anteriorly on the pterygopalatine fossa's posterior wall. The canal transmits its nerve and vessels; it is in the line of fusion of the pterygoid process and greater wing with the sphenoidal body. The *pterygoid fossa*, between the pterygoid plates, is completed antero-inferiorly by the palatal pyramidal process.

The lateral pterygoid plate (3.103) is wider than the medial. A variable *pterygospinous process* on its irregular posterior border is connected by a ligament (sometimes ossified) to the sphenoid spine. To its rougher, lateral surface is attached the lower head of lateral pterygoid and to the medial surface most of medial pterygoid. Attached to the lateral aspect of the *palatine pyramidal process* are some fibres of the superficial slip of medial pterygoid.



The greater wing's infratemporal surface is an attachment of the upper head of lateral pterygoid and is crossed by the deep temporal and masseteric nerves, between muscle and bone. **The foramen ovale** contains the accessory meningeal artery in addition to the mandibular nerve; to its sharp posterior border fibres of tensor veli palatine are attached between nerve and auditory tube. **The foramen spinosum**, in addition to the middle meningeal artery, transmits a meningeal branch of the mandibular nerve. Between foramen ovale and scaphoid fossa a small *sphenoidal emissary foramen* may contain an emissary vein from the cavernous sinus. Attached to the *spine of the sphenoid*, variably sharp or blunt, is the sphenomandibular ligament. The spine is related laterally to the auriculotemporal nerve, medially to chorda tympani, by which it may be grooved, and to the auditory tube. Posterior fibres of tensor veli palatini are attached posteriorly to it. The groove for the tube varies in width and depth, its roof occasionally completed by fibrous tissue; its lateral, sphenoidal wall gives attachment posteriorly to fibres of tensor tympani.

Laterally on the petrous temporal bone's posterior surface levator veli palatini is attached. **The foramen lacerum** is bounded in front by the sphenoid body and adjoining roots of the pterygoid process and greater wing, posterolaterally by the apex

of the petrous temporal, medially by the basi-occipital; it is nearly 1 cm long, but no large structure completely traverses it. The carotid canal's anterior orifice opens posteriorly; this artery and its venous and sympathetic plexuses ascend through its upper end. In the foramen the deep and the greater petrosal nerves join to form the nerve of the pterygoid canal, which opens low on the anterior wall. Meningeal rami of the ascending pharyngeal artery, and emissary veins from the cavernous sinus traverse the foramen. Cartilage in its lower part is a remnant of the chondrocranium.

The *mandibular fossa's* thin floor is below the most lateral part of the middle cranial fossa and covered by white fibrocartilage (p. 486). To the *tubercle of the root of the zygoma* is attached the lateral temporomandibular ligament. A thin edge of bone may appear at the medial end of the *squamotympanic fissure*; it is the lower border of the down-curved lateral edge of the tegmen tympani, a part of the petrous temporal. It partly divides the squamotympanic into *petrotympanic* and *petrosquamous* fissures. Through the former the chorda tympani, in its anterior canaliculus, escapes anteroinferiorly from the tympanic cavity; the anterior tympanic branch of the maxillary artery traverses the same fissure.

The temporal bone's tympanic part (3.107) is separated from the temporomandibular joint by the parotid gland, usually containing the auriculotemporal nerve. It is thinnest centrally and occasionally deficient (p. 380). Its grooved upper aspect forms the anterior wall, floor and lower posterior wall of the external acoustic meatus. Except where it ensheathes the styloid process, its posterior surface is fused with the petromastoid bone.

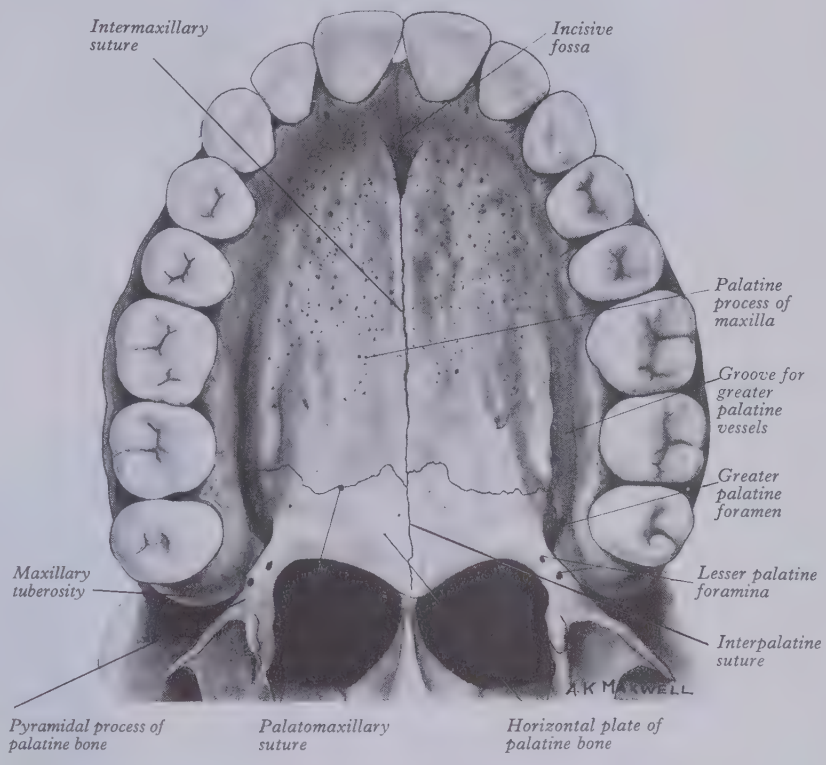
Posterior Part of Norma Basalis

Anteromedian in this region (3.103,104) is the *foramen magnum*, which is oval, wider behind, its greatest diameter being anteroposterior. It contains the medulla oblongata's lower end. Anteriorly its margin is slightly overlapped by the *occipital condyles*, projecting down to articulate with superior articular facets on the lateral masses of the atlas. Oval in outline, each condyle is oblique, its anterior end nearer the midline, markedly convex anteroposteriorly, less so transversely. Its medial aspect is roughened by ligamentous attachments. Above it, anteriorly, is the *hypoglossal (anterior condylar) canal*, directed laterally and slightly forwards from the posterior cranial fossa and containing the hypoglossal nerve. A

condylar fossa of variable depth, posterior to the condyle, is sometimes pierced by a *condylar canal* for an emissary vein from the sigmoid sinus. Incidence of condylar canals shows racial variation—from 13.3% in modern Palestinians to 70% in Peruvian crania; it also illustrates sexual variation, occurring in 58% of male Burmese, but only 31% of females (p. 395). Lateral to each condyle a *jugular process* joins the petrous temporal; its anterior border is the posterior boundary of the *jugular foramen*.

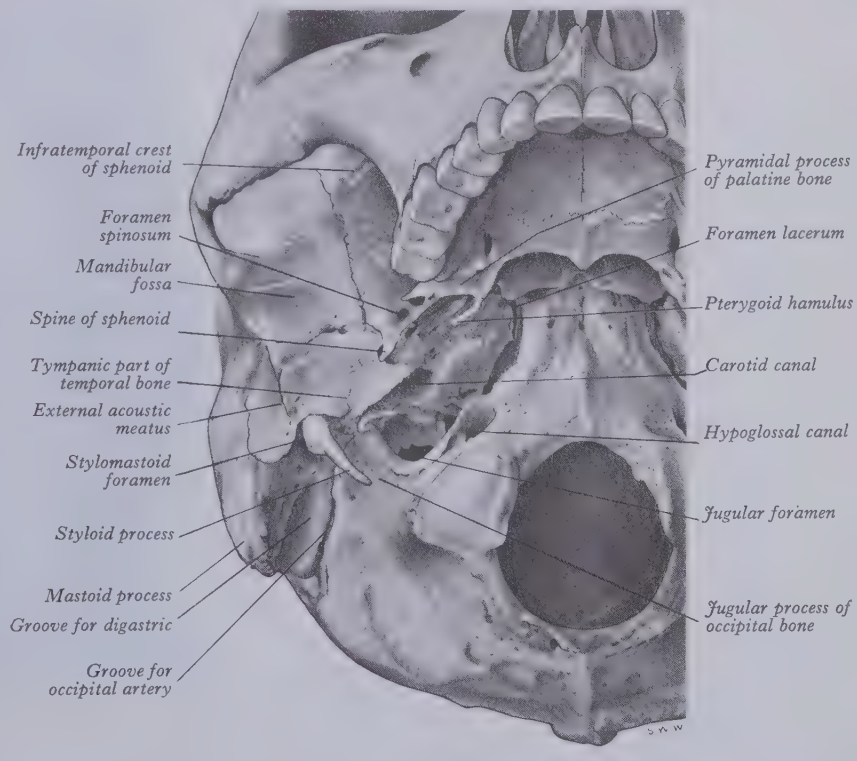
The jugular foramen is a large irregular hiatus *between* occipital and petrous temporal bones at the posterior end of the petro-occipital suture. Anteriorly it is separated from the inferior carotid orifice by a ridge, related laterally to the medial aspect of the styloid sheath and separated from the hypoglossal canal by a thin osseous bar. Its long axis is directed anteromedially, the right foramen usually being larger. Its anterior part contains the inferior petrosal sinus, its intermediate part the glossopharyngeal, vagus and accessory nerves and its posterior part the internal jugular vein. When the vein's superior bulb is well developed the jugular fossa of the petrous temporal is expanded superolaterally.

Posterior to the styloid process a *stylomastoid foramen* contains the facial nerve. Posterolateral to the foramen the *mastoid process* projects down and forwards as the lateral wall of the *mastoid notch*, in which the posterior belly of digastric is attached. Medial to the notch the temporal bone may be grooved by the occipital artery (**3**.107).



In the midline, posterior to foramen magnum, the occipital squama has a median *external occipital crest* to which is attached the ligamentum nuchae. The crest ends in the external occipital protuberance; *inferior nuchal lines* curve posterolaterally from its midpoint, almost parallel to the *superior nuchal lines*, which also extend from the protuberance and may form a distinct crest medially.

Further details. The foramen magnum is a wide communication between the posterior cranial fossa and vertebral canal. Anteriorly the apical ligament of dens and membrana tectoria are in it, both attached to the upper surface of the basi-occipital bone. Its wider, posterior part contains medulla oblongata and meninges. In the subarachnoid space spinal rami of the accessory nerves and vertebral arteries, with their sympathetic plexuses, ascend into the cranium; the posterior spinal arteries descend, posterolateral to the brainstem, as does the anterior spinal artery anteromedian to it. The cerebellar tonsils may project into the foramen. To its *anterior margin* is attached the anterior atlanto-occipital membrane, continuous on each side with capsular ligaments of atlanto-occipital joints, to its *posterior margin* the posterior atlanto-occipital membrane, and to rough medial condylar areas, the alar ligaments.



The hypoglossal canal also contains a meningeal branch of the ascending pharyngeal artery and an emissary vein from the basilar plexus. Sometimes it is divided by a spicule of bone (p. 373). To the inferior surface of the occipital jugular process rectus capitis lateralis is attached.

The jugular foramen (**3**.103B) ascends posteromedially; externally its apparent size is increased laterally by the jugular fossa, its floor separating the superior jugular bulb from the tympanic cavity. A minute *mastoid canaliculus* on the fossa's lateral wall transmits the vagal auricular branch. Passing laterally, this nerve is very near the facial canal, finally emerging in the tympanomastoid suture; it is extracranial at birth but surrounded by bone as tympanic plate and mastoid process develop. On or near the ridge between the jugular fossa and carotid canal is the *tympanic canaliculus*, transmitting to the middle ear the tympanic branch of the glossopharyngeal nerve. Medial on the upper boundary of the jugular foramen a small notch, more easily identified internally, contains the inferior glossopharyngeal ganglion. The orifice of the *cochlear canaliculus* (p. 379) is at the notch's apex; its projecting edges may reach the occipital bone to trisect the foramen.

The stylomastoid foramen is posterior to the styloid root at the anterior end of the mastoid notch. The facial nerve emerges from it near the digastric's posterior belly, supplying it before entering the parotid gland. The foramen also contains the stylomastoid artery. A groove across the inferior aspect of the temporal bone, medial to the mastoid notch, is related to the occipital artery; it is absent when the vessel is lower than usual, between splenius and longissimus capitis instead of medial to both. To the area below the *inferior nuchal line* are attached medially rectus capitis posterior minor, laterally rectus capitis posterior major (**3**.104B). In the interval between inferior and superior nuchal lines is attached, medially, semispinalis capitis and, laterally, obliquus superior. Medially to the *superior nuchal line* the highest fibres of trapezius are attached, laterally fibres of sternocleidomastoid and, more anteriorly, splenius capitis.

INTERIOR OF THE CRANIUM

The cranial cavity contains the brain, pineal and hypophysis cerebri, parts of cranial and spinal nerves, blood vessels, meninges and cerebrospinal fluid. It is contained by frontal, parietal, sphenoid, temporal and occipital bones and, in part, the ethmoid, all lined by fibrous *endocranium*, the external zone of the dura mater, which traverses various foramina to join the external periosteum, the *pericranium*. Both membranes are blended with sutural ligaments or cartilages in the narrow interosseous intervals.

The cavity's walls vary in thickness in different regions and individuals, but tend to be thinner where covered by muscles, e.g. in temporal and posterior cranial fossae. Most cranial bones display *outer* and *inner tables* of compact bone, separated by *diploë*, trabecular bone containing red bone marrow. The inner table is thinner and more brittle, the outer generally very resilient. Many bones are so thin that the tables are fused, e.g. vomer, pterygoid plates. The skull is thicker in some races and individuals, but no relation exists between this and cranial capacity; in all races, it is thinner in women and children. The interior may

3.108 (*left*) The internal (endocranial) surface of the skull cap or calva.

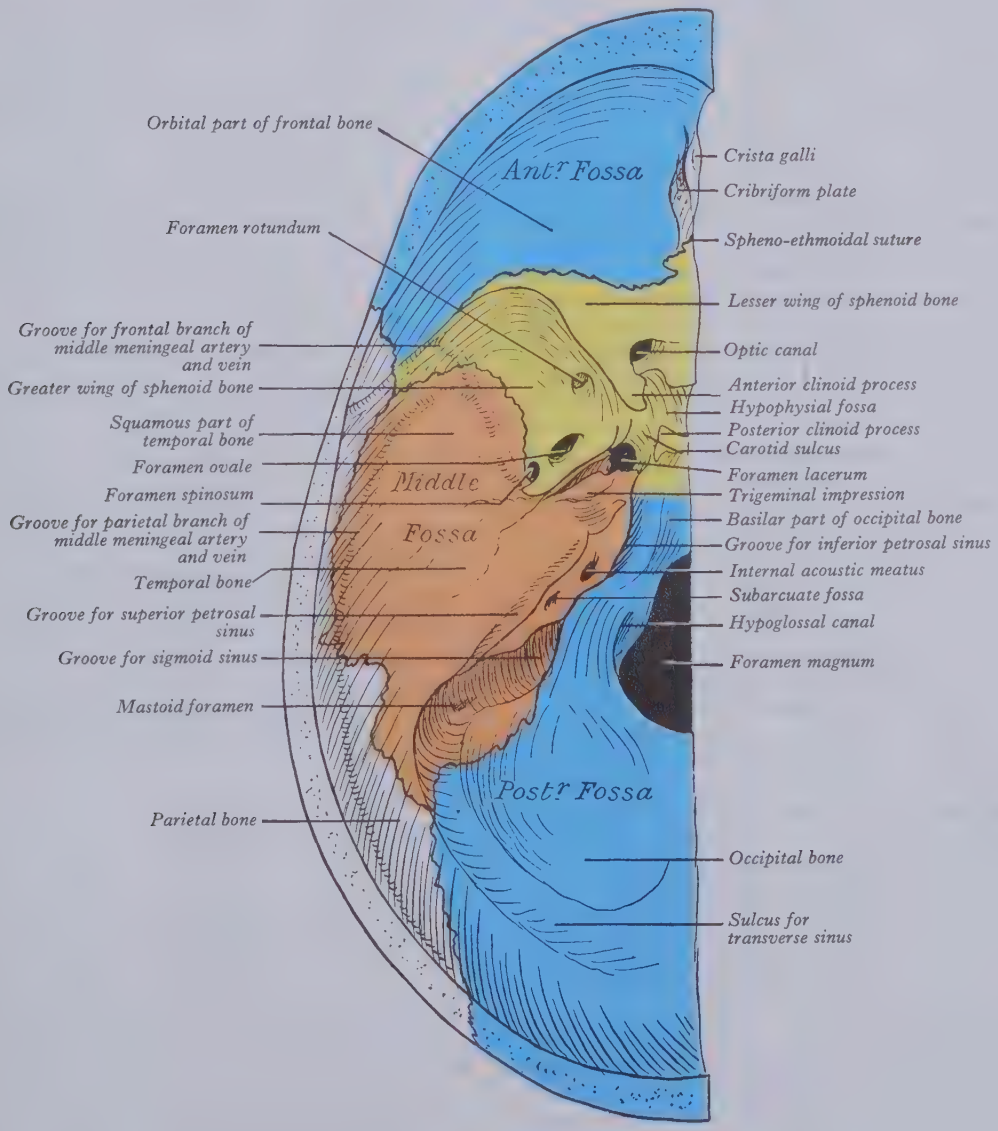
3.109A The internal (endocranial) surface of the left half of the base of the skull. Compare with Key, 3.109B.

be described in two parts: the internal surface of the skull 'cap' or calva and that of the cranial base.

Internal Surface of Cranial Vault (Calva)

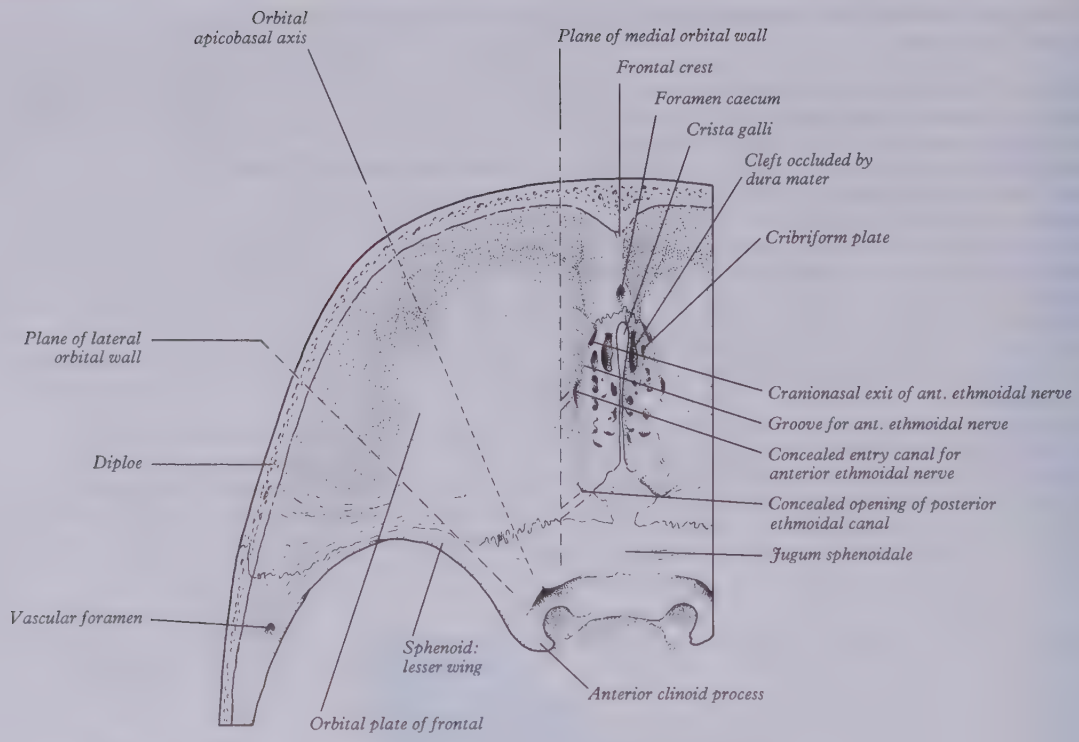
The *calva* (**3**.108) includes most of the frontal and parietal bones and the upper occipital squama and hence the coronal, sagittal and lambdoid sutures unless fusion, which begins internally, has obliterated them. The cranial vault, deeply concave, presents numerous vascular furrows and cerebral grooves.

The anteromedian *frontal crest* projects back for attachment of the falx cerebri, grooved by the commencement of the *sagittal sulcus*, accommodating the superior sagittal sinus, the groove widening as it progresses back below the sagittal suture. On each side of it are irregular depressions, *granular foveolae*, which become larger and more numerous as skulls age; they are adapted to arachnoid granulations.



The middle meningeal vein's frontal branch, and sometimes the artery's, groove bone deeply just behind the coronal suture, corresponding to the precentral cerebral sulcus. Rami of both and their parietal branches ascend backwards, grooving the internal parietal surface. Smaller grooves may mark the frontal and occipital bones. *Parietal foramina* may occur near the sagittal sulcus, about 3.5 cm anterior to the lambdoid suture, for emissary veins of the superior sagittal sinus. *Impressions for cerebral gyri* are less distinct on vault than cranial base, and most obvious near the latter.

Internal Surface of Cranial Base



This shows clear division into anterior, middle and posterior cranial fossae (**3**.109–112). It is irregular, partly due to impressions for cerebral gyri, especially conspicuous in the anterior and middle fossae, reflecting the pattern of corresponding cerebral surfaces. Dura mater is firmly adherent to the whole area and through all foramina and fissures its outer layer, endocranium, is continuous with the external periosteum.

Anterior Cranial Fossa

This fossa (**3**.109A,B,110) is formed at front and sides by the frontal bone, its floor by the frontal's orbital plate, the ethmoid's

3.109B The internal surface of the left half of the base of the skull (Basis cranii interna). Key to **3**.109A. Blue = frontal and occipital bones; yellow = sphenoid bones; brown = temporal bone; white = parietal and ethmoid bone.

3.110 Anterior cranial fossa.

cribriform plate, and the sphenoid's lesser wings and anterior part of its body.

The cribriform plate of the ethmoid spreads across the midline between the frontal orbital plates, but depressed below them, separating the anterior cranial fossa from the nasal cavity, whose roof it helps to form (3.144). Anteriorly its median *crista galli* projects up between the cerebral hemispheres. A depression between crista galli and *crest of the frontal bone* is crossed by the fronto-ethmoidal suture and displays the *foramen caecum*. On each side the crista galli is separated from the frontal bone by a narrow region with numerous small foramina transmitting olfactory nerves from nasal mucosa to olfactory bulb. Posteriorly each cribriform plate articulates with the sphenoid's body.

The orbital plates of the frontal form most of the fossa's floor on each side of the ethmoid, separating the orbital contents from the cerebral frontal lobe. Its convex cranial surface shows impressions for cerebral gyri and small grooves for meningeal vessels. Anteromedially it is split to contain part of the *frontal sinus*. Medially each orbital plate excludes the ethmoidal labyrinth from the anterior cranial fossa. Posteriorly it joins the *sphenoid's lesser wing's* anterior border. The frontal bone bears a median *frontal crest*, which projects between cerebral hemispheres and narrows upwards on the bone's internal surface.

The sphenoid bone completes the fossa's floor behind, centrally by the anterior part of its upper surface, the *jugum sphenoidale*; this separates the fossa from paired *sphenoidal sinuses* in the sphenoid body (3.114,115). Anteriorly the jugum articulates with the cribriform plate; posteriorly it is the anterior bank of the *sulcus chiasmatis* crossing the sphenoid body centrally in the middle cranial fossa and connecting the optic canals. Lateral to the jugum, the anterior fossa is floored by the *lesser wings* of the sphenoid, whose posterior margins overhang the middle fossa. Laterally each lesser wing tapers to a point, meeting the suture between the frontal bone and greater wing at or near the superolateral end of the superior orbital fissure. The medial end of its posterior border is the *anterior clinoid process*. Medially each lesser wing joins the sphenoid body by two roots, separated by the *optic canal*; the anterior, broad and flat, is continuous with the jugum sphenoidale, the posterior, smaller and thicker, joins the sphenoid body near the posterior bank of the chiasmal sulcus.

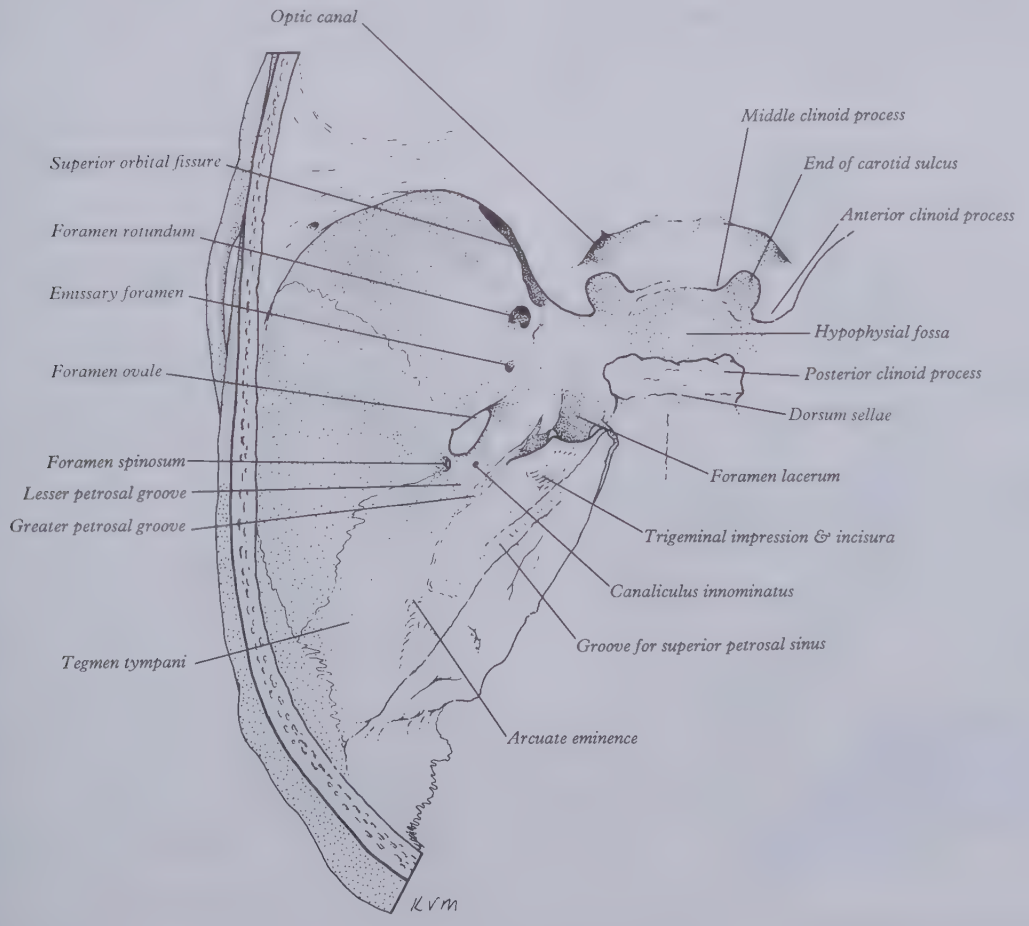
To the crista galli and frontal crest the falx cerebri is attached. The foramen caecum between them, usually blind, occasionally accommodates a vein from nasal mucosa to superior sagittal sinus. Lateral to the crista is the gyrus rectus; the olfactory bulb lies on the medial edge of the frontal orbital plate. The *anterior ethmoidal canal* opens in the cribrofrontal suture (3.98A,144) behind the crista galli and is difficult to identify, being overlapped by the orbital plate. It transmits the anterior ethmoidal nerve and vessels, which then run forward under dura mater to descend through a slit-like foramen at the side of the crista galli into the nasal cavity. The *posterior ethmoidal canal* opens at the posterolateral corner of the cribriform plate and is overhung by the sphenoid. It transmits the posterior ethmoidal vessels.

The posterior border of each lesser wing fits the stem of the lateral cerebral sulcus and may be grooved by the sphenoparietal sinus. Above is the inferior surface of the frontal lobe and, medially, the anterior perforated substance. Inferiorly, it bounds the superior orbital fissure, completing the orbital roof. Each anterior clinoid process receives the free border of tentorium cerebelli and is grooved medially by the internal carotid artery leaving the cavernous sinus. It may be connected to the middle clinoid process by a thin osseous bar, completing a *caroticoclinoid foramen* around the artery. Parts of gyri recti and olfactory tracts are above the jugum sphenoidale.

Middle Cranial Fossa

This fossa (3.109A,B,111), deeper and more extensive than the anterior, particularly laterally, is bounded in front by the posterior borders of the lesser wings, anterior clinoid processes and sulcus chiasmatis, behind by the superior borders of the petrous temporal bones and sphenoid's dorsum sellae, laterally by the temporal squamae, parietal bones and sphenoidal greater wings.

Centrally the floor is narrower and formed by the sphenoid body. The chiasmal sulcus, connecting the optic canals, is rarely in contact with the optic chiasma, which is usually posterosuperior. Each **optic canal**, between the roots of a lesser wing and, medially, the sphenoid body, descends a little anterolaterally, containing optic nerve, ophthalmic artery and meninges. Behind the sulcus the upper sphenoid surface is the *sella turcica*, whose anterior slope bears a median *tuberculum sellae*, behind which is the *hypophysial fossa* (3.109A). The fossa's floor is part of the roof of the sphenoidal sinuses (3.91,114,115); posterior



to it the *dorsum sellae* projects up and forwards. The superolateral angles of the dorsum are expanded as the *posterior clinoid processes*. Lateral to the sella turcica the sphenoid has a shallow *groove for the internal carotid artery*, here turning anteriorly from the foramen lacerum. A small elevation on the groove's medial edge is the *middle clinoid process*; it may be joined to the anterior process, as noted above. Posterolaterally the groove may be deepened by a small projecting *lingula* (**3**.126).

Laterally the middle fossa is deep and supports the temporal lobes. In front are the cerebral surfaces of sphenoid's greater wings, behind are anterior surfaces of petrous temporal bones and, laterally, cerebral surfaces of temporal squamae between the former two. Anteriorly are the orbits, laterally the temporal fossae, inferiorly the infratemporal fossae. The middle cranial fossa communicates with the orbits by **the superior orbital fissures**, each bounded above by a lesser wing, below by a greater wing, and medially by the sphenoidal body; each fissure is wider medially, with a long axis sloping inferomedially and forwards. Each transmits the terminal rami of the ophthalmic nerve, the ophthalmic veins, oculomotor, trochlear and abducent nerves and smaller vessels (vide infra).

The foramen rotundum, in the greater sphenoidal wing, is just below and behind the medial end of the superior orbital fissure. It leads forwards into the pterygopalatine fossa, to which it conducts the maxillary nerve (vide infra). **The foramen ovale** is posterior to the foramen rotundum, lateral to the lingula and posterior end of the carotid groove. It opens into the infratemporal fossa and transmits the mandibular nerve. **The foramen spinosum**, posterolateral to foramen ovale, transmits the middle meningeal artery which, with companion veins, ascends lateral to the temporal squama, turns anterolaterally across the sphenosquamosal suture to the greater wing to divide into frontal and parietal branches. The frontal ascends across the pterion (p. 352) to the anterior part of the parietal bone; at or near the pterion it is often in a bony canal. The parietal branch runs back and up on to the temporal squama, crossing the squamosal suture to gain the parietal bone. These arteries and veins groove the floor and lateral wall of the middle cranial fossa (vide infra).

At the posterior end of the carotid groove, posteromedial to the foramen ovale, is the foramen lacerum, bounded behind by the petrous apex, in front by the body and posterior border of the sphenoid's greater wing, where it contains the internal carotid artery and accompanying sympathetic and venous plexuses (vide infra). Posterior to the foramen the anterior surface of the petrous temporal has near its apex a shallow *trigeminal impression* adapted to the trigeminal ganglion. Posterolateral to this is a shallow pit, limited posteriorly by a rounded *arcuate eminence*, and produced by the anterior semicircular canal, where it is closely related to the floor of the fossa. Lateral to the impression a narrow groove passes posterolaterally into the *hiatus for the greater petrosal nerve*, lateral to which is the *hiatus for the lesser petrosal nerve*. Anterolateral to the arcuate eminence the anterior petrous surface is formed by the *tegmen tympani*, a thin osseous lamina in the roof of the tympanic cavity, extending anteromedially above the auditory tube. Lateral to the eminence the posterior part of the tegmen tympani roofs the mastoid antrum (which is continuous anteriorly with the tympanic cavity). The superior border of the petrous temporal separates middle from posterior cranial fossae. Behind the trigeminal impression it is grooved by the superior petrosal sinus.

On each side of the sphenoid body a cavernous sinus extends from the superior orbital fissure to the apex of petrous temporal bone. It contains the internal carotid artery, its sympathetic plexus, oculomotor, trochlear, abducent and ophthalmic nerves, but only the artery contacts bone. An anterior intercavernous sinus crosses the tuberculum sellae and a posterior sinus crosses the dorsum sellae; they connect the two cavernous sinuses. The diaphragma sellae surrounds the infundibulum, spreading from the tuberculum in front to the dorsum sellae behind. To the

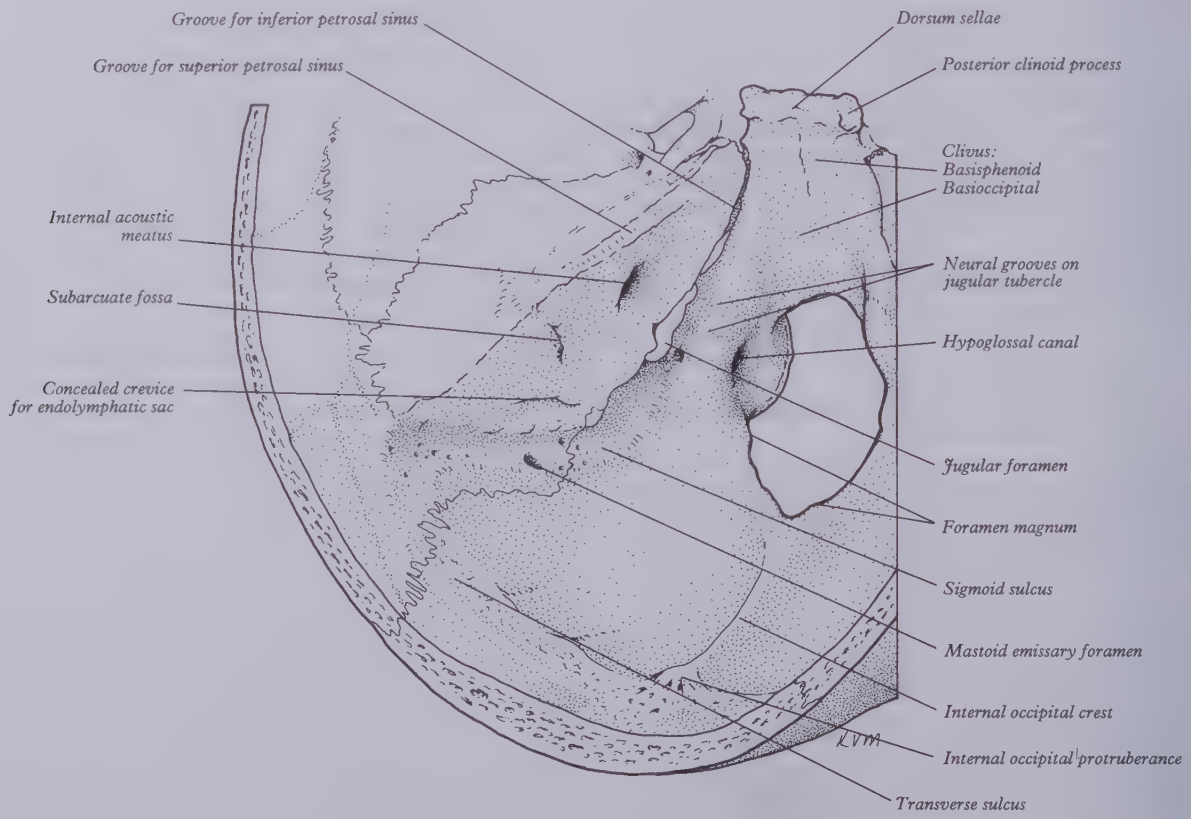
3.111 Middle cranial fossa.

posterior clinoid process are attached the anterior limit of the fixed margin of the tentorium cerebelli and also the petrosphenoidal ligament (p. 11077).

Further details. The superior orbital fissure (3.96) is between the orbit's roof and lateral wall. To its lower border is attached the common tendinous ring. At its superolateral end the greater wing articulates with the frontal orbital plate (p. 347). **The foramen rotundum**, like the superior orbital fissure's medial end, is near the lateral wall of the sphenoidal sinus. Originally part of the fissure, the latter is secondarily separated. Medial to it a small foramen may occur at the root of the greater wing; this *emissary sphenoidal foramen* transmits a vein from the cavernous sinus. **The foramen ovale** transmits the mandibular nerve, accessory meningeal artery and, sometimes, the lesser petrosal nerve. **The foramen spinosum** contains the middle meningeal artery and meningeal branch of the mandibular nerve. Both foramina are at first notches on the greater wing's margin and later converted into foramina. **The foramen lacerum** (p. 361) is a short canal completely *traversed* only by meningeal branches of the ascending pharyngeal artery and small veins. The internal carotid artery pierces its posterior wall and curves to ascend through its upper end. The greater petrosal nerve, leaving its hiatus, runs in its groove on the petrous temporal bone, then turns down to partly traverse the foramen lateral to the artery and joins the deep petrosal nerve. The nerve of the pterygoid canal, thus formed, leaves the foramen lacerum by a *pterygoid canal* in its anterior wall.

In young skulls a petrosquamous suture may be visible at the lateral limit of the *tegmen tympani* but is obliterated in adults; the tegmen then turns down as a lateral wall of the osseous auditory tube; its lower border may appear in the squamotympanic fissure (p. 359). Lateral to the tegmen's anterior part, the temporal squama is thin over a small area near the mandibular fossa's deepest part.

Anteromedial to the groove for the superior petrosal sinus, on upper border of petrous temporal, a smooth *trigeminal notch* leads into the *trigeminal impression*; here the trigeminal nerve separates sinus from bone. To a tiny spicule, directed anteromedially at the notch's anterior end, is attached the petrosphenoidal ligament; anterior to it the abducent nerve bends sharply across the upper petrous border between this ligament and the dorsum sellae.



Posterior Cranial Fossa

The posterior cranial fossa (3.109A,B,112), the largest and deepest of the cranial fossae, is bounded in front by the dorsum sellae and posterior aspects of sphenoidal body and basi-occipital bone, behind by the lower part of the occipital squama, laterally by petrous and mastoid parts of the temporal bone and lateral parts of the occipital and, above and behind, by the mastoid angles of the parietal bones. It contains the cerebellum, pons and medulla oblongata.

The foramen magnum (p. 359) is in the fossa's floor, surrounded by the basilar part of the occipital bone in front, its lateral parts on each side and a small part of its squama behind. Anterior to its transverse diameter it is narrowed by the two occipital condyles, being hence somewhat ovoid and wider behind. Its anterior part is above the dens of the axis; its posterior part communicates with the vertebral canal and here medulla oblongata and spinal cord become continuous.

Anterior to the foramen, in sequence, the basi-occipital, the posterior part of the sphenoid's body and then the dorsum sellae form a sloping *clivus*, which is concave transversely and placed antero-inferior to the pons and medulla oblongata. On each side the clivus is separated from the petrous temporal bone by a petro-occipital fissure, filled by a thin plate of cartilage and limited behind by the jugular foramen. Its margins are grooved by the inferior petrosal sinus.

The jugular foramen (p. 359), sited at the posterior end of the petro-occipital fissure, descends anterolaterally to the exterior. Its upper border is sharp and irregular, with a *notch for the glossopharyngeal nerve*; its lower border is smooth. Posteriorly is the sigmoid sinus, continuous below with the internal jugular vein, and anteriorly are the accessory, vagus and glossopharyngeal nerves from behind forwards. Medial to its lower border is

364 3.112 Left posterior cranial fossa. Viewed obliquely from a position above, slightly behind, and to the right.

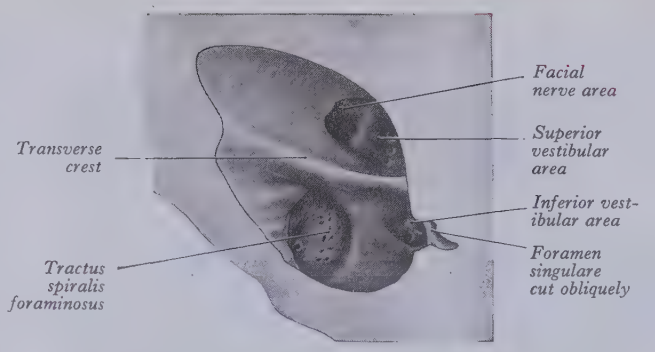
the rounded *jugular tubercle*, anterosuperior to the internal opening of *the hypoglossal canal*, at the junction of basilar and lateral parts of the occipital bone.

The petrous temporal bone's posterior surface forms much of the posterior cranial fossa's anterolateral wall. Anterosuperior to the jugular foramen the *internal acoustic meatus* (3.109,111,112) runs laterally. It is about 1 cm long, closed laterally by a plate of bone separating it from the internal ear and perforated by facial and vestibulocochlear nerves, nervus intermedius and labyrinthine vessels.

Behind the petrous temporal, the posterior fossa's lateral wall, is the mastoid part of the temporal bone. Anteriorly is a wide *sigmoid sulcus* running forwards and downwards, then downwards and medially and finally forwards to the jugular foramen. It contains the sigmoid sinus, (3.109,133). Superiorly, where it touches the parietal bone's mastoid angle, the groove is continuous with one for the transverse sinus, and crosses the parietomastoid suture. It descends *behind the mastoid antrum* and here is sited a *mastoid foramen* for an emissary vein from the sinus. The lowest part of the sulcus crosses the occipitomastoid suture and grooves the occipital bone's jugular process. The right sulcus is usually larger.

Behind the foramen magnum the occipital squama has a median *internal occipital crest*, ending above in an *internal occipital protuberance*, on each side of which a wide sulcus curves laterally with an upward convexity, to the parietal bone's mastoid angle. Produced by the transverse sinus, it is usually deeper on the right and, on both sides, continuous with its sigmoid sulcus. Below this *transverse sulcus* the internal occipital crest separates two shallow fossae, adapted to the cerebellar hemispheres.

When a *condylar canal* is present (3.122–124), its internal orifice is posterolateral to that of the hypoglossal canal. It contains a sigmoid emissary vein.

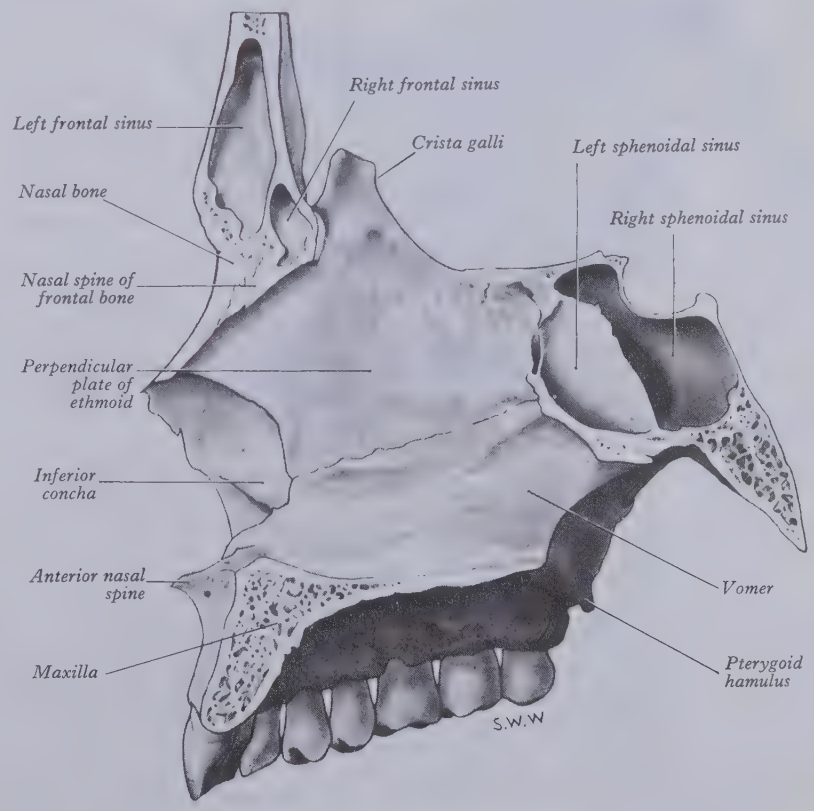


The clivus (anterior wall of the posterior fossa) is related to the plexus of basilar sinuses connecting inferior petrosal sinuses and joining below the internal vertebral venous plexus. Anterior to the foramen magnum the membrana tectoria is attached to the basi-occipital (4.29), behind attachment of the apical ligament. The jugular tubercle is often grooved by glossopharyngeal, vagus and accessory nerves as they enter the jugular foramen. In addition to its nerve the hypoglossal canal, often subdivided (p. 373), transmits a meningeal branch of the ascending pharyngeal artery. To the rough medial aspect of the occipital condyle (3.123) the alar ligament is attached.

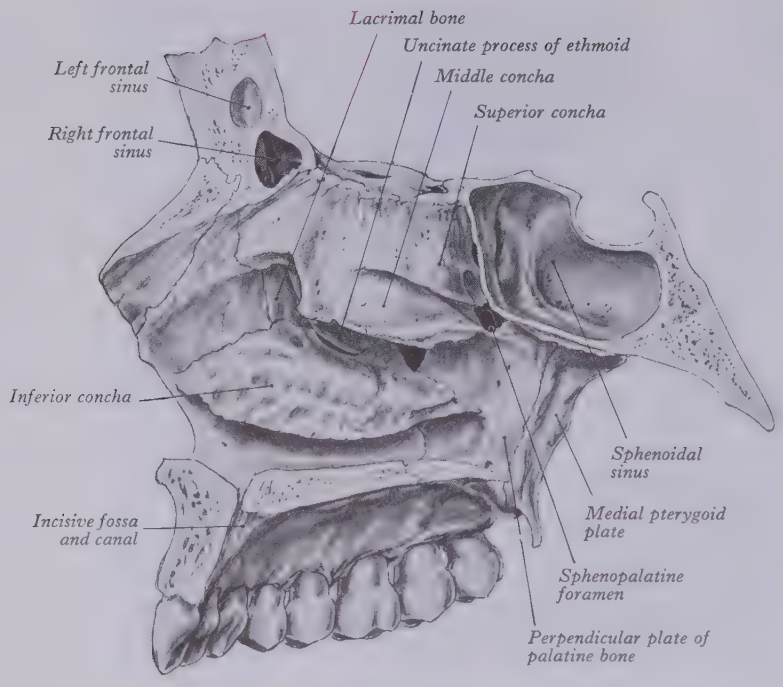
The lower, posterior borders of the jugular foramen (pp. 359, 364) are smooth, its upper border being sharp and notched; sometimes the margins of the notch extend to divide the foramen into two or three compartments. In the deepest part of the notch appears the *cochlear canaliculus*, containing the perilymphatic 'duct' (p. 1230).

The internal acoustic meatus is separated at its lateral *fundus* from the internal ear by a vertical plate divided unequally by a *transverse crest* (3.113), above which anteriorly is a *facial canal* conducting its nerve through the petrous temporal to the stylomastoid foramen. Posterior to this a small, depressed *superior vestibular area* presents openings for nerves to the utricle and anterior and lateral semicircular ducts. Below the crest is an anterior *cochlear area* in which a spiral of small holes, the *tractus spiralis foraminosus*, encircles the central cochlear canal. Behind this the *inferior vestibular area* bears openings for saccular nerves. Most postero-inferior is a *foramen singulare* for the nerve to the posterior semicircular duct.

Behind the internal acoustic meatus a thin plate with an irregularly curved margin projects back, bounding a slit containing the *vestibular aqueduct's opening* (3.133); within, it carries the saccus and ductus endolymphaticus (p. 1233) and a small artery and vein. Between internal acoustic meatus and aqueductual opening is a small *subarcuate fossa*, containing (3.109B,133) dura mater; near the superior petrous border the fossa is pierced by a small vein. In infants the fossa is a relatively large blind tunnel under the anterior semicircular duct, it corresponds to the floccular fossa of some animals.

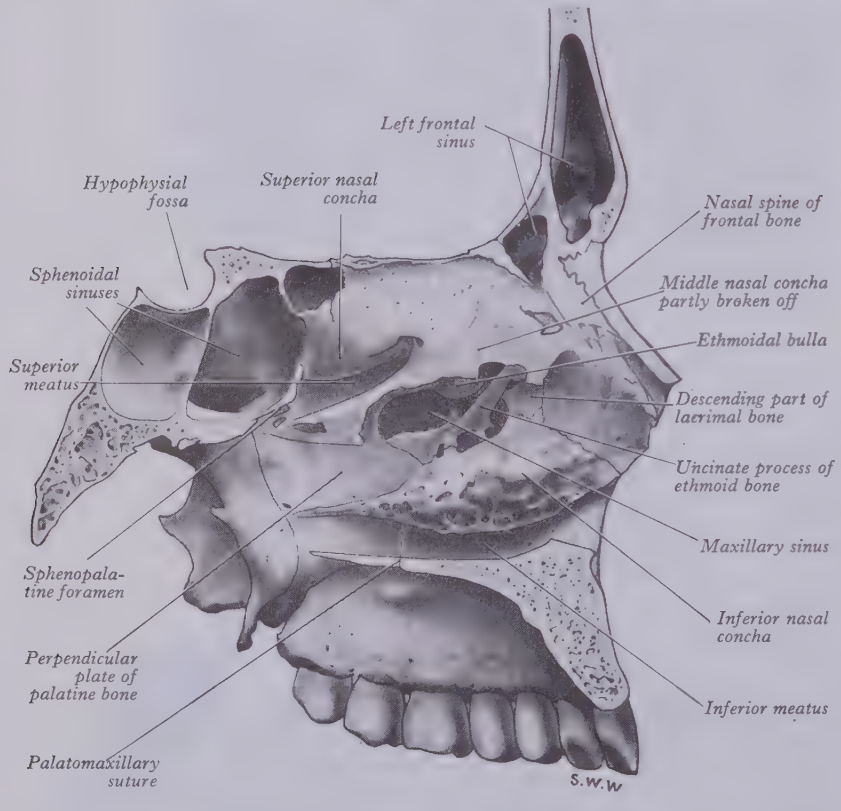


In addition to its emissary vein the *mastoid foramen* transmits a meningeal branch of the occipital artery, sometimes large enough to groove the occipital squama. The internal occipital crest, to which falx cerebelli is attached, may be grooved by the the occipital sinus. Its lower end adjoins the inferior vermis. The internal occipital protuberance is close to the confluence of sinuses and bilaterally grooved by the transverse sinuses, to the margins of which are attached the two layers of the tentorium cerebelli. Bone flanking the internal occipital crest is thin, even translucent, contrasting with the occipital's thick crest and protuberance.



3.113 The fundus of the right internal acoustic meatus, exposed by a section through the petrous part of the right temporal bone nearly parallel to the line of its superior border.

The Nasal Cavity



The nasal cavity, an irregular space between buccal roof and cranial base, is divided by a vertical *septum* (3.114), approximately median. In macerated skulls the septum is deficient anteriorly, leaving a single *anterior nasal aperture* in norma frontalis, but it reaches the posterior limit of the cavity, leading into the nasopharynx through a pair of *posterior nasal apertures*, above the posterior osseous (hard) palatal border. The cavity is wider below than above, but widest and vertically deepest in its central region. It communicates with frontal, ethmoidal, maxillary and sphenoidal sinuses. Each half cavity has a roof, floor, lateral and medial walls, the medial being the nasal septum.

3.114 The bony nasal septum: left side. An enlarged part of 3.117.

3.115 The roof, floor and right lateral wall of the right nasal cavity.

3.116 The lateral wall of the left nasal cavity, with an irregularly shaped portion removed from the lower part of the middle concha, exposing much of the middle meatus.

The roof (3.114–117) is centrally horizontal but descends in front and behind. The anterior slope is formed by the frontal's nasal spine and nasal bones, contributing to the external nose. The horizontal region is the ethmoid's cribriform plate separating the nasal cavity and median region of anterior cranial fossa's floor. Its numerous small perforations contain the olfactory nerves. The posterior slope is formed by the sphenoid's body and is interrupted, on each side, by an orifice of a sphenoidal sinus.

The floor is smooth, concave transversely, and slopes up from anterior to posterior aperture. It is the upper surface of the osseous palate. Anteriorly the maxillary palatine processes and, behind them, palatine horizontal plates articulate in the midline and with each other. Anteriorly, near the septum, a small infundibular opening in the nasal floor leads into the *incisive canals* (p. 389).

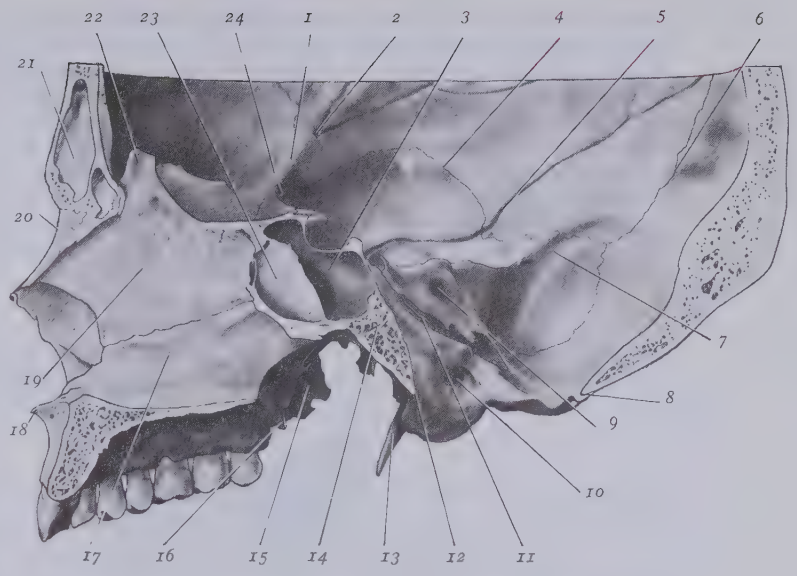
The medial wall or *nasal septum* (3.114,117), between roof and floor, is a thin sheet of bone with a wide anterior deficiency occupied by septal cartilage; its bony part is largely vomer and perpendicular plate of the ethmoid. The *vomer* extends from the sphenoidal body to bony palate, forming the postero-inferior region, including the posterior border; it is furrowed by vessels and nerves. The *perpendicular plate of the ethmoid* forms the septum's anterosuperior part (3.114), continuous above with cribriform plate (p. 384). The septum is often deviated, most commonly at the vomero-ethmoidal suture.

The lateral wall (3.115,116,148) is irregular, due to three projections: inferior, middle and superior nasal *conchae*. It is formed largely by the maxilla antero-inferiorly, by the palatine's perpendicular plate posteriorly and superiorly by the ethmoidal labyrinth, separating nasal cavity from orbit. The conchae curve inferomedially, each roofing a groove, or meatus, open to the nasal cavity.

The *inferior concha*, thin, curved and an independent bone, articulates with the nasal surface of maxilla and palatine perpendicular plate; its free lower border is gently curved; the subjacent *inferior meatus* reaches the nasal floor. It is the largest meatus, extending along almost all the lateral nasal wall. It is deepest at the junction of anterior and middle thirds, where the inferior orifice of the nasolacrimal canal appears.

The *middle* and *superior conchae* are medial processes of the ethmoidal labyrinth. The *middle concha*, much the larger, extends back to articulate with the palatine bone's perpendicular plate above the *middle meatus*, whose lateral wall can be examined only after the removal of the concha (3.116); its upper part is the rounded *ethmoidal bulla*, which contains middle ethmoidal air cells; antero-inferior to this a thin, curved *uncinate process of the ethmoid* descends back across the large opening of the maxillary sinus. The curved gap (3.116) between process and bulla is the *hiatus semilunaris*; at its upper end it is continuous with the *ethmoidal infundibulum*, a short canal receiving anterior ethmoidal air cells and then ascending in the labyrinth to the frontal sinus. But the infundibulum very often ends blindly; the frontal sinus then opens directly into the middle meatus. The middle ethmoidal air cells open above, or near, the bulla.

The *superior concha*, a small curved lamina, posterosuperior to the middle, roofs the *superior meatus*, shortest and shallowest of the three; into it open the posterior ethmoidal air cells. Posterior to it the sphenopalatine foramen (occluded by mucosa) leads into the pterygopalatine fossa. A narrow *spheno-ethmoidal recess* separates superior concha and anterior aspect of the sphenoid's body, through which the sphenoidal sinus connects with the nasal cavity.



The posterior nasal apertures, or *choanae*, are separated by the posterior vomerine border, each being limited below by the posterior border of the palatine bone's horizontal plate, above by the sphenoid and laterally, on each side, by its medial pterygoid plates.

Further details. The anterior nasal aperture is described on page 343. In addition to the cribriform plates the horizontal part of the roof has a separate, anterior foramen for the anterior ethmoidal nerve and vessels. The roof's posterior slope is the anterior aspect of the sphenoid's body, with which the sphenoidal conchae (p. 325) are fused; below this are the vomerine alae and palatine bones' sphenoidal processes.

The nasal floor (3.115) is crossed at the junction of middle and posterior thirds by the palatomaxillary suture. Anteromedian are the incisive canals (p. 389), descending to the palatine incisive fossa; they may traverse the union of os incisivum (premaxilla) with maxillae; they represent a primitive bucconasal communication (p. 389).

At upper and lower limits of **the medial wall** (3.116) other bones make minor contributions to the septum: antero-superior are the nasal bones and frontal's nasal spine, posterosuperior are the sphenoid's rostrum and crest, and inferiorly, the maxillary and palatine nasal crests. The vomer is grooved by nasopalatine nerves and vessels.

The lateral wall (3.115,116,148), additionally, is formed anterosuperiorly by the nasal bone and maxillary's frontal process. Behind the latter, and articulating with its posterior border, lies the lacrimal bone which reaches the middle meatus to articulate with the lacrimal process of the inferior concha, thus forming the nasolacrimal canal's medial wall (3.116,151), which conveys the nasolacrimal duct to the inferior meatus. Posteriorly the lacrimal bone articulates with the ethmoidal labyrinth to complete some ethmoidal air cells. The *uncinate process* from this part of the labyrinth curves postero-inferiorly in the lateral middle meatal wall. It is thin, fragile, about 3 mm wide, curving across the maxillary hiatus to the inferior conchal ethmoidal process. Its concave, posterior border forms the medial edge of the hiatus semilunaris; it helps to form a medial wall of the maxillary sinus; its convex anterior border is free only above. The *maxillary hiatus*, a wide defect in the maxillary's nasal surface (3.160), is much reduced by neighbouring bones; it is covered below by the inferior concha and its maxillary process, above by ethmoid's uncinate process, behind by palatine's perpendicular plate and antero-superiorly by small parts of ethmoidal labyrinth and lacrimal bone (3.116). Thus the hiatus is sometimes reduced to a single orifice in the floor of the posterior part of the hiatus semilunaris, but usually additional openings exist both between the inferior concha and the uncinate process and also behind the latter. The *ethmoidal bulla*, variable in size and shape, may be fused with the uncinate process, and then the duct of the frontal sinus opens into middle meatus medial to the blind end of the infundibulum. A *concha suprema* often exists on the medial surface of the ethmoidal labyrinth posterosuperior to the superior concha's posterior end (spheno-ethmoidal recess); it is merely a ridge, separated from the superior concha by a depression. The *sphenopalatine foramen* (3.115) is posterior to the superior meatus and transmits the sphenopalatine artery and nasopalatine and superior nasal nerves from the pterygopalatine fossa. The foramen is bounded above by sphenoidal body and concha, below by the superior border of palatine perpendicular plate, in front and behind by the palatine's orbital and sphenoidal processes (3.160–162).

3.117 Sagittal section through the lower part of the skull, slightly to the left of the median plane. 1. Frontosphenoidal suture. 2. Bony canal for middle meningeal vessels, frontal branches, upper orifice. 3. Right sphenoidal sinus. 4. Squamosal suture. 5. Groove for parietal branches of middle meningeal vessels. 6. Lambdoid suture. 7. Groove for transverse sinus. 8. Posterior margin of foramen magnum. 9. Internal acoustic meatus. 10. Hypoglossal canal. 11. Petro-occipital suture in floor of groove for inferior petrosal sinus. 12. Anterior margin of foramen magnum. 13. Styloid process. 14. Line of occipitosphenoidal junction. 15. Lateral pterygoid plate. 16. Pterygoid hamulus. 17. Vomer. 18. Anterior nasal spine. 19. Perpendicular plate of ethmoid. 20. Nasal bone. 21. Frontal sinus. 22. Crista galli. 23. Left sphenoidal sinus. 24. Bony canal for frontal divisions of middle meningeal vessels, lower orifice.

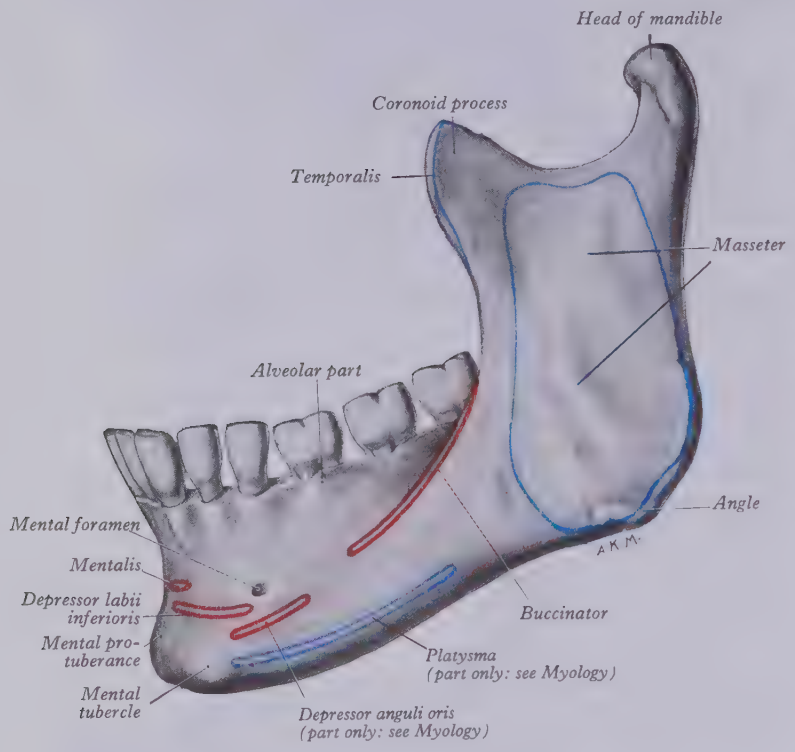
THE INDIVIDUAL CRANIAL BONES

The Mandible

The mandible (3.118A,B) the largest, strongest and lowest bone in the face, has a horizontally curved *body*, convex forwards, and two broad *rami*, ascending posteriorly.

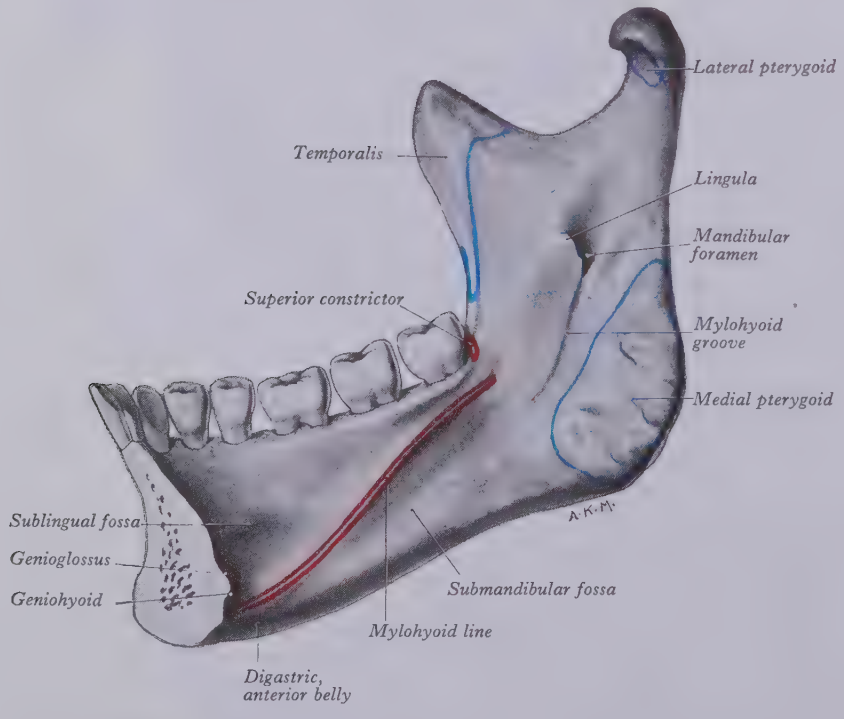
The mandibular body, somewhat U-shaped, has external and internal surfaces, separated by upper and lower borders. Anteriorly, the upper *external surface* shows a faint median ridge, often absent, indicating fusion of the halves of the fetal bone (*symphysis menti*); inferiorly this ridge divides to enclose a triangular *mental protuberance*, its base centrally depressed but raised on each side as a *mental tubercle*. Below the interval between the premolar teeth, or the second premolar, is the *mental foramen*, from which emerge the mental nerve and vessels; its posterior border is smooth accommodating the dorsolaterally emerging nerve (Warwick 1950). A faint *oblique line* ascends backwards from each mental tubercle, sweeps below the foramen, then becomes more marked as it continues into the anterior border of the ramus.

The body's lower border, the *base*, extends posterolaterally from the symphysis into that of the ramus behind the third molar tooth. Near the midline, on each side, is a rough *digastric fossa*, behind which the base is thick, rounded, with a slight anteroposterior convexity. As the ramus is approached, this changes to a gentle concavity; thus, in profile, the whole base is sinuous.



The upper border, the *alveolar part*, contains 16 *alveoli* for roots of teeth, varying in size and depth, some being multiple.

The *internal surface* is divided by an oblique *mylohyoid line*, sharp and distinct near the molars, faint in front and extending from behind the third molar, a centimetre from the upper border, to the mental symphysis between the digastric fossae. Below this line is the slightly concave *submandibular fossa*; the area above it widens anteriorly into a triangular *sublingual fossa*. Above the latter and extending back to the third molar, the bone is covered by oral mucosa. Above the anterior ends of the mylohyoid lines, the posterior symphysial aspect has a small elevation, often divided into upper and lower parts, the *mental spines* (genial tubercles). Posteriorly the *mylohyoid groove* extends down and forwards from the ramus below the mylohyoid line's posterior part. Superior to the mental spines most mandibles display a median pit opening into a canal (Ingram, personal communication). As yet its development and contents are uncertain but it is a useful radiological landmark (p. 395): the name *genial foramen* has been proposed. (See also *accessory mandibular foramina*, p. 1304.) Above the mylohyoid line, medial to the molar roots, a rounded torus mandibularis sometimes appears: for its incidence consult Mayhall et al (1970) and Berry (1975).



The mandibular ramus (3.118A,B) is quadrilateral, with two surfaces, four borders and two processes. The flat *lateral surface* has oblique ridges in its lower part; the *medial* presents, a little above centre, an irregular *mandibular foramen*, leading into the *mandibular canal*, curving down and forwards into the body to its mental foramen (but vide infra and p. 1304). Anteromedially the foramen is overlapped by a thin, triangular *lingula*. The *mylohyoid groove* descends forwards from behind the lingula; the surface behind it is marked by short ridges. The *inferior border*, continuous with mandibular base, meets the posterior border at the *angle*. This is typically everted, but in females frequently incurved. The thin *upper border* bounds the *mandibular incisure*,

surmounted in front by the somewhat triangular, flat, *coronoid process*, behind by a strong *condylar process*. The *posterior border*, thick and rounded, extends from condyle to angle, being gently convex backwards above, and concave below; it is in contact with the parotid gland. The *anterior border* is thin above and continuous with that of the coronoid process, and thicker below and continuous with the oblique line.

The coronoid process projects up and slightly forwards. Its posterior border bounds the mandibular incisure, its anterior continues into that of the ramus. Its margins and medial surface are attachments for most of the temporalis.

3.118A The left half of the mandible: lateral (external) aspect.

3.118B The right half of the mandible: medial (internal) aspect.

The condylar process is apically enlarged as a *head* or *condyle*, covered by fibrocartilage. It articulates with the temporal bone's mandibular fossa, with an articular disc between. It is convex in all directions, its transverse dimension greater. Its lateral aspect is a blunt projection, palpable in front of the auricular tragus. As the mouth opens the condyle descends forwards, admitting a finger-tip towards its vacated fossa. Below the head is the narrower *neck*, slightly flattened from before backwards, its anterior aspect overlapped laterally by the mandibular incisure's margin, medial to which the neck's anterior surface bears a rough *pterygoid fovea*.

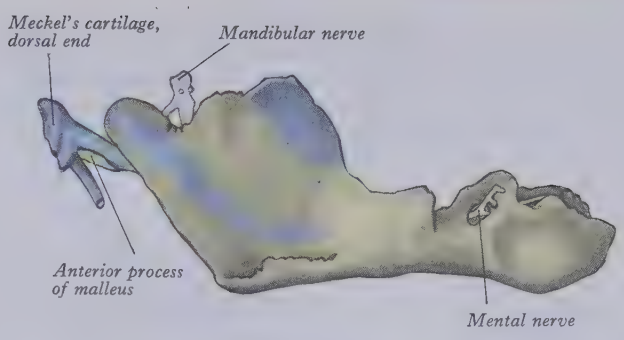
The mandibular canal descends obliquely forwards in the ramus from the mandibular foramen, then horizontally forwards in the body below the alveoli, with which it communicates by small canals. It contains the inferior alveolar nerve and vessels, from which branches enter dental roots, periodontal sockets and septa. Between the roots of the first and second premolars, or below the second, the canal divides into *mental* and *incisive* parts; the mental canal swerves up, back and laterally to the mental foramen; the incisive canal continues below the incisor teeth. (See p. 1304 for variations.)

The mandibular body bears a small shallow *incisive fossa* below the incisors, an attachment for mentalis and part of orbicularis oris. To the anterior ends of the oblique lines are attached depressores labii inferioris and anguli oris, and platysma to bone below and backwards beyond them. Adjoining the alveolar border bone is covered by oral mucosa and, below this in the molar region, the buccinator has a linear attachment extending medially behind the last molar to the pterygomandibular raphe.

To the mylohyoid line is attached the mylohyoid muscle and, above its posterior end the superior pharyngeal constrictor, some retromolar fasicles of the buccinator, and the *pterygomandibular raphe* behind the third molar. Although usually described separately, here the constrictor, buccinator and the raphe are blended and jointly attach to the mandibular periosteum. The lingual nerve reaches the tongue above the mylohyoid line, closely related to bone near its posterior end (p. 1105); often the nerve is accommodated in a shallow, curved groove. To the superior mental spines are attached the genioglossi, to the inferior the geniohyoids. The *submandibular fossa* adjoins submandibular lymph nodes as well as the salivary gland; the facial artery usually descends here to curl round the base of the mandible, sometimes making a shallow groove. The *digastric fossa* is for attachment of the muscle's anterior belly.

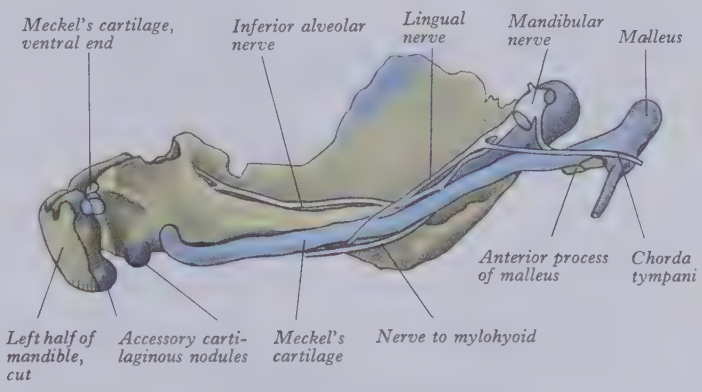
The mandibular ramus and its processes provide attachment for muscles of mastication, much of its *lateral surface* to masseter, except posterosuperiorly, where it is covered by the parotid gland; the *medial surface* receives the medial pterygoid on the roughened area postero-inferior to the mylohyoid groove. To the *lingula* the sphenomandibular ligament is attached, posterior to which the mylohyoid nerve and vessels enter the *mylohyoid groove*, reaching the mandibular body below the mylohyoid line; they then pass superficial to mylohyoid. Below the lingula, but above the roughened attachment mentioned above, the medial surface of the ramus is related to the medial pterygoid, the lingual nerve being between muscle and bone. The lowest attachment of temporalis descends beyond the coronoid process to the anterior ramal border and particularly its adjoining medial surface. To the area posterosuperior to the mandibular foramen the maxillary artery and its inferior alveolar branch are related, and lateral pterygoid to the area near the mandibular incisure. The *mandibular incisure* transmits the masseteric nerve and vessels from the infratemporal fossa.

The coronoid process is covered laterally by the anterior part of masseter descending to its attachment on the ramus. Its anterior border is palpable below the zygoma; this is most evident during mouth opening. **The condylar process** projects more at its medial pole. Its *articular surface* descends only a little on its anterior surface, covers the whole of its superior aspect and descends 5 mm posteriorly. Its projecting lateral part is separated from the cartilaginous external acoustic meatus by the parotid. Laterally on its *neck* the joint's lateral ligament is attached (**4**.18), covered by parotid gland. The pterygoid fovea, anterior on the



neck, receives the lateral pterygoid. The neck's medial surface is related to the auriculotemporal nerve above and maxillary artery below.

The *parotid gland* is below the external acoustic meatus and lies between the ramus and mastoid process, with the styloid process medial; but it extends forwards lateral to the temporomandibular joint and to the exposed ramus behind the masseter. It also curls round the posterior border to the medial aspect of the ramus above the attachment of the medial pterygoid.



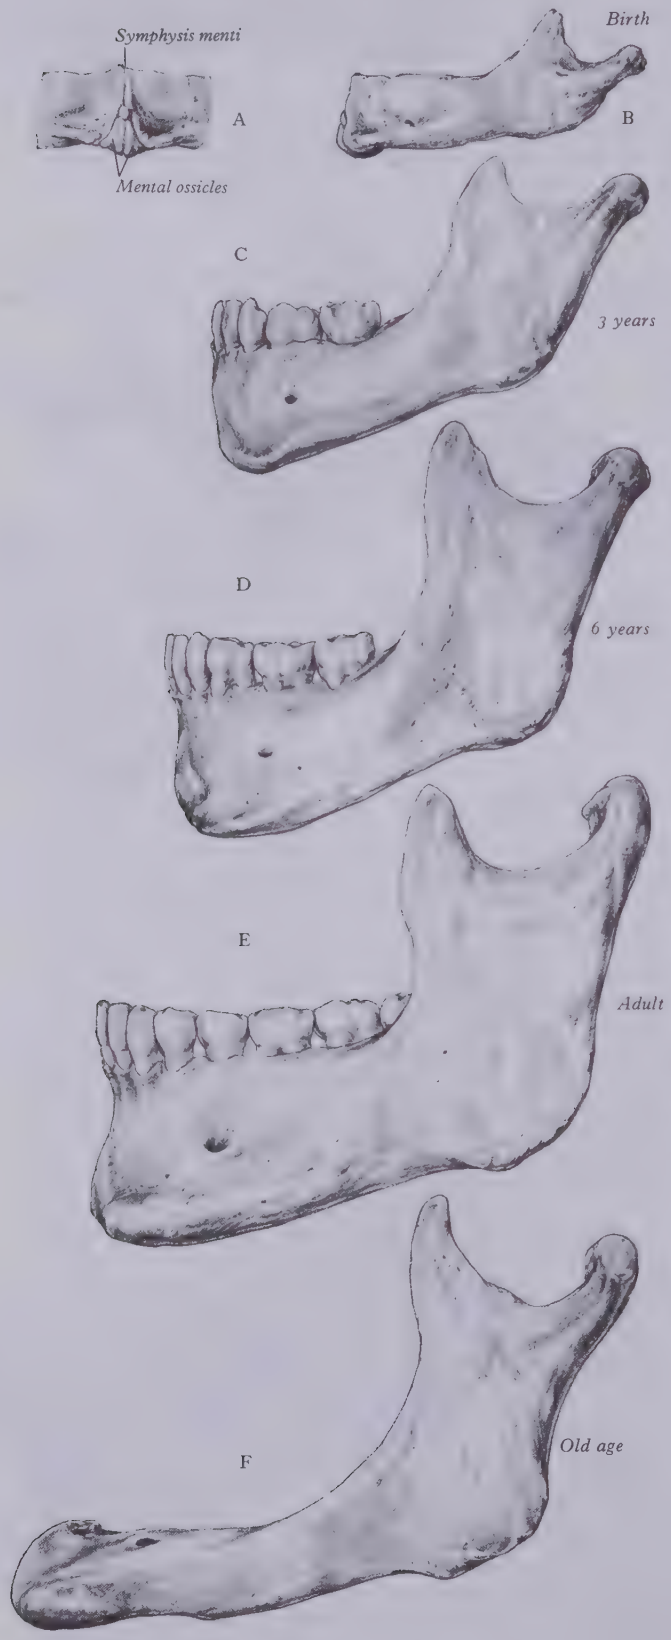
Accessory foramina of the mandible are usually unnamed and infrequently described. Yet a study of 300 mandibles yielded a count of 2449 accessory foramina (Sutton 1974). Since many transmit auxiliary nerves to teeth (from facial, mylohyoid, buccal, transverse cervical cutaneous and other nerves), their occurrence is significant in dental blocking techniques. **Further mandibular variants** include *lingual depressions*, molar or canine, *variable position of mental foramen, multiple mental foramina, lingual fenestrations* of molar sockets, *retromolar foramina* and *condylar defects*. For incidences in 125 mandibles see Azas & Lustmann (1973).

Aspects of mandibular structure. In addition to variable mandibular canals (Fawcett 1895, Carter & Keen 1971), numerous analyses have been made of the structure of surface tables and buttresses of compact bone and the geometry of trabeculation in attempts to relate these to habitual functional stresses (Beltrani 1945, Seipel 1948, Dal Pont 1960, Scott & Symons 1977, Mercier et al 1970 a,b). Holographic interferometry has been used to study surface strains induced by orthodontic forces (Hewitt 1977).

Ossification. The mandible forms in dense fibromembranous tissue lateral to the inferior alveolar nerve and its incisive branch and also in the lower part of Meckel's cartilage (**3**.119A,B). Each half is ossified from a centre appearing near the mental foramen about the sixth week, i.e. just after the clavicle's primary centre (p. 405). From this, ossification spreads medially and dorsocranially to form body and ramus, first below, then around the inferior alveolar nerve and incisive branch and upwards, initially forming a trough and later crypts for developing teeth. By the tenth week Meckel's cartilage below the incisor rudiments is surrounded and invaded by bone (p. 172). Secondary cartilages appear later (**3**.119A,B): a conical mass, the *condylar cartilage*, extends from mandibular head down and forwards in the ramus, contributing to its growth in height; though it is largely replaced by bone by mid-fetal life, its proximal end persists as proliferating cartilage under articular fibrocartilage until the third decade. The orientation and growth patterns in the condylar cartilage are one (of many) important determinants of co-ordinated craniofacial growth. Another secondary cartilage, which soon ossifies, appears along the anterior coronoid border, disappearing before birth. One or two cartilaginous nodules also occur at the symphysis menti; about the seventh month these may ossify as variable *mental ossicles* in symphysial fibrous tissue, uniting to adjacent bone before the end of the first postnatal year (Lebourg & Champagne 1951, Sicher 1962, Scott & Symons 1970, and **3**.120A). It may be mentioned here that ^{3}H-thymidine labelling in the *rat* showed no interstitial growth in condylar cartilage, which expanded by surface accretion only (Kvinnsland & Kvinnsland 1975).

3.119A The right half of the mandible of a human embryo, 95 mm long: lateral aspect. Blue = cartilage; yellow = bone. (Reconstruction by A Low.)

3.119B The right half of the mandible of a human embryo, 95 mm long: medial aspect. The developing bone is shown in yellow, and the cartilage in blue. (Reconstruction by A Low.)



Age Changes in the Mandible

At birth (**3**.120A,B) the two halves of the mandible are united by a fibrous *symphysis menti*. Anterior ends of both rudiments are covered by cartilage, separated only by a symphysis. Until fusion occurs new cells are added to each cartilage from symphysial fibrous tissue, ossification on its mandibular side proceeding towards the midline; when the latter process overtakes the former, extending into median fibrous tissue, the symphysis fuses but details are uncertain. At this stage the body is a mere shell, enclosing imperfectly separated sockets of deciduous teeth. The mandibular canal is near the lower border, the mental foramen opens below the first deciduous molar and is directed forwards (Warwick 1950). The coronoid process projects above the condyle.
